EXPERIENCES IN PROLOG-BASED DFT RULE CHECKING

Gianpiero CABODI Paolo CAMURATI Paolo PRINETTO

Dipartimento di Automatica e Informatica
Politecnico di Torino
Corso Duca degli Abruzzi 24, I-10129 Torino Italy

Abstract

Since testing of VLSI is becoming increasingly important, many methodologies have been introduced to enhance Design For Testability (DFT). Manual verification is becoming more and more difficult as the size of designs increases and automation is thus essential. A method and a tool to check whether a given hardware design verifies or not a set of high level DFT rules (LSSD and BILBO) is presented.

The work reported in this paper is based on Prolog. This logic programming language is used in many ways: as a basis for a predicative representation of hardware, as a means to encode the knowledge of DFT techniques, as an interpreter to support the implementation of a frame- and rule-based expert system kernel. Eventually conclusions are drawn on its effectiveness.

1 INTRODUCTION

The increasing complexity in VLSI challenges CAD tools designers, since more and more computer aid is necessary to take full advantage of technological improvements.

A field in which CAD is essential is testing, not only because of the need for Automatic Test Equipments (ATE) and Automatic Test Pattern Generators (ATPG), but also because cost-effective testing requires VLSI circuits to be designed to guarantee testability.

Many approaches to Design for Testability have been proposed in recent years [1] and are widely accepted in both the industrial and academic world. CAD tools designers are now moving in two major directions: they try to include such DFT techniques in their logic synthesis systems or they produce automatic compliance verification programs. As far as the first entry is concerned, a lot of work is going on, as reported in [2], [3], [4], [5], and [6]. This approach is being confronted by the same problems of synthesis and silicon compilation. As far as verification is concerned, its goals seem to be more immediate. Algorithmic methods have already been introduced [7], but their main limit resides in the scarce flexibility of the system with respect to the knowledge it encodes. Since knowledge is rapidly varying, it seems useful to gather a large knowledge base and exploit it resorting to knowledge engineering techniques [4]. Most DFT techniques are already expressed in a rule form [1], therefore rules seem to be very suitable as a knowledge representation formalism. Prolog [8] provides an easy way to express rules and clauses representing knowledge both about DFT methods and about hardware, and, moreover, puts at the user's disposal a built-in inference engine. This separation of inference and control strategies from the knowledge base allows the CAD tool designer to concentrate on the latter, leaving utilization problems apart, at least in the preliminary phase.

This paper presents a prototypical DFT rule verifier using Level Sensitive Scan Design (LSSD) [9] and BILBO [10].

In the sequel, we shall cover the following topics: predicative representation of hardware, DFT rules in Prolog form, the use of the Prolog reasoning mechanism to verify designs, and a frame- and rule-based expert system kernel implemented in Prolog. The project's current status and future plans are described. Conclusions are eventually drawn justifying the validity of this choice, discussing its limits and possible improvements.

2 HARDWARE REPRESENTATION FORMALISMS

It is possible to describe hardware, i.e., the knowledge we have about the circuit in several ways, among which Hardware Description Languages (HDLs) [11] and clauses are the most widely used.

HDLs have been introduced to describe models to be used in simulation and test pattern generation. They describe hardware structurally and/or behaviourally, possibly resorting to different abstraction levels.

Many efforts are currently directed to provide efficient and effective executable

CH2345-7/86/0000/0909$01.00 © 1986 IEEE

specification formalisms. Such executable specifications can be used for simulation as well as verification purposes. Most formalisms are related to first-order predicate calculus and/or to subsets of logic [12], [13], [14].

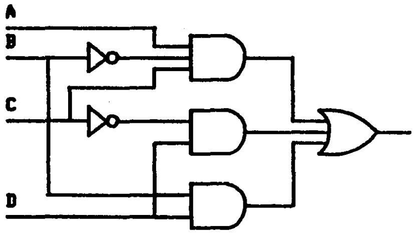
A very popular form of knowledge representation uses rules and Horn clauses [14], [15], [16] since they are Prolog-like and Prolog provides a simple, yet effective inference mechanism. Some formalisms used to represent hardware in rule form are briefly illustrated in the sequel. A general classification is adopted to distinguish them according to their main characteristics into Functional, Extensional, and Definitional methods.

2.1 The Functional Method

The functional method [14] can easily represent combinational acyclic circuits in which a single output signal is function of several input signals.

The function symbol together with its arguments identifies the output of the block itself.

The connection relationship between blocks is purely functional: the syntactic form of a given term determines its connections. An example is shown in Fig. 1.



or(and(a,not(b),c),and(not(c),d),and(b,d))

Fig. 1

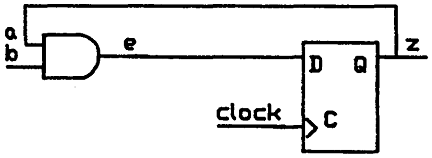
Input signals are named by a constant symbol. Blocks are named by the corresponding function symbols. Functions have an arbitrary number of inputs, but only one output. This formalism allows processing the circuit by recursive descents, transforming a given term in another one.

There are two main disadvantages to this technique. First, only acyclic circuits can be described, and this precludes the specification of realistic sequential ones. Second, a separate expression must be used to represent each output of a circuit.

2.2 The Extensional Method

The extensional method [15], [16] represents blocks and connections as clauses in which constants are used to indicate the connections between modules.

In the example of Fig. 2 the "module" predicate has three arguments, describing its function, its input list, and its output list. Connections between modules are specified by the "connect" predicate. This predicate has two arguments, each indicating the module type and the connected port.



```
module(and,[a,b],[e])
module(latch,[D,C],[Q])
connect(latch(Q),z)
connect(and(a),z)
connect(and(e),latch(D))
connect(clock,latch(C))
```

Fig. 2

The circuit is thus described as a set of module and connection predicates.

It is usual to consider the module and connection relations as templates, and their arguments as variables standing for any instance of the template.

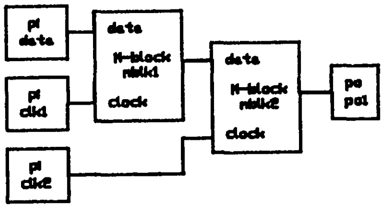
This method can accommodate arbitrary types of circuits such as multiple output cyclic circuits. However, the main disadvantage stems from the fact that the modules are not represented by a single term, rather they are represented extensionally, with no syntactic relationship among them.

Variations of this formalism are used in a number of systems. We shall now focus the attention on a particular one introduced in [15], [17].

The design description contains two general types of statements. The first kind of clauses describes the nodes' functions and their interconnections. Each clause contains a node name, a node function, a list of the come_from nodes (and pin names), and a list of go_to nodes (and pin names).

The second type of statements consists of clauses stating the special behaviour of the node itself. This is particularly useful when modelling clock inputs.

A simple description with this method is shown in Fig. 3 [17].



```
data(p1,(),(connect(mblk1,data,_))).
clk1(pi,(),(connect(mblk1,clock,_))).
clk2(pi,(),(connect(mblk2,clock,_))).
clk1(clock).
clk2(clock).
mblk1(m-block,(connect(data,data,_),
               connect(clk1,clock,_)),
     (connect(mblk2,data,_))).
mblk2(m-block,(connect(mblk1,data,_),
               connect(clk2,clock,_)),
     (connect(po1,_,_))).
po1(po,(connect(mblk2,_,_)),()).
```

Fig. 3

Since every block has one output only, the output's name is the same as the block's one. It is possible to modify this formalism to include inputs and outputs of the block in its template.

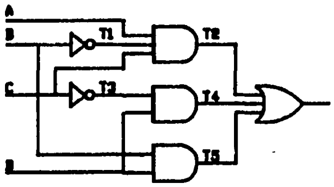
2.3 The Definitional Method

In the definitional method [12], [18] blocks having n ports are represented as n_ary predicate symbols.

Modules are described by Horn clauses whose head is the module to be defined, and whose body is a composition of either already defined or primitive modules.

The ":-" operator is interpreted as "is defined by". The order of modules in the body of the clause is not important.

A simple description with this method is shown in Fig. 4.



```
comb(A,B,C,D,E):-not(B,T1),and(A,T1,C,T2),
                 not(C,T3), and(T3,D,T4),
                 and(B,D,T5),or(T2,T4,T5,E).
```

Fig. 4

Primitive modules are a priori defined by rules describing their behaviours.

This method has numerous advantages:

- the circuits may be directly represented by Prolog clauses;
- the module's name is explicitly part of the specification and this allows easy modular decomposition;
- internal connections are named by variables which do not appear in the head of the clause.

2.4 Our Approach

The approach we adopted combines some features of the definitional and extensional methods. This approach is especially tailored to the representation of Finite State Machines, both in Moore and in Mealy form.

The circuits we consider consist in combinational networks and registers as shown in Fig. 5.

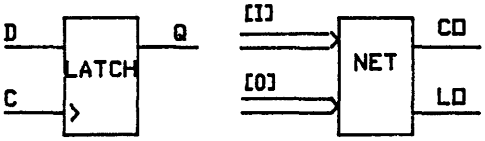


Fig. 5

We are not concerned with the internal structure of the combinational networks, but only with their connection to registers. This consideration leads to the introduction of two simple predicates to describe the circuit in a definitional way: REGISTER()

and NET(). "REGISTER" describes a block having a pulse input (C), a level input (D) and a level output (Q).

The register is described by following predicate:

```
register(D,C,Q).
```

"NET" describes logic networks with n level inputs (n>=0), m clock inputs (m>=0) and either a level output or a clock output.

The network is described by following predicate:

```
net ( [I], [C], LO, CO )
```

where:

```
[I] is the level input list
[C] is the pulse input list
LO  is the level output
CO  is the pulse output.
```

Lists are used to represent networks with multiple inputs. Since each network has only one output, either CO or LO is missing.

It is necessary to distinguish the input clocks of the circuit, hereinafter called Primary Input Clocks (PICs) from other inputs. An ad hoc predicate PIC(x) has therefore been introduced to define them.

3 DFT RULES IN PROLOG FORM

The Prolog clauses which represent LSSD and BILBO methodologies may be found in [19]. In this paragraph we present a flash on a particular rule, just to give the taste of how it is represented. All rules in Prolog form return true if and only if the corresponding DFT rule is violated. It would have been possible to rewrite all rules in order to have true returned only when the corresponding DFT rules were satisfied. Such alternative approach is much more complex and the readability of the system's output is reduced.

We shall consider the following LSSD rule:

> "a latch X may gate a clock Ci to produce a gated clock Cig which drives another latch Y if, and only if, clock Cig does not clock latch X, where Cig is any clock produced from Ci."

This rule may be violated if and only if the following situation arises:

> "there are two latches and one combinational network connected in such a way that the input clock of the second latch is fed by the output of the combinational network one of whose inputs is the output of the first latch".

This rule is effectively violated if the input clock of the first latch is equal to any of the input clocks of the combinational network. The structural situation is shown in Fig. 6, while Fig. 7 reports the corresponding Prolog rule.

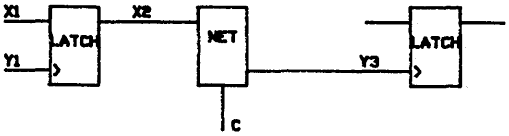

Fig. 6

```
lssd22(X1,X2) :- latch(X1,Y1,X2),
                 network4(C,X2,Y3),
                 latch(_,Y3,_),
                 clock(X1,Y1,C).
```

Fig. 7

The first three predicates on the right side check the applicability of the rule itself. The fourth checks if the rule is violated. More in details, predicate "network4" searches for a net in the circuit description that is connected to the output of the latch(X1,Y1,X2):

```
network4(C,X2,Y3) :- net(T,C,_,Y3),
                     input(X2,T).
```

The "clock" predicate tests for violation looking for equal or dependent clock inputs of the first latch and of the combinational network:

```
clock(X1,Y1,[]).

clock(X1,Y1,[H|T]) :- case(X1,Y1,H),
                      clock(X1,Y1,T).
```

Equality or functional dependency between clocks is encoded in the "case" predicate [19].

4 THE FRAME- AND RULE-BASED DFT EXPERT SYSTEM KERNEL

In the initial phase of this project we decided to use Prolog both as a specification and as implementation language because of its simplicity, power, and availability of a built-in interpreter. All these features allowed a rapid prototyping of the system. At the end of this phase, it contained approximately 60 clauses, 40 for LSSD and 20 for BILBO. The prototype was first developed on an IBM PC and later migrated to a VAX 11/780 running VMS. The only explanation facilities available were messages dispatched by the verifier and the Prolog interpreter's tracing facilities. The main theoretical limits of this approach were that knowledge could be represented only under the form of rules and that the Prolog interpreter has a fixed backward reasoning mechanism. These limits have been encountered by many researchers working on analogous fields and three directions have been proposed to overcome them [20]:

- to extend Prolog both as a language and as an interpreter,
- to build a meta-interpreter over Prolog,
- to define a new, higher level form of DFT knowledge representation and to implement a preprocessor which translates it into executable Prolog clauses.

The first two approaches were difficult and complex, while, as far as the third is concerned, we could benefit from a preprocessor prototype developed at the University of Turin [20]. From the toolmaker's point of view, DFT knowledge may be represented as a hierarchical frame structure, where the body of each frame consists of a production system. This allows to structure DFT knowledge modularly and makes it easier to add new methodologies or to change rules. Moreover, the toolmaker may specify whether such rules must be interpreted either with forward or backward reasoning. The preprocessor translates such specifications and, adding appropriate control statements, generates the actual clauses for the Prolog interpreter. Since we plan to integrate the DFT verifier into a knowledge-based CAD tool, particular attention has been paid to make frame control strategies as general as possible, supporting width-first, depth-first, and heuristic search.

5 CONCLUSIONS

The DFT rule checker we developed is not yet a full system, since it takes into account only 2 methodologies, it relies on a simplified formalism to describe hardware, and it has a reduced user interface. We plan to extend it to other DFT methodologies and to integrate it into a complete CAD system, comprehensive of synthesis, verification, and redesign facilities. This is why particular attention has been paid to the frame- and rule-based expert system which will represent the kernel of the overall CAD tool.

In the preliminary phase, the prototype has been used to verify simple circuits, such as 2 bit binary counters and a systolic priority queue.

We can conclude from our experience that rules are adequate to represent LSSD and BILBO designs and that they may be easily expressed in Prolog. Anyway, the direct description of designs in Prolog yields rough results or needs an excessive number of clauses to represent hardware with the same level of detail of an HDL. Therefore we plan to introduce a high-level language, possibly an already existing HDL, for hardware descriptions, while keeping Prolog clauses as the internal, executable form.

Although it is difficult to produce figures of merit for the current prototype of the system, our experience demonstrates that the combined use of some Artificial Intelligence techniques and DFT methodologies is a good approach to the testability problem of VLSI devices.

A RULE BASED SYSTEM FOR THE OPTIMAL STATE ASSIGNMENT OF CONTROLLERS

E. DUPONT, J. IDT, G. SAUCIER

Laboratoire "Circuits et Systêmes" IMAG
46, avenue F. Viallet 38031 GRENOBLE FRANCE

ABSTRACT :
We present a rule based system for choosing a state assignment which enables the layout of controllers on PLAs of minimal area. The knowledge base is built from the study of the elementary simplification mechanisms in the next state equations and in the output equations. The comparison between the state graph and the rule base yields a set of constraints between the codes of the states. Then the system solves the problem of finding a state assignment consistent with the constraints, and yields the simplified equations.

INTRODUCTION

Automatic synthesis of controllers has been extensively studied in the literature.

The starting point is the description of the controller in an abstract form, in a high level language or through a classical flowchart. The final implementation may use different types of memory points and different types of logic (random logic, PLAs, ROMs...). The logic, essentially for PLAs, may furthermore be partitioned according to precise constraints (maximum size, regularity etc...). In order to minimize the controller area, the crucial problem is the choice of the state assignment.

The minimization of the next state equations or output equations has been extensively studied in the past [1..8]. More recently, heuristics applied to larger and more "realistic" controllers have been presented [9, 10]. Considered from a practical point of view, it is obvious that the optimization process depends a lot on the target structure (microprogrammed or PLA based controller, relative importance of the next state equation part and of the output equation part etc...). Therefore, the optimization rules for the state encoding must be parameterized. This is obtained in our approach by applying an artificial intelligence technique. The constraints on the state encoding are expressed by a set of rules. These rules depend on the choice of the memory points and are chosen by the designer among a set of rules. He can also create and add his own rules. An inference system applies these rules and leads to an optimal encoding. This software is a part of a larger software dealing with all the aspects of controller design. This software is organized around a high-level, object oriented language CADOC [14,15] and leads to several hardware implementations.

I - CONTROLLER DESCRIPTION

The controller may be described, as said before, in different manners (abstract descriptions like regular expressions, high level language, control flow graph). The example that we shall take throughout this paper is an arbiter circuit for MC 68000 microprocessor : it is described by its control flowgraph (figure 1). The circles are the states of a Mealy machine. The transitions of the machine are labelled with the input conditions leading to the next states and with the output signals associated with the couples (state, inputs). The meaning of the graph is illustrated using state 3 of figure 1 :

CH2345-7/86/0000/0915$01.00 © 1986 IEEE

- Transition from state 3 to state 4 if dtak is true ; the output signals bgak, as, uds, lds are emitted.
- Transition frome state 3 to state 3 if dtak is false , the signals bgak, as, uds, lds are emitted.

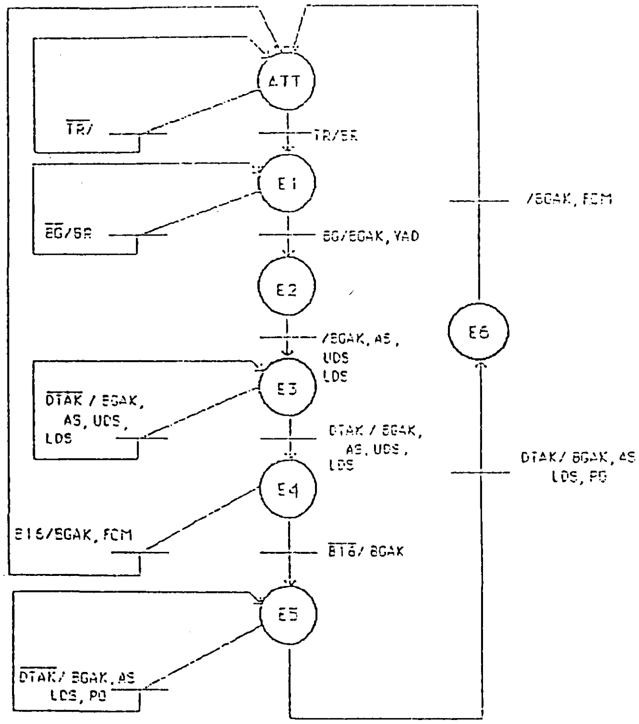

Figure 1

II - SET OF RULES FOR THE STATE ASSIGNMENT

The set of rules for the state assignment depends on the type of memory points (JK, RS, D flip-flops) and the designer's objective. We shall give as an example the set of rules for an implementation on D flip-flop and PLA. A first subset of rules concerns the next state equations, a second one the output equations. The weight given to these two aspects depends on the designer's choice or on the relative importance of the logic blocks.

2.1 - Notations

Let n denote the number of bits used for the state assignment.

The code of state i is denoted C(i).

$\{Y_i\}$ denotes the set of state variables equal to 1 in the code of state i.

Example :

$\{Y_i\} = \{y_1, y_3\}$ if C(i) = (1010)

f(i) denotes the product term associated with the state i.

$$f(i) = \prod_{\substack{j=1 \\ y_j \in \{Y_i\}}}^{n} y_j \prod_{\substack{k=1 \\ y_k \notin \{Y_i\}}}^{n} \overline{y_k}$$

The "always true" input condition is denoted by 1 in the figures.

Inclusion : C(i) is included in C(j) if $\{Y_i\} \subset \{Y_j\}$
Notation : C(i) c C(j).

Adjacence : C(i) and C(j) are adjacent if they differ only by one bit.

Notation : C(i) adj C(j).

In this case, the sum f(i)+f(j) reduces to one minterm, denoted $\lfloor f(i)+f(j) \rfloor$.

2.2 - Example of optimization rules for next state equations for an implementation on PLA with D flip-flops

The first two rules shown here deal with the "fork" and "join" situations in a flowchart and are based on the contribution of a node in the next state equations. It is well known that for D flip-flops the next state equations have the following form :

$$\{Yi\} = \sum_{j \in (\text{antecedent states of state } i)} f(j) \text{ x (input condition of the arc } j \to i)$$

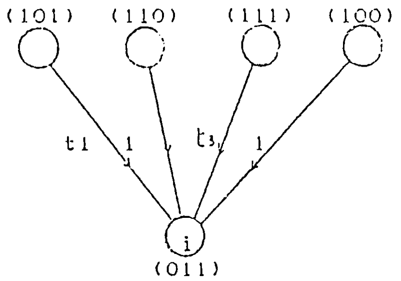

Figure 2

The contribution of state i in Figure 2 to the equations is :

$$Y_2,Y_3 = t_1Y_1\overline{Y}_2Y_3 + Y_1Y_2\overline{Y}_3 + t_3Y_1Y_2Y_3 + Y_1\overline{Y}_2\overline{Y}_3$$

To minimize the contribution of a node, rules a and b may be applied.

<u>RULE a</u>

If a node is connected to p antecedents ($2^{k-1} < p < 2^k$) with the same input condition on the arcs,

Then : - assign to k out the n bits of the code of the antecedents a p-subset of the 2^k codes.

- do not use the (2^k-p) remaining codes in the state assignment.
- let the other (n-k) bits be "invariant".

Example : 6 states are connected to state i by arcs with transition "1", in a graph with 50 states (encoding on 6 bits) (Figure 3).

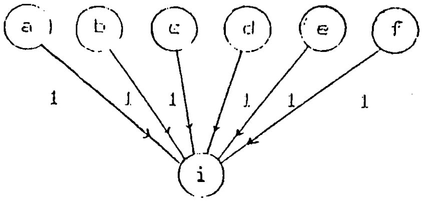

Figure 3

A possible encoding is :

0 0 0 0 1 1
0 0 1 0 1 1
0 1 0 0 1 1
1 0 0 0 1 1
1 1 0 0 1 1
0 1 1 0 1 1

The codes : (101011) (111011) cannot be used for the state assigment.

The contribution of state i is : $\overline{Y}_4\ Y_5\ Y_6$

Remark : - This rule allows p product terms to be replaced by one product term

- The degrees of freedom are the position of the "invariant" bits and the code assignment within the set of k bits.

<u>RULE b</u>

If a node is connected to p successors ($p = 2^k$) with a sum of input conditions appearing on the arcs equal to 1 then :

- assign to the successors an exhaustive encoding on k out of n bits
- let the (n-k) remaining bits be invariant or "replicate" one or several of the first k bits.

Example :

A possible state assignment is (on 4 bits) :

i	0 0 1 0
j	0 1 1 0
k	1 0 1 1
l	1 1 1 1

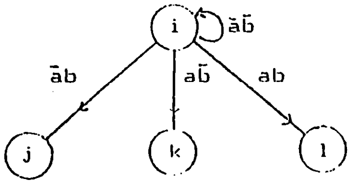

Figure 4

Equations : $Y_1 = a.f(i)$

$Y_2 = b.f(i)$

$Y_3 = f(i)$

$Y_4 = a.f(i)$

Remark : we generate three product terms af(i), b(fi) and f(i) instead of four product terms.

Remark : - This rule allows $p = 2^k$ product terms to be replaced by (k+1) product terms. Only k input conditions are appearing in the equations, instead of 2^k.

- The degrees of freedom are the position and value of the "non significant" bits.

- In the case k = 1, the conclusion of rule b is : C(j) c C(k) or C(k) c C(j), j and k being the successors.

RULE c

If p nodes are connected through a path with the same input conditions on the transitions, then for p' nodes ($p' = 2^k-1 < p$) assign on k of the n bits an optimal sequence of codes (see (13)); the (n-k) remaining bits are invariant.

This rule leads to 2(k-1) product terms instead of 2^k-2.

We can notice that, if k=2, $2(k-1) = 2^k-2 = 2$. Rule c must be restricted to k>3, ie p'>7

The degrees of freedom are the positions and the values of the "non significant" (n-k) bits. As an example, let us consider the sequence of figure 5.

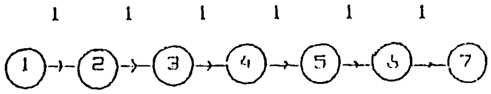

Figure 5

A possible state assignment is (on 5 bits) :

1	1 0 0 1 0
2	0 1 0 1 0
3	1 0 1 1 0
4	1 1 0 1 0
5	1 1 1 1 0
6	0 1 1 1 0
7	0 0 1 1 0

We have 4 product terms instead of 6.

OTHER RULES

Other rules, which address more complex situations, have been defined. Some graphical examples are shown :

	Encoding constraints : C(u) adj C(x) C(z)cC(y) OR C(y)cC(z) 3 product terms : af(u), bf(x), [f(u)+f(x)] OR āf(u), b̄f(x), [f(u)+f(u)]
	Encoding constraints C(x) adj C(x') C(y)cC(z) AND C(y')cC(z') OR C(z)cC(y) AND C(z')cC(y') C(y) XOR C(z)=C(y') XOR C(z') 3 product terms : āf(x), āf(x') [f(x)+f(x')] OR af(x), af(x') [f(x)+f(x')]
	Encoding constraints C(x) adj C(u) C(z) c C(y) 2 product terms : af(x), [f(x)+f(u)]

Figure 6

All the rules are not listed here. They may address more complex situations or dedicated targets of the designer (for example, partitioned PLAs).

2.3 - Rules for the output equations

Two examples of basic rules will be given here. The second rule shows the dependancy and the contradiction which may exist between two rules.

RULE a'

If p states send (for the same input condition in a Mealy machine) one or more identical control signals then for $2^{k-1}<p\leq 2^k$

- assign to k of the n bits the 2^k possible values
- assign to the (n-k) bits an invariant code.

Remark

The gain is weighted by the number of identical outputs associated with the nodes.

RULE b'

If one or several control signals are sent by one and only one state then do not apply rules a and b to this state.

This last rule shows that the output rules may conflict with the next state equations rules.

III - GENERAL STRATEGY OF THE INFERENCE SYSTEM

The flowchart of the system is given on Figure 7. The system is organized in modules $M_1 \ldots M_6$. The rule base is independent of the modules, so that the set of rules may be enlarged with new rules, and that only part of the rules may be used.

The first **module M_1** asks for the designer's graph, strategy and "initial" constraints (for example, which state must be encoded (0...0)). M_1 performs a selection of the suitable rules in the rule base, according to the chosen target. The source code is 200 LISP lines.

A second **module M_2** performs inferences between the selected rules and the graph. All selected rules are tried, and in case of success, their consequences are memorized.

The heuristic is the following : try first the rules liable to yield a high gain (for example, rule c) ; compute the gains ; if these gains are small (case of loose constraints), apply the more complex rules (figure 6). The module M_2 also collects the "external" constraints provided by the designer. Its output is a set of constraints (either between the codes of individual states, or between the encodings of groups of states) associated with gains and with symbolic simplified equations.

The source code is 1000 LISP lines.

The **module M_3** then analyses these results : as a matter of fact, satisfying different constraints may lead to conflicts ; the effective state assignment is a complex problem and requires a high CPU time.

M_3 has to deal with two sorts of constraints : inclusions and adjacences between codes. Some constraints are incoherent, whatever the number of bits may be, others are related to the number of bits. Let us give two examples of such impossibilities :

(C(0)cC(1), C(1)cC(2) ; C(2)cC(3) ; C(3)cC(4))

is impossible in the case of an encoding with 3 bits, but possible on 4 bits.

$$\left.\begin{array}{l}\text{C(1) adjacent to C(2)}\\ \text{C(2) adjacent to C(3)}\\ \text{C(1) adjacent to C(3)}\end{array}\right] \text{ is impossible.}$$

The result of M_3 is a new set of constraints, rid of such impossibilities.

The task of the following **module M_4** is to find a state assignment satisfying all the constraints, if there exists one. The procedure is not quite the same according to the size of the problem, but it is based on the same technique : try to encode the states the one after the other, while satisfying the constraints at each step ; backtrack in case of failure, until either a solution is found or all combinations have been tried. The problem is to try all possible solutions as far as they are not equivalent. At each step equivalent choices are identified to avoid trials of equivalent encodings after backtracking.

In the case of large size circuits, a two-level encoding and backtrack mechanism is used : first find a possible partial encoding of the different sets of states, then assign codes in each set. The source code is about 1200 LISP Lines.
If no solution is found, the program asks for the designer's advice :
- try to code on n+1 bits, instead of n ?
- eliminate some constraints according to gains using **module M_5** and return to M4.
The source code is about 500 LISP lines.

A last **module M_6** collects the results, fetches the simplified equations related to constraints which have been satisfied, and deduces the equations. The source code is about 700 LISP lines.

Its result is an encoding of the states and the equations to be implemented. These equations can be furthermore processed by a rule based boolean minimizer and lead to an automatic layout on PLAs, gate arrays or complex MOS gates [13].

IV - EXAMPLE : ENCODING OF THE GRAPH OF AN ARBITER CIRCUIT

The state graph of the case study is given on figure 1 ; two solutions are proposed. In section 4.1 only the next state equations are optimized. In section 4.2 the output equations are also taken into account.

4.1 - Next state equations optimization

An external encoding constraint is given by the designer : the state 0 (ATT) must be encoded with (0..0). The graph has 7 states, which will be denoted (0,1,...6).
We shall try to code on 3 bits.
The application of rule b is yielding the constraints of table 1.
The application of the complex rules described on figure 6 are yielding the constraints of tables 2 and 3.

ANTECEDENT STATES	SUCCESSOR STATES	CONSTRAINTS	MINTERNS GENERATED
0	0 1	C(1) c C(0) OR C(0) c C(1)	($\overline{tr}$f(0) and f(0)) OR (trf(0) and f(0))
1	1 2	C(1) c C(2) OR C(2) c C(1)	(bgf(1) and f(1)) OR ($\overline{bg}$f(1) and f(1))
3	4 3	C(3) c C(4) OR C(4) c C(3)	(dtak f(3), f(3)) OR ($\overline{dtak}$ f(3), f(3))
4	0 5	C(0) c C(5) OR C(5) c C(0)	(b_{16} f(4), f(4)) OR ($\overline{b_{16}}$ f(4), f(4))
5	5 6	C(5) c C(6) OR C(6) c C(5)	(dtak f(5), f(5)) OR ($\overline{dtak}$ f(5), f(5))

Table 1

ANTECEDENT STATE	SUCCESSOR STATE	CONSTRAINTS	MINTERMS GENERATED

3 , 5	(4 3),
	(6 5)
		C(5) adj C(3)
		[C(3)cC(4) and C(5)cC(6)] OR
		[C(4)cC(3) and C(6)cC(5)]
		C(3)XOR C(4) = C(5)XOR C(6)
			3 minterms :
			(f(3), f(5)) AND
			dtak [f(3) + f(5)] OR
			f(3), f(5) AND
			dtak [f(3) + f(5)]

Table 2

ANTECEDENT STATE	SUCCESSOR STATE	CONSTRAINTS	MINTERMS GENERATED

2 3	(3) and
	(3 4)
		C(2) adj C(3)
		C(3) c C(4)
			2 minterms
			[f(2) + f(3)]
			dtak. f(3)

Table 3

The treatment of the list of constraints yields the following encoding (with 3 bits).

STATE	Y_1	Y_2	Y_3
0	0	0	0
1	0	1	1
2	0	0	1
3	1	0	1
4	1	1	1
5	1	0	0
6	1	1	0

Table 4 : encoding

This symbolic next state equations are :

$$Y_1 = [f(2) + f(3)] + \overline{b_{16}}\ f(4) + f(5)$$

$$Y_2 = bg.\ f(1) + dtak\ [f(3) + f(5)]$$

$$Y_3 = tr.\ f(0) + f(1) + [f(2) + f(3)]$$

There are 7 different product terms :

$[f(2) + f(3)]$	ie $\overline{Y}_2\ Y_3$
$\overline{b_{16}}.f(4)$	ie $\overline{b_{16}}\ Y_1Y_2Y_3$
$f(5)$	ie $Y_1\overline{Y}_2\overline{Y_3}$
$bg.f(1)$	ie $bg.\ \overline{Y}_1Y_2Y_3$
$dtak\ [f(3)+f(5)]$	ie $dtak\ Y_1\overline{Y_2}$
$tr.\ f(0)$	ie $tr.\ \overline{Y}_1\overline{Y}_2\overline{Y}_3$
$f(1)$	ie $\overline{Y}_1Y_2Y_3$

Only 4 input conditions appear in the equations, though 8 input conditions are given in the graph.

4.2 - Taking into account the output equations

The strategy chosen here is to look for a minimization of the next state equations, while taking into account the output equations.
The method is to prevent the applications of the next state assignment rules which would lead to the suppression, in the next state equations, of a product term which is a prime implicant of the output equations.
The symbolic equations of the outputs are :

$\mathrm{fcm} = b_{16}\ f(4) + f(6)$

$\mathrm{br} = \mathrm{tr}\ f(0) + \overline{\mathrm{bg}}\ f(1)$

$\mathrm{vad} = \mathrm{bg}\ f(1)$

$\mathrm{uds} = f(2) + \overline{\mathrm{dtak}}\ f(3) + \mathrm{dtak}\ f(3)$

$\mathrm{bgak} = b_{16}\ f(4)+f(6)+\mathrm{bg}\ f(1)+f(2)+\overline{\mathrm{dtak}}\ f(3)+$
$\quad \mathrm{dtak}\ f(3)+b_{16}\ f(4)\overline{+\mathrm{dtak}}\ f(5)+\mathrm{dtak}\ f(5)$

$\mathrm{as} = f(2)+\overline{\mathrm{dtak}}\ f(3)+\mathrm{dtak}\ f(3)+\overline{\mathrm{dtak}}\ f(5)+\mathrm{dtak}\ f(5)$

$\mathrm{lds} = f(2)+\overline{\mathrm{dtak}}\ f(3)+\mathrm{dtak}\ (f3)+\overline{\mathrm{dtak}}\ f(5)+\mathrm{dtak}\ f(5)$

$\mathrm{p0} = \overline{\mathrm{dtak}}\ f(5)+\mathrm{dtak}\ f(5)$

Irreducible minterms in the output equations

A simple algorithm enables them to be found :
$f(6)$; $b_{16}f(4)$; $\overline{\mathrm{bg}}\ f(1)$; $\mathrm{tr}\ f(0)$; $\mathrm{bg}\ f(1)$; $f(5)$
In this case, we prevent the application of rule b to the pair of states (1,2), leading to the elimination of one of the product terms : bgf(1) or $\overline{\mathrm{bg}}$f(1) which are prime implicants of the output equations.
The treatment of the both systems (next state equations, output equations) leads to the following list of constraints :
(C(0) c C(1)) ; (C(3) c C(4)) ; (C(0) c C(5)) ;
(C(3) adj C(5)) ; (C(2) adj C(3)) ;
((C(3) c C(4)) and (C(5) c C(6))) OR
((C(4) c C(3)) and (C(6) c C(5))) ;
C(3) XOR C(4) = C(5) XOR C(6).

This leads in this case to the same encoding as previously, but the next state equations are different (for Y_3)

Results

Next state equations

$Y_1 = \lfloor f(2)+f(3)\rfloor + \overline{b_{16}}\ f(4) + f(5)$

$Y_2 = \mathrm{bg}\ f(1) + \mathrm{dtak}\lfloor f(3) + f(5)\rfloor$

$Y_3 = \mathrm{tr}\ f(0) + \mathrm{bg}\ f(1) + \overline{\mathrm{bg}}\ f(1) + \lfloor f(2)+f(3)\rfloor$

Output equations

$\mathrm{fcm} = b_{16}\ f(4) + f(6)$

$\mathrm{br} = \mathrm{tr}\ f(0)+\overline{\mathrm{bg}}\ f(1)$

$\mathrm{vad} = \mathrm{bg}.f(1)$

$\mathrm{uds} = \lfloor f(2)+f(3)\rfloor$

$\mathrm{bgak} = \lfloor f(2)+f(3)\rfloor+f(6)+b_{16}\ f(4)+\overline{b_{16}}\ f(4)$
$\quad +\mathrm{bg}\ f(1)+f(5)$

$\mathrm{as} = \lfloor f(2)+f(3)\rfloor+f(5)$

$\mathrm{lds} = \lfloor f(2)+f(3)\rfloor+f(5)$

$\mathrm{p0} = f(5)$

Set of product terms

The encoding leads to 9 product terms :

$\lfloor f(2)+f(3)\rfloor$	ie $(\overline{Y}_2Y_3)$;
$\overline{b}_{16}\ f(4)$	ie $(\overline{b_{16}}\ Y_1Y_2Y_3)$;
$\mathrm{bg}.f(1)$	ie $(\mathrm{bg}.\overline{Y}_1Y_2Y_3)$;
$\mathrm{dtak}\lfloor f(3)+f(5)\rfloor$	ie $(\mathrm{dtak}.Y_1\overline{Y}_2)$;
$\mathrm{tr}\ f(0)$	ie $(\mathrm{tr}.\overline{Y}_1\overline{Y}_2\overline{Y}_3)$;
$\overline{\mathrm{bg}}\ f(1)$	ie $(\overline{\mathrm{bg}}\ \overline{Y}_1Y_2Y_3)$;
$b_{16}\ f(4)$	ie $(b_{16}Y_1Y_2Y_3)$;
$f(6)$	ie $(Y_1Y_2\overline{Y}_3)$;
$f(5)$	ie $(Y_1\overline{Y}_2\overline{Y}_3)$

Performance

The program is developed on Vax 11/780. The example presented here requires 22 sec CPU, 25 sec when the output equations are taken into account.

Area gain

The circuit is implemented on a PLA, the area of which is proportional on one hand to the number of product terms, on the other hand to the sum : ni+3n+nO, where ni is the number of controller inputs, n is the number of encoding bits, nO is the number of outputs.

The state assignment enables to obtain 9 product terms (instead of 11 in the worst case) and 5 inputs (instead of 8).

We shall choose $g = \frac{S'-S}{S'}$ as an estimate of the gain

S' = area in the worst case

S = area corresponding to the state assignment

g = 28 %

Other examples have been treated and the characteristics of the circuits, the state assignment and the gain estimate are presented in table 5. The circuits labelled 1,2,3,4 are presented in the references [12], [17], [16], [18]

				worst case		obtained results		
Circuit	ns	nO	n	NPT	ni	NPT	ni	Area gain
1	20	8	5	38	18	27	13	37%
2	4	4	2	12	4'	°	3	38%
3	7	3	3	14	2	11	2	21%
4	11	0	4	17	6	9	4	53%

Table 5

In table 5, ns is the number of states, NPT the number of product terms, n the number of bits, ni the number of input conditions taken into account
in the PLA, nO the number of outputs.

CONCLUSION

We have presented here a rule based system for optimal encoding of the states of a controller, taking into account the next state and output equation minimization. The rules imply constraints on the encoding such as adjacences, inclusions...The set of rules may be modified to take into account the target structure (types of flip-flops, type of combinatorial circuits).

The example presented here addresses only a small size circuit but it demonstrates the principle of the method. The system works fairly well for such circuits, it is being improved for larger circuits, in order to reduce the CPU time.

The system is very flexible, because of its organization with an independent rule base, which may be extended by addition of new rules.

The encoding sytem is included in a complete design system, allowing a top down design, from the specification to the layout.

Constructive Solid Geometry: A Symbolic Computation Approach

L. Leff
David Y. Y. Yun

Department of Computer Science and Engineering
Southern Methodist University

ABSTRACT

A method of parametcrizing an object that is represented by constructive solid geometry (CSG) is provided. A method is developed for generating the constraint equations on the parameters which provide a sufficient condition so that the object remains geometrically similar as the parameters are varied. These constraints and the symbolic form of CSG are important to the problem of geometric optimization which is part of Computer Aided Engineering.

1. Introduction

Constructive Solid Geometry (CSG) is now the method of choice for representing mechanical engineering objects such as machine parts inside a computer and is replacing other methods such as boundary representations in the CAD-CAM systems of the 80's. [5]

In CSG, an object is represented as the boolean operations, union, difference and intersection, as applied to regular sets such as the set of points enclosed by rectangles and circle in two dimensions or rectangular pyramid and right circular cylinder in three dimensions.

Tilove [5] has shown how an object represented in Constructive Solid Geometry can be converted into its boundary representation. This is important for displaying the object and determining the equivalence of two objects among other purposes.

A method was developed to represent an object that has dimensions whose values are symbolic expressions based on the boundary representation. [1] Each point where two segments of the boundary representation intersect has symbolic values for its coordinates. The connectivity of these points by means of faces and edges are also stored. A method for representing part families and for setting up CSG objects whose dimensions are variables is discussed in the spirit of tolerancing in [3]. In constructive solid geometry, as the dimensions of the primitives vary, the object changes shape. In a boundary representation, the faces may intersect each other as the locations of the points of intersection vary when the parameters change. For CSG objects, we provide a method for generating a set of equalities and inequalities, such that their satisfaction provides a sufficient condition for the object to be similar to the original one as the parameters are varied. Two objects constructed by parametric CSG are defined to be similar when their representation by means of the techniques of [1] are equal. A more formal definition follows later in the paper.

This set of inequalities can be put into a geometric optimization program. Geometric optimization programs are used to determine the structure of minimum weight or cost. The constraints include those relating to the partial differential equations, e. g. the stress in the object must not exceed a given value, the geometric constraints insuring that varying the parameters do not change the form of the symbolic solution, as well as additional ones entered by the user.

In this paper, we illustrate the techniques and concepts with the two dimensional case where the primitive used is a rectangle whose faces are parallel to the x and y axis. For a discussion of arbitrary curved surfaces, canonical forms and other aspects of geometric optimization, see [2].

2. Constructive Solid Geometry

In constructive solid geometry, we represent an object and the union, difference or intersection of simple objects or of other objects so defined. The mechanical engineer doing constructive solid geometry can enter the location of two simple objects. He can then indicate that they should be combined into a new object by taking the intersection, union or difference of the sets of points represented by the objects.

This process can continue recursively, since the intersection, union and difference operations can be applied to objects previously created and to additional simple objects. These operations can be expressed by an expression where the operands are primitives and the operators are union, difference or intersection. We can define the syntax of this expression as follows:

E -> (E O E) | P

where E represents an expression, O an operator, and P a primitive.

These expressions can be represented in the computer by the equivalent binary tree with the operators at the nodes and the primitives as leaves. Each primitive will be represented by a record with four real numbers, the x and y position of the lower left hand corner and the height and width. The operators will simply be tree elements with left and right sons and an indicator for the type of operator (union, intersection or deletion).

Figure 1 shows four different CSG trees corresponding to the same physical object.

3. CSG Tree to boundary conversion algorithm

A frequent operation in mechanical engineering CAD-CAM is to convert the constructive solid geometry to a boundary representation. This is needed for drawing the object on a graphics device. In addition, it is possible to tell whether two objects (e. g. A and B) represent the same by taking the symmetric difference of A and B, (A–B)∪(B–A). If the result of the symmetric difference has no boundaries, then A represents the same object as B.

We will use this later as the main part of our canonical simplification function for CSG trees and in modified form as part of the geometric constraint generator.

The algorithm [4] takes each edge of each primitive and propagates it down the CSG tree. When the edge reaches a primitive it is divided into those segments on, off or in the primitive. Then

CH2345-7/86/0000/0925$01.00 © 1986 IEEE

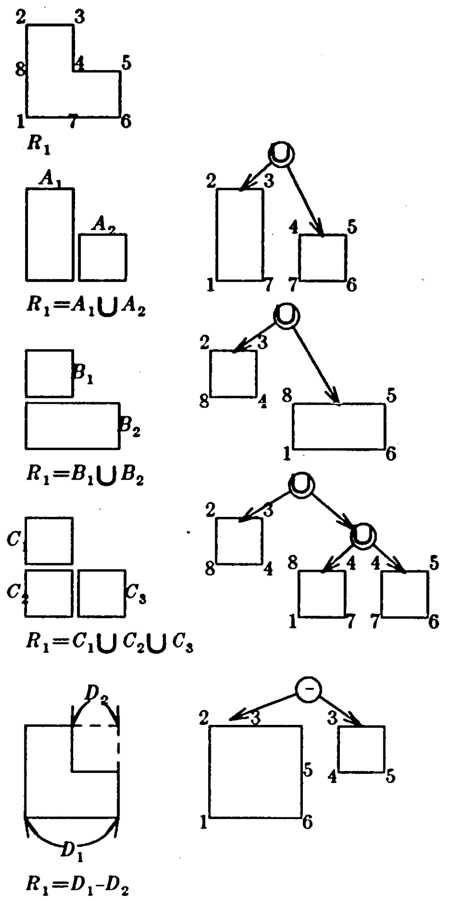

Figure 1

at each node, the results of dividing the segment for each subtree are merged together to produce the classification of the edge for the object represented by the subtree at that node.

We do this with the following algorithm:

```
function edgelist (T) ; T is a CSG tree (returns list of edges
on the boundary of the object
represented)
        edgelist <- nil
        for each primitive P_i
                for each edge E of P_i
                        (EinS, EonS, EoutS) <- M [E,T]
                        merge (EinS,Eon,EoutS) with edgelist
                end /for/
        end /for/
remove edges in or out of object leaving edges on
end /procedure/
```

Algorithm to Classify an edge against a primitive

```
function M(Edge, T) ; T is a CSG Tree (returns edge divided into
segments with on, off or in indicated plus for on whether shape is
above or below)
if T is a primitive then
        perform a primitive classification
else
        classify the Edge with respect to the left hand and right
        hand sons of T by calling M recursively
        for each part of the edge after it is divided at any point
        where it intersects any primitive
                determine its classification using on, off or in informa-
                tion and neighborhoods as passed up from calling M
                on left and right hand subtrees
end /function/
```

This algorithm works by taking the edge of each primitive and determining whether or not it is on the object's perimeter. The union of these edges will be the boundary of the object.

The working of the algorithm is illustrated with the object, $A_1 \cup (A_2 \cup A_3)$, which is illustrated by figure 2. Figures 3,4 and 5 show the line segments generated when each of the four edges of A_1, A_2, and A_3 are respectively in the outer loop of the function edge list.

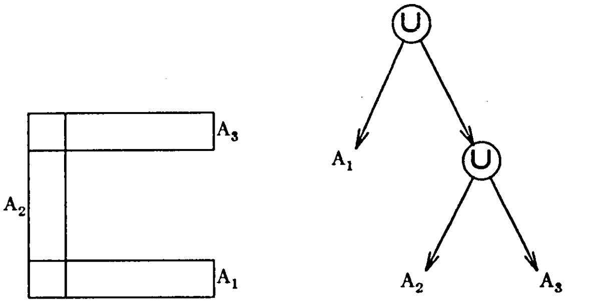

Figure 2

When we take the edges of A_3 and find out which are in the object, we get:

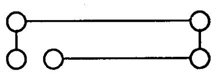

Figure 3

For A_2, we get

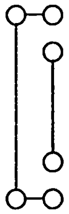

Figure 4

For A_1, we get

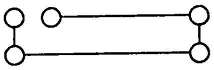

Figure 5

The union of these shapes form the perimeter of the total object.

The algorithm M [5] classifies the edges. Each edge is classified against both the left and right hand subtrees of any node. The result coming back up will indicate what parts of the edge are on, in or off the object represented by the subtree. These can be combined by a complicated rule system which depends on the classification of the edge of each subtree, the type of operator and in the case of on segments which side the object the segment is on. Figure 6 shows how the edge 1-2 is classified in A in the trees A∪B, A∩B and A-B

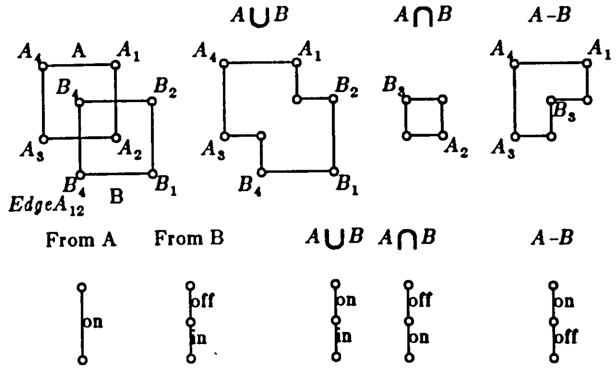

Figure 6

4. Symbolic Constructive Solid Geometry

In symbolic constructive solid geometry, each rectangle has the x and y position, height and depth represented both as an arbitrary symbolic mathematical expression and as a constant. The constraints generated will insure that any value substituted for the parameters into the symbolic expressions will yield an object geometricly similar to the one given when the primitives have the dimensions given by the constants. The constant dimensions can also be used in displaying the object or as starting values for the iterations in geometric optimization.

In addition to the expression defining the CSG primitive, the user inputs a table listing for each primitive both the symbolic and constant values for the x and y coordinates of the lower left hand corner as well as Δx and Δy, the width and height respectively. The user can also provide the symbolic location of a primitive by defining a vector whose components are expressions between a corner of another primitive and a corner of the new primitive. The graph formed by these connections should form a forest where the nodes are the primitives and an edge exists between two nodes when there is a connection between the corresponding primitives.

(In the discussion that follows values that are symbolic will have a .s prefix while the values that are constants will not.)

Figure 7 illustrates a T-bar and the tree corresponding to the CSG expression entered with parametric CSG. Tables 1 and 2 show the other information.

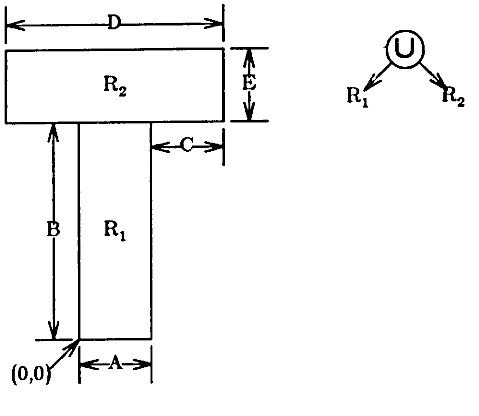

Figure 7

Table 2: Connection Table for Figure 7

Figure 8 illustrates a more complicated representation, a square with a hole in it formed by four rectangles. Notice the different methods of connecting juxtaposed rectangles. Rectangles 1 and 2 are connected with a connection list item. The system determines that rectangles 2 and 3 are juxtaposed from the values of the constants, i. e. that G = 0 and H = B + E. The connections between rectangles 3 and 4 are determined in the same manner. Of course, the end of rectangle 4 is inside rectangle 1.

5. Algorithm for Generating Geometric Constraints

We define similarity as mentioned in section 1. Let E2 be the object produced from the CSG tree for E1 by simply changing the values of the parameters in the symbolic CSG tree defining E1. Let G1 and G2 be graphs formed from E1 and E2 respectively. The nodes correspond to the positions in two dimensional space where a horizontal and a vertical boundary segment intersect. There will exist an edge between node i and node j of the graph if there is a primitive that has a corner at the point corresponding to node i and one node at the point corresponding to node j. If the new set of values for the parameters obeys the constraints, then G1 and G2 will be isomorphic and for all pairs of nodes mapped by the isomorphism, the two nodes will have the same expressions for x.s and y.s.

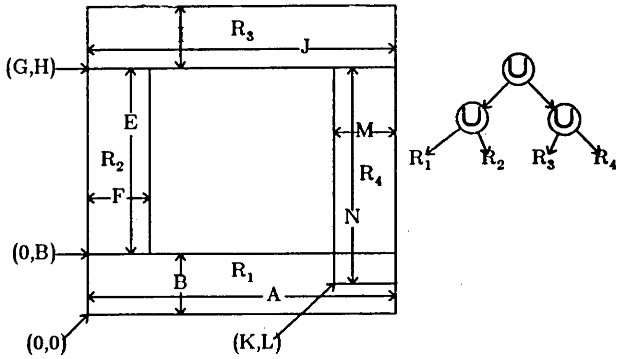

Figure 8a

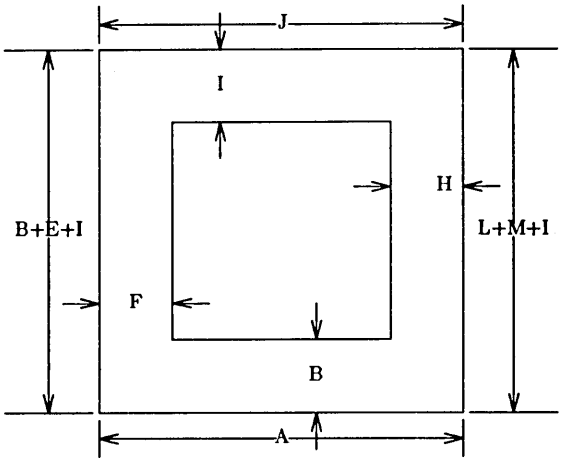

Figure 8b

This algorithm uses as its principal component an adaptation of the Tilove algorithm for finding the boundary segments. In addition to generating the boundary segments of the object, it generates the constraints necessary to insure that those are the boundary segments. There are five steps.

1. For each expression that appears in the $\Delta x.s$ or the $\Delta y.s$ field of the rectangle term, add the inequality that the expression is > 0 to the inequality list.
2. Perform a depth-first search of the graph formed by the items on the connection list. Compute the symbolic values for the x and y coordinates of the four corners of each rectangle: x.sw.s,y.sw.s,x.se.s,y.se.s,x.nw.s,y.nw.s,x.ne.s, and y.ne.s.
3. Run a modified version of the Tilove algorithm for finding the boundary segments of an object constructed with CSG. It generates the boundary segments as before. However, the end points of each segment are labeled with the symbolic values for the coordinates as well as the numeric values. In the classification of a segment against a primitive and in the M routine for two lists of the same segment, we generate equalities and inequalities needed to provide a sufficient condition that any classification done would remain the same as the parameters are varied. (See below for details.)
4. Convert the equality list into a set of substitutions. In the general case, this can be done with a Groebner basis algorithm. If all the dimensions and locations were simply single variables (as is often the case in practice), then this can be done by reducing the coefficient matrix to a reduced row echelon form. Apply the set of substitutions to the inequalities.
5. Remove any redundant inequalities and make obvious simplifications by combining terms such as replacing $B < B + D$ with $0 < D$.

The resulting list of inequalities is the set of geometrical constraints.

The following is a detailed description of the part of the primitive classification routine that generates the inequalities and equalities. Only the part for classifying a horizontal segment is shown. The part for classifying vertical segments is analogous with the roles of x and y reversed. The notation AddI (blah) means add the inequality blah to the list of inequalities, AddE (blah1) means add the equality blah1 to the list of equalities. The shorthand GI (blah2) means: if list = nil then list = blah2 else list = list or blah2. The routine receives as input a rectangle and a horizontal edge where the coordinates left and right end points are referred to be the subscripts 1 and 2 respectively and whose Y value is referred to as Y_0.

```
List = nil
If $Y_0$>Y.nw or $Y_0$<Y.sw or $X_0$>=X.se or $X_1$≤X.sw then
        If $Y_0$>Y.nw then
                GI (Y.nw.s>$Y_0$.s)
        If $Y_0$ < Y.sw then
                GI ( $Y_0$.s<Y.sw.s)
        If $X_0$≥X.se then
                GI ( $X_0$.s≥X.se.s)
        If $X_1$<=X.sw then
                GI ( X1.s <= X.sw.s )
If list not = nil then AddI(list)
else
        If $X_0$<X.sw then
                AddI ( $X_0$.s<X.sw.s )
        If $X_0$>X.sw then
                AddI ($X_0$.s>X.sw.s)
        If $X_0$=X.sw then
                AddE( $X_0$.s=X.sw.s)
        If $X_1$>X.se then
                AddI(X.se.s<$X_1$.s)
        If $X_1$<X.se then
                AddI (X.se.s>$X_1$.s )
        If $X_1$=X.se then
                AddE(X.se.s=$X_1$.s)
        If $Y_0$>Y.sw and $Y_0$<Y.nw then
                AddI($Y_0$.s>Y.sw.s)
                AddI($Y_0$.s<Y.nw.s)
        If ($Y_0$=Y.sw) then
                AddE($Y_0$.s=Y.sw.s)
        If ($Y_0$=Y.nw) then
                AddE($Y_0$.s=Y.nw.s)
end /if/
```

When the M routine is invoked at a given operator node, it calls itself recursively for the left and right hand subtrees. After control is returned after these two calls, the routine has two chains of horizontal segments to be classified against each other. From these two chains, we generate additional equalities and inequalities that must be satisfied.

Let A_1–A_n and A_1.s–A_n.s represent the list of x coordinates of the segments returned from the call from the left hand subtree and their symbolic values respectively arranged in ascending order by numerical x value. B_1–B_m and B_1.s–B_m.s represent the x coordinates for the right hand subtree.

We generate inequalities and equalities as follows:

```
For all i
        If i <  n then if $\exists_j$ ($B_j$>$A_i$ $\wedge$ (j=1 $\vee$ $B_{j-1}$<$A_i$ )) $\wedge$
        $\exists_k$ ($B_k$<$A_{i+1}$ $\wedge$ (k=m $\vee$ $B_{k+1}$>$A_{i+1}$)) then
                AddI( $A_i$.s<$B_j$.s )
                AddI( $A_{i+1}$.s>$B_k$.s )
```

```
For all i
    if $i < m$ then if $\exists_j (A_j>B_i \wedge (j=1 \vee A_{j-1}<Bi)) \wedge$
    $\exists_k (A_k<B_{i+1} \wedge (k=n \vee A_{k+1}>B_{i+1}))$then
            AddI( $B_i.s<A_j.s$ )
            AddI( $B_{i+1}.s>A_k.s$ )
if $B_i<A_i \wedge (i=m \vee B_{i+1}>A_i)$ then
        AddI( $B_i.s<A_i.s$ )
if $A_i<B_i \wedge (i=n \vee A_{i+1}>A_i)$then
        AddI( $A_i.s<B_i.s$ )
if $B_i>A_n \wedge (i=m \vee B_{i-1}<A_n)$ then
        AddI( $B_i.s>A_n.s$ )
if $A_i>B_m \wedge (i=n \vee A_{i-1}<B_m)$ then
        AddI ( $A_i.s>B_m.s$ )
for each i and j such that $A_i=B_j$ AddI ( $A_i.s=B_j.s$)
```

Note that when we pass up the list of segments we insure that only one of the two symbolic expressions, $A_i.s$ and $B_j.s$ that are equal is used as a coordinate value for an endpoint.

To illustrate these points, I will show how the inequalities are generated for the parametric CSG objects in Figures 7 and 8. In step 1, we generate the constraints: $A > 0$, $B > 0$, $D > 0$ and $E > 0$. For the T-shaped object, step 1 computes that the southeast corner is at (A+C,B). x.sw.s and y.sw.s are A+C-D and B respectively. All inequalities are generated by the primitive classification of the lower edge of rectangle 2 against rectangle 1. We generate the following line and inequalities:

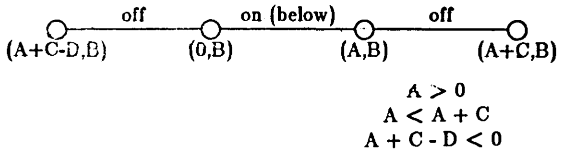

Figure 9

In step 5, the second inequality is simplified and this set is combined with the set generated in step 1. The resulting set of inequalities is:

$A > 0$ $C > 0$ $B > 0$
$D > 0$ $E > 0$ $A + C - D < 0$

When we apply the algorithm to the object in figure 2, step 1 generates the following inequalities: $A > 0$, $B > 0$, $F > 0$, $J > 0$, $I > 0$ and $M > 0$. Step 2 assigns the x.s and y.s values for R_2 as 0 and B respectively. In step 3, we illustrate the algorithm as it works on the upper edge of R_1, the lower edge of R_3, and the lower edge of R_4. These edges happen to be sufficient to generate all the applicable inequalities. In Figure 11, we see the steps in classifying the top edge of R_1. Steps 1,2, 3 and 4 represent the classification of the edge against the primitives R_1, R_2, R_3 and R_4 respectively. In step 5 we combine the results from R_1 and R_2 and in step 6, we combine the results from R_3 and R_4. Finally step 7 is the final combination of the edges. In figure 12, we see the same steps for the lower edge of R_3.

Lastly we illustrate the processing of the lower edge of R_4. We only show the first four steps since no inequalities or equalities are added in the later steps.

Going into step 4, we have the inequalities:

$H > B$	$F<G+J$	$K<G+J$
$K>G$	$F<A$	$H>B$
$L<B$	$K<A$	$F<K$
$A>0$	$B>0$	$F>0$
$J>0$	$I>0$	$M>0$
$(K>F)$or$(L<B)$	$G<F$	

and the equalities:

$B+E=H$ $G=0$ $L+N=H$
$G+J=K+M$ $K+M=A$

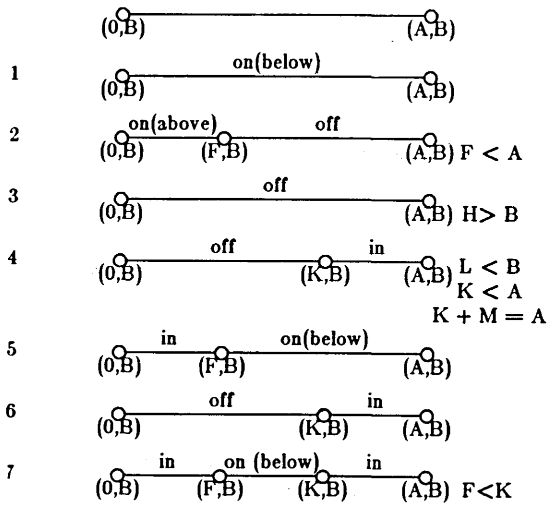

Figure 10

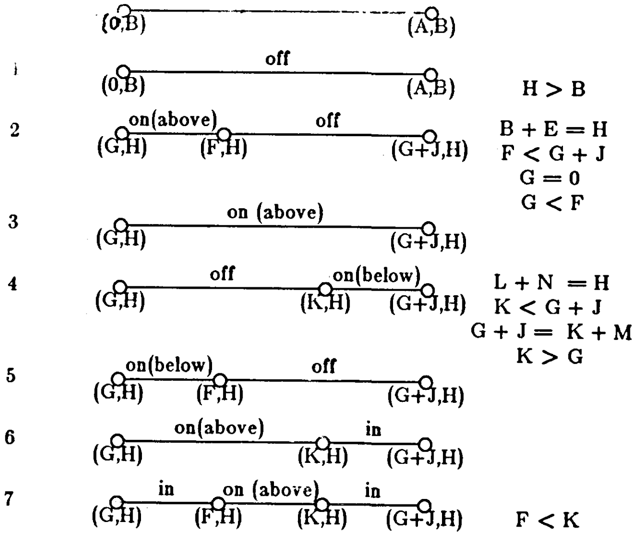

Figure 11

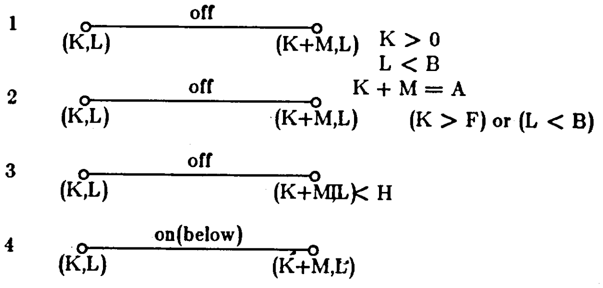

Figure 12

In step 4, the equalities are converted into a substitution list as follows:

B -> L+N-E
G -> 0
H -> L+N
J -> K+M
A -> K+M

In step 5, we apply the substitutions generating and eliminate redundancies getting as our final result for the constraints:

$K+M > 0$	$F < J$	$K < J$
$K > 0$	$F < K+M$	$H > B$
$L < B$	$F < K$	$L + N - E > 0$
$F > 0$	$I > 0$	$M > 0$

6. Computational Complexity Issues

6.1. Generating Geometric Constraints

Let N be the number of primitives. Then the number of edges in the boundary, n, must be $O(N^2)$ [5]. Also the number of points on the boundary where two segments intersect is O(n). k is the number of different types of terms in the expressions for distances. For example, if we had the expressions for distances as n^2, n, $3*n$, $2*n$ then we would have $k = 4$. We count variables raised to different powers separately but not terms with different constant factors.

In the conventional algorithm for finding the boundary segments, the number of times that a pair of line segments must be matched is $O(N^3)$. In our modified algorithm, each time we match a pair of line segments we generate O(1) new inequalities. Since this generation does not involve manipulating the expressions, this modification does not change the $O(N^3)$ behavior. However, the total number of equalities and inequalities is $O(N^2)$. For each edge of a primitive, we have up to four equalities or inequalities generated for each of the O(N) primitives. Since there are O(N) edges, there are $O(N^2)$ inequalities.

Step 1 is trivially O(N). Step 2 to go through the connection lists corresponds to depth first search on a graph. Since there is a maximum of one connection item per primitive which might involve adding polynomials where the result might become as large as O(k), this step is O(kN).

In this subsection the times given will be for the important practical case of the dimensions being simple parameters. Equality constraints are only generated when two rectangles have edges that end at the same place. Thus there can only be O(N) such constraints. In the special case where each dimension is a single variable, the number of variables, k, = O(N) so the time to convert the coefficient matrix to row echelon form is $O(N^3)$.

We perform up to N substitutions on each inequality, each of which can involve adding two k term polynomials so the total time for this step is $O(N^3k)$.

Each simplification takes up to O(k) time per inequality. Eliminating redundant inequalities, if we do this by using an O(z log z) sort first, will take $O(N^2 \log Nk+N^2 k \log k)$. The k log k term comes from the time to put the expressions composing each inequality in lexicographic order so they can be compared in O(k) time. However $k = O(N)$ so the total time for this step is $O(N^3k)$.

The actual evaluation of the inequalities which will occur once per iteration in geometric optimization will be $O(N^2k)$ operations since we have $O(N^2)$ inequalities with up to k terms apiece.

CREATION AND SMOOTH-SHADING OF STEINER PATCH TESSELLATIONS

David E. Breen

Center for Interactive Computer Graphics
Rensselaer Polytechnic Institute
Troy, NY 12181

Abstract

Motivated by recent work with Steiner patches, a method has been developed to create C0 tessellations of Steiner patches which approximate high order biparametric surfaces. An accompanying technique has also been created to smooth-shade the tessellation in order to produce high quality color raster images. The whole process is an extension of the tessellation and rendering process using polygons. The Steiner patch method provides a better approximation with fewer geometric elements and non-jagged silhouettes.

The tessellation algorithm utilizes the properties of the Bernstein-Bezier representation of Steiner patches. The algorithm fits Steiner patches to ordered surface point and normal data. The resulting tessellation is C0 everywhere and C1 at the data points. The unique normal vectors at the data points are interpolated over the tessellation during rendering in order to produce a smooth looking surface.

Introduction

The tessellation of complex curved surfaces into polygonal meshes is a common and successful method used to facilitate rendering. The method transforms a mathematically complex geometric description (e.g. bicubic patches) into a far simpler geometric approximation - a polygonal mesh[1]. This transformation greatly simplifies the mathematics and algorithms of rendering. With the simplification also comes significant increases in rendering speeds. Polygons are commonly used because of their mathematical simplicity. Many algorithms have been developed to create smooth shaded images of polygonal meshes[2, 3, 4]. These methods utilize some form of interpolation in order to blend the faceted surfaces of polygonal meshes.

The work presented here is based on the ideas previously mentioned. Complex surfaces are tessellated into a network of simpler components in order to simplify the mathematics and shorten rendering times. Once a tessellated mesh is created, a shading algorithm is applied to the mesh in order to produce a smooth shaded image of a tessellated surface. The simpler components being used are Steiner patches[5]. The Steiner patch is the simplest biparametric patch. Therefore this application of it is a logical extension of current rendering techniques using polygons.

This work has been motivated by the results and mathematics produced by Sederberg and Anderson[6]. They have presented a method for ray tracing Steiner patches. Their results are based on a parametric surface implicitization method developed by Sederberg[7].

The implicitization and ray tracing algorithm was studied and implemented by the Computer Animation Group at RPI's Center for Interactive Computer Graphics. The software to ray trace Steiner patches was incorporated into the group's ray tracer, BART. One of the main goals of the group is to produce high quality ray traced computer animation. Because this task is so computationally expensive and time consuming, the group investigated ways to save time and CPU cycles[8]. Creating meshes of approximating Steiner patches which are subsequently ray traced offers that possibility.

Geometry

Before continuing, it is necessary to briefly describe the geometric entities which are discussed and utilized in this paper. The two most referenced are Steiner patches and superquadrics. The Steiner patch is the essential geometric element in the tessellation algorithm. The algorithm has been applied to a certain type of biparametric surface - the superquadric.

Steiner Patches

The Steiner patch receives its name from the German mathematician Jakob Steiner, who studied it extensively in 1844 during a stay in Rome[9]. The Steiner patch is easily visualized as a triangular quadratic Bernstein-Bezier patch. In this form, the patch can be represented by six control points and a triangular parameter space (domain)[10]. See Figure 1. The six points form a triangular control net which contains and controls the patch. Three of the six points are on the patch surface at the corners, P00, P20, P02. The patch is bounded by three quadratic curves P00-P20, P00-P02, P02-P20. The most important feature, at least to this project, is that each corner control point and its two neighboring interior control points define the tangent plane at the corner control point. This feature of the Steiner

CH2345-7/86/0000/0931$01.00 © 1986 IEEE

patch is central to the approximation algorithm.

A Steiner patch represented in the Bernstein-Bezier basis is written as:

$$\vec{B}_2(u,v) = \sum_{\substack{i+j <= 2 \\ i,j >= 0}} \vec{P}_{i,j} \left(\frac{2!}{i!\, j!\, (2-i-j)!} \right) u^i v^j (1-u-v)^{2-i-j} \qquad (1)$$

$$u >= 0, \quad v >= 0, \quad u+v <= 1$$

Note the bounds of the parameters U,V. The edges of the patch are defined by the U=0, V=0, U+V=1 curves and are parabolas.

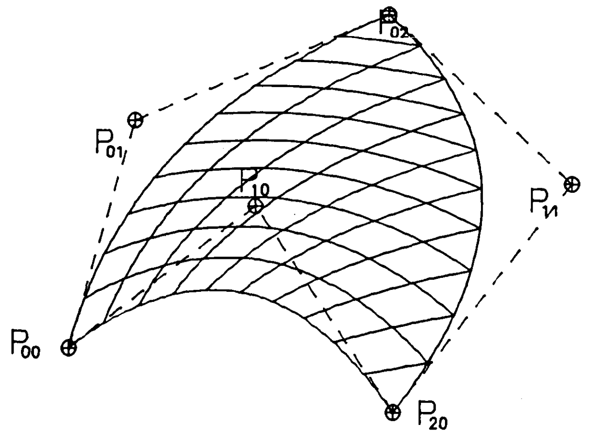

Figure 1. Steiner Patch with Control Points

Superquadrics

Superquadrics are a generalization of the quadric surfaces. The mathematics of this two-parameter family of geometric primitives was formalized by Barr[11]. He defines the parametric form of superellipsoids, superhyperboloids of one and two sheets and supertoroids. An implicit inside-outside function is also provided for each of them. Specifically our work applied the tessellation and smooth shading algorithm to superellipsoids. Exponentiating the sine and cosine terms in the parametric form of the ellipsoid gives a variety of curved, beveled and pinched shapes which is the superellipsoid.

Tessellation and Smooth-Shading Algorithm

In order to create a smooth-shaded rendering of a Steiner patch mesh, three steps are required.

1. Create a CO continuous Steiner patch tessellation which approximates the original surface. Create it in such a way to guarantee tangent plane continuity at common patch vertices.

2. Ray-trace, calculating ray intersections and determining the u,v values of the intersection.

3. Instead of calculating the actual normal to the surface at the intersection, calculate the interior normals as a linear combination of the normals at the vertices.

The tessellation algorithm can be summarized as the following.

1. Triangulate the parameter space of the original surface.

2. Calculate the points and tangent planes associated with each u,v value at the triangle vertices.

3. Using these points and tangent planes, an interpolating Steiner patch is fit to each triangular segment.

Subdivision of Parameter Space

The first step in the algorithm is to subdivide the parameter space of the patch which is being approximated by a network of Steiner patches. More accurately stated, the parameter space should be triangulated, because the Steiner patch is defined on a triangular domain. There are basically two ways to subdivide the parameter space, recursively and iteratively. The recursive subdivision begins by breaking the parameter space into two or four triangles. At each level of subdivision, each triangle is split into four more triangles. The number of triangles grows as 4 raised to the nth power, where n is the number of subdivisions. The iterative subdivision splits the original parameter space into n^2 squares. Each square is then split into two or four triangles. The same iterative and recursive techniques can be applied to a triangular parameter space.

Subdivision of a spherical parameter space, like the superquadric's, can be a bit trickier. It can be split up like a triangular space. The parameters of the first octant can be mapped to a triangle. The top vertex will be the value $\eta = \pi/2$, where η is the angle of elevation. The left bottom vertex is the value $\omega = 0$, $\eta = 0$, where ω is the azimuthal angle. The right bottom vertex is the value $\omega = \pi/2$, $\eta = 0$. Another possible method would be to subdivide first along isoparametric lines and then split any rectangular subdivisions into two or four triangles.

A particular subdivision method cannot be recommended at this point. The method must be chosen to meet the requirements of a specific surface, application and implementation. Factors, such as the growth of the number of triangles per subdivision, best approximation to original surface and ease of implementation, must be considered before a decision is reached. The iterative method is recommended if the growth of the number of the triangles is a concern. It also offers a smoother transition between levels of approximation. The recursive technique is substantially easier to implement.

Irregardless of the technique, one rule must be followed when subdividing. The subdivision must be uniform. All vertices of the triangles must only overlap vertices of adjacent triangles. A vertex of a triangle should never lie on an edge of a neighboring triangle. See Figure 2. Ignoring this precaution will undoubtedly lead to cracks in the composite surface. This result will become evident, as the algorithm is further explained.

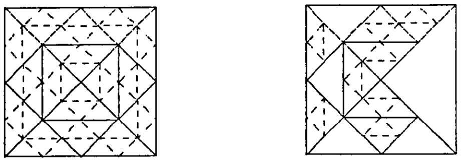

Figure 2. Uniform & Non-Uniform Subdivisions

How much should a surface be subdivided? Again, this is a question which does not have a single answer. The level of subdivision must be determined based on a number of factors, accuracy of approximation, visual effects and/or number of triangles.

Determination of Bernstein-Bezier Control Points

Once the parameter space has been triangulated, a Steiner patch is calculated for each triangle. This is done by calculating six Bernstein-Bezier control points for each resultant triangle. If each triangle in parameter space is mapped into a Steiner patch, a C0 tessellation of the original surface is produced.

Corner Points

The three corner points are the easiest of the six to calculate. The parameter values at the three vertices of the triangle are plugged into the approximated surface equation. This produces three points in 3-space. The points are the corner control points of the approximating Steiner patch. See Figure 3.

Interior Points

To determine the interior mid-edge control points is a bit more difficult. To begin, recall the properties of the Bernstein-Bezier control points for a Steiner patch. The corner control point and its two adjacent interior control points define the tangent plane of the patch at the corner point.

Now consider any of the interior control points. Each one lies on two tangent planes. They are the tangent planes of the patch at the two adjacent corner points. Intersecting the two tangent planes gives a line on which the interior mid-edge control points are allowed to lie. See Figure 4.

To determine a unique point on the line, requires a third plane. The third plane can be created by picking three points on the appropriate edge of the approximated surface. The three points are defined in parameter space as two vertices on a triangle and the midpoint of the edge lying between them. See Figure 5. Mapping these three parameter values into 3-space gives the three points. These three points define the third plane needed to determine a unique interior control point. See Figure 6.

There are numerous ways to calculate the third intersecting plane. The previous method was chosen because it provides orthogonal boundaries between the octants of geometric objects defined in a spherical parameter space. This will aid in the implementation of the algorithm and will be further explained at a later point.

The algorithm for calculating the interior control points on an approximating Steiner patch is:

For each edge of the triangular parameter space.

1. Calculate the points in 3-space which correspond to the two endpoints.

2. Calculate the tangent plane of the approximated surface at the two endpoints, by taking the cross-product of the tangent vectors emanating from an endpoint.

3. Calculate the point in 3-space which corresponds to the midpoint of the edge common to the two endpoints in parameter space.

4. Determine the plane which is defined by the three previously calculated points.

5. Intersect the three previously calculated planes. Their intersection point is the interior control point for that edge.

The algorithm is summarized in Figure 3 through Figure 7.

If followed, the algorithm will give three interior control points. With the three corner points previously calculated, the Steiner patch is defined. If the algorithm is performed for all triangles in the parameter space, the original surface will be approximated with Steiner patches. Discussion of the accuracy of the approximation is presented in my thesis[8].

Continuity Considerations

The tessellation algorithm creates a C0 mesh of Steiner patches which is C1 continuous at the data points, but is C1 discontinuous along Steiner patch boundaries.

When the parameter space of an approximated surface is uniformly subdivided, the algorithm guarantees positional continuity. When adjacent triangles share an edge in parameter space, they also share the points and tangents planes in 3-space which define the control points along their common edge. Since they have common control points along their border, there will be positional continuity along their common boundary edge[1,2].

At any vertex where Steiner patches come together, a single tangent plane exists. The algorithm guarantees that all adjacent interior control points to a corner point all lie on one plane. This guarantees that all patches at the corner point share the same tangent plane. The common tangent plane is an important geometric by-product of the tessellation algorithm that is exploited by the smooth-shading algorithm.

Smooth-Shading the Tessellation

Normal vectors which give a smooth-shading over a C1 discontinuous tessellation must meet certain criteria. They are

1. A single normal vector must be assigned to each common vertex.

2. The interior normals of one patch should be independent of other patches.

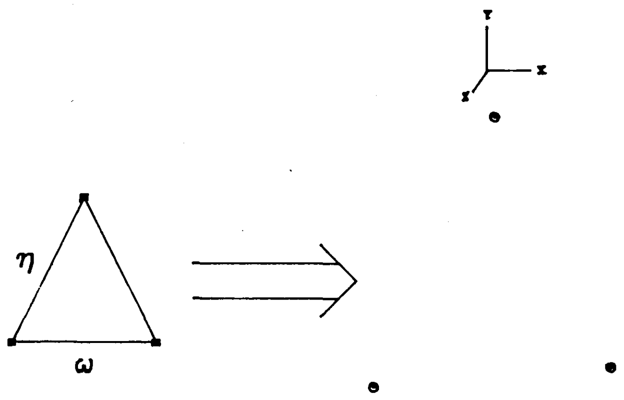

Figure 3. Calculate Corner Points

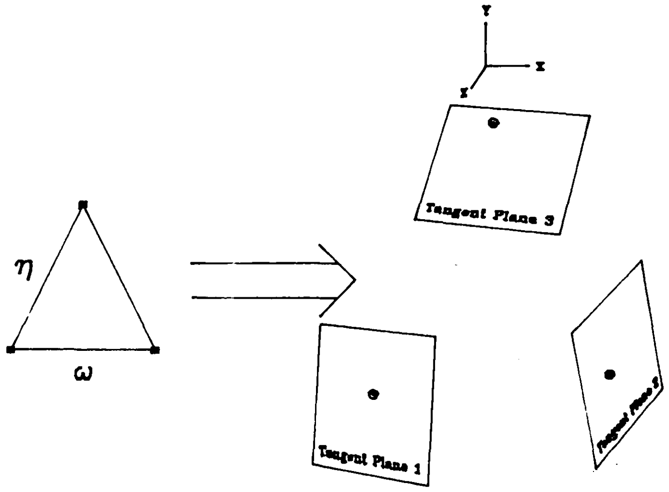

Figure 4. Calculate Tangent Planes at Corner Points

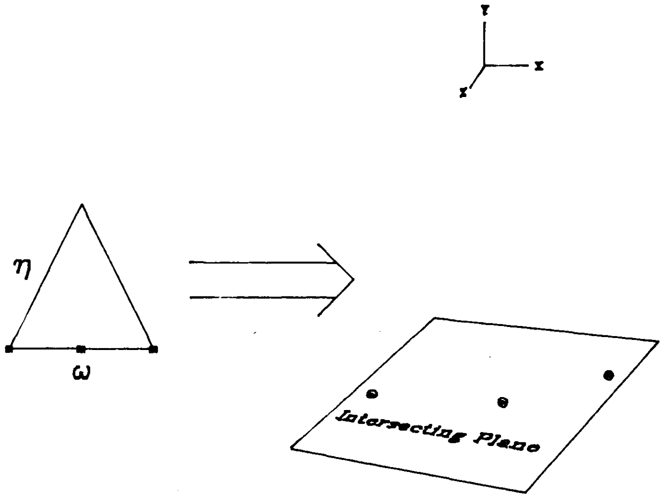

Figure 5. Determine Intersecting Plane for All Edges

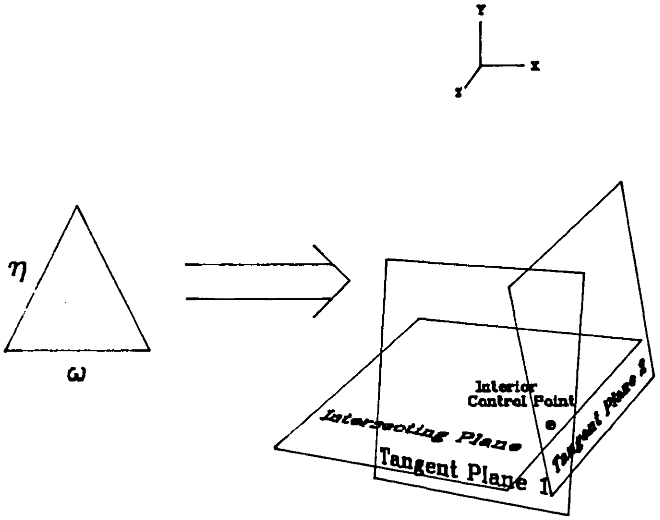

Figure 6. Intersect All Planes To Give Interior Control Point

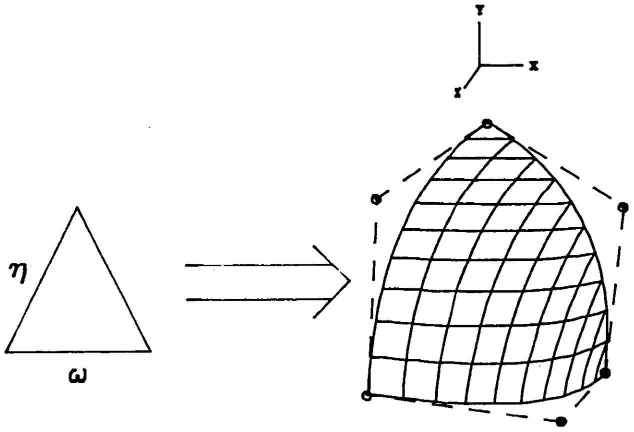

Figure 7. Six Points Define a Steiner Patch

3. The normal function should be continuous on the patch.

4. The normals along a boundary edge should only be a function of the normals at the endpoints of the boundary, i.e. an interpolation.

A normal vector function for each patch which meets these criteria has been developed and implemented for Steiner patch tessellations. It is based on the concept of normal vector interpolation presented by Phong[3], namely,

$$\vec{N}(u,v) = \vec{N0} * u + \vec{N1} * v + \vec{N2} * (1 - u - v) \qquad (2)$$

where N0 is the Steiner patch normal at (1,0), N1 is the normal at (0,1) and N2 is the normal at (0,0).

The first criteria is met by the tessellation algorithm itself. It guarantees that there is a unique tangent plane and therefore normal direction at each vertex of the tessellation. The formula explicitly states that the normals in the interior of the patch are a function of the normals at the vertices of the patch, making the normals independent of other patches. The function is continuous. It can also be noted that the normals along the boundary edges are a function only of the normals at the edge endpoints. This fact and the first criterion guarantee that there will be smooth and continuous shading across patch boundaries.

In order to smooth shade the C0 tessellation, the Steiner patches are ray traced. When a patch is intersected by a ray, the u,v value of the intersection is determined. Rather than calculating the actual normal of the Steiner patch at the intersection, the above formula is used during the shading calculation. The new normals provide a smooth shading across the whole network of Steiner patches.

Implementation

The tessellation and smooth shading algorithm has been implemented and incorporated into the CICG's animation system, The Clockworks[13, 14, 15]. The Clockworks is an object-oriented computer animation system implemented in C[16]. As previously stated, the algorithm was implemented to approximate superellipsoids. The superellipsoid was the first geometric primitive supported by the geometric modeling subsystem of The Clockworks, so it was a natural choice.

The first step in the implementation was to subdivide the parameter space of the superellipsoid. Because it is symmetric, Steiner patches are only calculated for the first octant and are reflected into the the other seven. The first octant of a superellipsoid is bounded by $\eta = 0$ to $\eta = \pi/2$ and $\omega = 0$ to $\omega = \pi/2$. η is the elevation angle and ω is the azimuthal angle. The octant was interpreted as a triangle and subdivided.

After some initial investigation an iterative subdivision implementation was chosen over a recursive one. The iterative subdivision was more difficult to implement but offered a smoother transition between levels of subdivision; therefore providing more subdivision options. For the iterative technique, the number of triangles per octant is n^2, where n is the level of the subdivision. Since the Steiner patches of the first octant are reflected into the other seven, the total number of Steiner patches for the whole superquadric is $8 * n^2$.

Results

The following pictures illustrate the preliminary results of the superquadric implementation. Figure 8 is an image comprised of four superquadrics ray-traced directly. Figure 9 is the same four superquadrics approximated by 72 Steiner patches each. This is a level 3 subdivision. The patches are ray-traced directly. The C1 discontinuities of the tessellation are visible near the poles of all four surfaces. Figure 10 is the same as Figure 9 except that smooth-shading is applied in order to blend the apparent surface normals. Figure 11 displays one superquadric approximated with four different levels of subdivision. The Steiner patches are ray-traced directly. The bottom right shape is the original superquadric. Again C1 discontinuities are evident across most patch boundaries. Figure 12 is the same as Figure 11 except that smooth-shading has been applied to to the tessellations removing visual discontinuities along patch boundaries. Figure 13 is two superquadrics ray traced directly. Figure 14 is the smooth shaded tessellation of the same geometry. It is only subdivided to two levels, which produces 32 Steiner patches.

Analysis

Figure 10, Figure 12, and Figure 14 provide visual evidence of the algorithm's capability. Still

many questions have to be answered. Do Steiner patches offer faster rendering speeds? Are Steiner patches worth the effort? Why use Steiner patches instead of polygons?

Preliminary tests were run to determine if Steiner patches had fulfilled their promise. Steiner patches were first explored in the hope that they would offer the user a way to shorten rendering times. The following tests were conducted and showed that there are certain advantages to using Steiner patches over other geometric primitives.

Steiner Patches Versus Superquadrics

The first tests that were conducted ray-traced superquadrics directly and then their Steiner patch tessellations. Is it faster to ray trace a superquadric directly or its Steiner patch tessellation? The geometry of Figure 8 and Figure 13 was used to answer this question. The results are favorable with the superquadric ray-tracing times being 125 CPU-minutes and 90 CPU-minutes on a Data General MV/10000 for the images of four and two superquadrics respectively. Ray-tracing the tessellations of these superquadrics with 72 Steiner patches each took 70 CPU-minutes and 56 CPU-minutes. Clearly there is a savings in time of 44% and 38% when using the Steiner patch approximation. Examining Figure 10 and Figure 14 shows that acceptable visual results are also produced.

Normalizing BART and STRAW

The next question investigated was "Is it more time-efficient to tessellate and smooth-shade a polygonal approximation rather than a Steiner patch approximation when ray tracing curved surfaces?". Even though the software at RPI prevents the forming of an outright conclusion, the results produced from benchmarking do give a strong indication that using Steiner patches is more efficient for ray tracing curved surfaces than polygons.

Using a rough midpoint error estimation, it was determined that 32 Steiner patches can approximate the surface of a superquadric as well as 200 triangles[8]. The method used to make the error estimation first calculates the midpoint along an edge of an approximating Steiner patch. Next the associated point in the approximated surface's parameter space is determined. It will be a midpoint on the edge of a parameter space triangle. That point is mapped into 3-space. The distance between the previous two points is calculated and averaged with the corresponding distance for each edge of the tessellation. The average value of these distances can be used to gauge the quality of the tessellation. A similar technique is applied to the approximating triangles. This is far from an exact error calculation, but is satisfactory for the scope of our initial investigations.

Our results indicate that a Steiner patch tessellation of level 2 will provide the same level of approximation to a superquadric as a planar approximation of level 5. A level 2 tessellation corresponds to 32 approximating entities, while level 5 translates to 200. It appears that 32 Steiner patches can approximate a superquadric as well as 200 triangles. It is this 32 to 200 ratio that was used to determine if it is more time-efficient to tessellate and smooth-shade Steiner patches rather than triangles when ray tracing curved surfaces.

Unfortunately a common software system which ray-traces both triangles and Steiner patches is unavailable at RPI. BART, a ray-tracer developed at RPI's Center for Interactive Computer Graphics, ray-traces superquadrics, Steiner patches, spheres, cubes and cylinders. STRAW, a ray-tracer developed at RPI's Image Processing Lab by Mike Potmesil, ray-traces spheres, polygons, quadric surfaces, and bicubic patches[17, 18]. These two programs were used to run a benchmarking time test of Steiner patches versus triangles. Another factor to be considered is that BART and STRAW reside on different machines. STRAW runs on a PRIME 500 and BART is on a DATA GENERAL MV/10000.

Since conclusions are being drawn from the use of two different pieces of software running on two different machines, a method had to be found to normalize the performance of the two programs. Common geometric primitives were identified. Each program had two geometric entities in common, spheres and cubes. BART detects spheres and cubes as degenerate superquadrics. STRAW supports spheres as a separate primitive. A cube can be constructed from six polygons in STRAW. Scenes with these two common primitives were constructed and ray-traced. One scene contained six spheres of various sizes. The other contained six cubes of various sizes. The CPU time needed to generate the images was noted. The ratio of the time it took to render the same geometry on the different programs can be used as a normalization factor. BART, on the average, used 10 CPU-minutes to generate the image of the spheres and 60 CPU-minutes to generate the cubes. STRAW needed an average of 45 CPU-minutes to render the spheres and 80 CPU minutes to render the cubes. From these rendering times a worst and best case normalization factor can be deduced. STRAW running on a PRIME 500 can take anywhere from 4.5 to 1.33 times longer to render a geometric scene than BART running on a DATA GENERAL MV/10000. These factors will be used in an attempt to normalize the results of the final test.

Steiner Patches Versus Triangular Polygons

The superquadrics in Figure 13 were tessellated with 32 Steiner patches and 200 triangular polygons each. The each set of the tessellated superquadrics was then ray-traced. These tessellations produced similar approximation error. On the average, BART used 42.5 CPU-minutes to render the image. The same superquadric tessellated with triangles rendered by STRAW used 13.5 CPU-hours. These are striking differences in rendering times. Even if the worst normalization factor of 4.5 is applied to STRAW's time of 13.5 hours on a PRIME 500, the rendering time is normalized to 3 CPU-hours on an MV/10000. This time still far exceeds the 42.5 CPU-minutes of BART's image. Ray-tracing a Steiner patch tessellation appears to be significantly quicker than ray-tracing a comparable polygonal tessellation.

In order to understand what might be happening during the rendering of the two tessellations, the facts must be reviewed. Using the worst case normalization, the triangular tessellation takes 4 times longer to render than the Steiner patch tessellation. There are 6.25 times more triangles being rendered than Steiner patches. It is assumed that the majority of the CPU-time of ray tracing an image without shadows, reflections and refractions (i.e. ray-casting) is spent calculating the intersections of a ray with the geometric primitives. This implies that it takes only 56% (1-6.25/4) more work to determine if and where a ray intersects a Steiner patch rather than a polygonal planar patch. The inverse statement is that the determination of the existence and position of a ray intersection on a triangular polygon is only 36% less work than Steiner patches. At first glance this is difficult to accept considering the complexity of Steiner patches and the simplicity of polygons. Examining the code of STRAW and BART provides further insight into the results.

The next step taken was the actual counting of operations needed to determine the existence and calculate the intersection of a line with a Steiner patch and triangular polygon. To calculate the intersection of a line and a Steiner patch takes approximately 450 multiplies/divisions and 400 additions/subtractions[19]. To calculate the intersection for a triangular polygon takes approximately 55 multiplies/divisions and 55 additions/subtractions. These numbers were initially deceiving, because it showed that Steiner patches took 820% more work than triangular polygons, not 56%. Further study of the code showed that 80 multiplies and 80 adds of the Steiner patch calculations were in bounding box and bounding hull checking. While no bounding surface calculations were being made for any individual triangular polygons. It is these last figures and the bounding surface structures in both renderers which gave the final insight into the results.

In BART bounding boxes and convex hulls are computed for each Steiner patch. While in STRAW the triangular polygons for a single superquadric are grouped together into a polyhedron. A single bounding sphere is then placed around the whole tessellation, not around any particular polygon[20]. Therefore when calculating a ray intersection with a Steiner patch, the ray intersections with the convex hull and bounding box are first computed. In most cases, there will be no intersections. Therefore the line-Steiner patch intersection operation will only take 80 multiplies and 80 adds. On the other hand STRAW will have to attempt to intersect almost every triangular polygon for every ray because the polygons have no bounding box information. This operation takes 55 multiplies and 55 adds. For the usual case it clearly makes sense to compare the triangular polygon intersection operations with the Steiner patch bounding box intersection operations. When that is done, the original result is produced. 80 / 55 = 1.45. In words, the bounding box and bounding hull intersection takes 45% (approximately 56%) more operations than then the triangular polygon intersection.

These results clearly show that the Steiner patch's greatest advantage is its convex hull. By exploiting the convex hull property of the patch, advances in rendering can be made. Steiner patch tessellations not only take up less space, but by utilizing their geometric properties wisely less time can be spent rendering complex geometry.

This experiment does not prove outright that using Steiner patches when tessellating and rendering curved surfaces will always prove to be more time-efficient than other methods. It does though, give an indication that Steiner patches offer an improved method for rendering in some instances. An obvious example would be where the Steiner patches are relatively small and polygons cannot be reasonably bounded. It is in this situation where the convex hull property of the Steiner patches can be exploited.

Conclusion

The generation of images which consist of Steiner patches offer visual proof of the validity of the tessellation and smooth-shading algorithm. The algorithm provides a positionally continuous mesh of Steiner patches which approximate a surface of arbitrary order. The Steiner patches can then produce a smooth looking surface by simply applying normal vector interpolation across each patch.

Tessellating and smooth-shading Steiner patches offers an improved and quicker way to render curved surfaces. In the case of superquadrics, a significant improvement in calculation times is evident. Ray tracing Steiner patches appears to be more efficient than ray tracing either superquadrics directly or their polygonal tessellations. One of our major goals has been attained by Steiner patches. They are time-savers during rendering.

The visual results of Steiner patch tessellations are good. With 3 levels of approximation (72 patches), a very good copy of a superquadric can be made with Steiner patches. There are visual differences though. Steiner patch tessellations can sometimes appear lumpy and the shading is not as evenly distributed as it could be. Even with this in mind, Steiner patches can offer a remarkable approximation to superquadrics.

Steiner patch tessellations also offer clear-cut advantages over polygonal tessellations. They not only reduce rendering times, but also use less memory during processing because fewer Steiner patches are needed to approximate a curved surface as compared to polygons. Also the silhouette of a Steiner patch tessellation is curved, not jagged like a polygonal tessellation, making Steiner patches visually superior to polygonal patches. The one disadvantage of Steiner patches is the complexity of the code needed to intersect a Steiner patch with a line. This is a one time cost that can pay for itself if the code is extensively used.

An Algorithm for Normal Vector Interpolation on Polygonal Surfaces

Phillip H. Getto

Rensselaer Polytechnic Institute
Center for Interactive Computer Graphics
Troy, New York

Abstract

A new algorithm for the interpolation of ''smoothed'' normals across a polygonal surface is presented. The algorithm produces surface normals which are invariant under rotation of the image plane about its normal. Different versions are derived for use with visible surface algorithms which use scan line coherence or do not use any coherence, such as ray tracing. An analysis of the time complexity for each version of the algorithm is shown.

Introduction

Computer synthesized imagery of curved surfaces is often generated in three steps. First, the surfaces are approximated by polygonal surfaces. Second, the visible polygons or parts of polygons are determined. Finally, the intensity of the visible polygon or polygons is calculated for each point on the image plane. The intensity is a function of many parameters, including the surface normal, material characteristics and light sources. The specific parameters and calculations vary from shading model to shading model.[1,2,3,4] However, all but a few, use the surface normal extensively. To produce realistic images of curved surfaces the polygonal normals must be massaged in some way. Otherwise, discontinuities of the normal across the surface will be visible.

Gouraud [5] originally described a method to interpolate intensities across the surface to ''smooth'' out the resulting image. The intensity of each vertex of a polygon is calculated from either the normal to the original surface at the vertex or the average of the normals to the polygons sharing the vertex, using any shading model desired. The intensity of a point on an edge is a weighted average of the intensities of the vertices on the edge. The intensity of an interior point is a weighted average of the intensities at the points of intersection of the scan line and the edges of the polygon.

Phong[6] described an improved algorithm, in which normals are interpolated across the edges and scan lines rather than intensities. The intensity of each pixel is computed using any desired shading model and the interpolated normal.

Both Gouraud's and Phong's interpolation techniques have serious drawbacks. First, only local information is used to compute the intensity of a pixel. That is, the intensity is a function of the intensities / normals only at the vertices of the edges intersecting the current scan line. Because of the locality of the information used to compute the intensities / normals, a vertex on an edge intersecting the current scan line will be used, even if there exists a closer vertex. If only a subset of the vertices on a polygon are used to interpolate an intensity / normal, it would be desirable to use the closest ones, as they would presumably better represent the point in question. With these algorithms, it is not possible for all of the vertices on a polygon to contribute to an interpolated intensity / normal. This can lead to some very undesirable artifacts.

The second problem with the Gouraud and Phong techniques is the lack of rotation invariance. By rotation invariance, we mean the intensity / normal of a point on a polygon should remain the same when the image plane is rotated about its normal, (vis-a-vis, the eye is rotated), or alternatively, when the entire model, including lights, is rotated about the axis normal to the image plane. This is not the case in the Gouraud and Phong schemes.

To illustrate, consider an octagon, as in Figure 1 below.

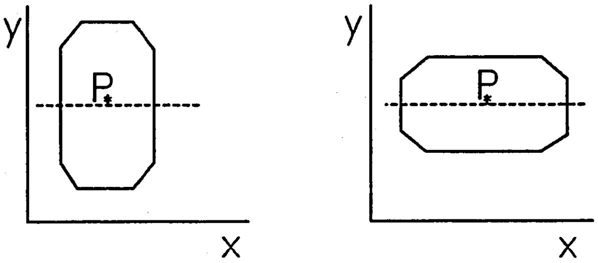

Figure 1: Normal interpolation over an octagon, using Phong's algorithm

Without loss of generality, assume the current scan line passes through the central vertical edges. If we are to rotate the image plane about 90 degrees its normal, (turn the page on its side), we would note the current scan line would intersect the two central horizontal edges. Since the edges do not share end points the normals can be assumed to be different. Thus, at the intersection point of the two scan lines, the resulting interpolated intensity / normal

would be different.
The remainder of this paper describes an algorithm, which overcomes the problems described above. Variations of the algorithm are presented for point sampling, ray tracing,[3,4,7,8] and scan line coherent visible surface algorithms. An analysis the complexity of the algorithm is made, for each version.

Normal Vector Interpolation Algorithm

The Gouraud and Phong schemes suffer from artifacts and lack rotation invariance, because they always interpolate along the current scan line, and they do not use global information about the polygon. If algorithms which always interpolated along a scan line, were to use a combination of the all of the normals the interpolated values would be rotation invariant. In fact, for triangles, the Gouraud and Phong interpolated normals are rotation invariant, because normals from all three vertices have a part in all interpolations.

Alternatively, if the line along which the interpolations are computed were to remain constant, relative to the polygon, under a rotation of the image plane about its normal, then the interpolated normals would be rotation invariant; even if only subset of the the polygon's normals are used in the computation. We will now present an algorithm which uses a combination of these two methods to be immune from scan line artifacts and be rotationally invariant.

The question of interest is how to chose the line along which we will interpolate. For the sake of clarity in what follows immediately, we will restrict ourselves to convex polygons. An easy solution is to select the line of constant u or constant v in the plane of the polygon going through the point of interest as in Figure 2 below.

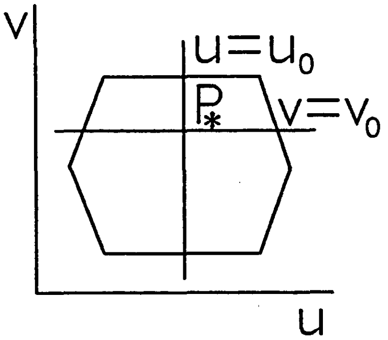

Figure 2: Interpolation along lines of constant u or v

One could use an interpolation scheme similar to Phong's, except the interpolation would be along the line $u = u_*$ or $v = v_*$. This solution provides the desired rotation invariance. However, it is subject to the same artifacts as Phong's scheme, because it does not use the normals at vertices on the edges not intersecting the line of interpolation. A better solution which can use all of the normals follows.

Chose the line of interpolation, for a given point $\overline{P}_*$, to the be line through the centroid of the polygon, $\overline{P}_c$, and $\overline{P}_*$, as in Figure 3 below.

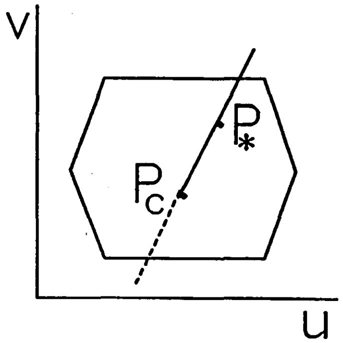

Figure 3: Interpolation along the ray from $\overline{P}_c$ through $\overline{P}_*$

Instead of interpolating the normal at $\overline{P}_*$ by averaging the normals at $\overline{P}_{e_1}$ and $\overline{P}_{e_2}$, let it be the weighted average of the normals at $\overline{P}_c$ and $\overline{P}_{e_1}$. If we define the normal at $\overline{P}_c$ to be the average of the normals at all of the vertices, then $\overline{N}_*$ is a function of all of the normals of the polygon. In effect we are interpolating along a ray from the centroid through the point of interest. As the point moves around the polygon different edges are used in the interpolation, in effect triangulating the polygon.

The following presents the algorithm in a more formal manner, first comparing its results to that of a baricentric parameterization of a triangle. The algorithm is then extended to convex polygons and to non-convex polygons, possibly including holes. We will then derive a method for incrementally calculating the interpolation parameters. A time complexity analysis will be given for each version.

Random Point Sampling Version

Consider, for the moment a triangle, (for which the Gouraud and Phong techniques have the desired characteristics). If we represent a point on the triangle using a baricentric coordinate system we have the following,

$$\overline{P}(\overline{\lambda}) = \lambda_0\overline{P}_0 + \lambda_1\overline{P}_1 + \lambda_2\overline{P}_2, \tag{1}$$

$$\sum_{i=0}^{2} \lambda_i = 1, \quad \lambda_i \geq 0.$$

Then, the optimal interpolated normal is expressed as,

$$\overline{N}(\overline{\lambda}) = \lambda_0\overline{N}_0 + \lambda_1\overline{N}_1 + \lambda_2\overline{N}_2. \tag{2}$$

The λ's provide a natural weighting of all of the normals, and are rotation invariant, exactly fitting the desired characteristics. However, it is not possible, in general, to determine the λ's for a planar polygon with more than three vertices. One obvious solution is to limit the polygons, for which we will interpolate normals, to triangles; expression (1) could then be solved for the λ's. If we are willing to restrict ourselves to triangles, we could use the Gouraud or Phong techniques which have the desired characteristics for triangles. This solution may be acceptable in certain situations, especially when triangular data is given; however, it seems too limiting in general. Furthermore, triangulating complex polygons is slow and generates many more polygons.

A better solution in most cases is to find some sort of extension to the baricentric coordinates, which still preserves the desired characteristics. Before we show our proposed extension on a general polygon, we first prove it is equivalent to the baricentric coordinate system for a triangle. The algorithm is then developed to handle convex polygons and finally non-convex polygons possibly containing holes.

Consider the triangle below.

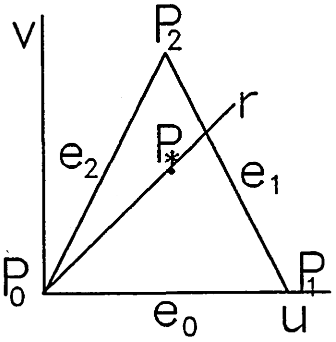

Figure 4: Representative triangle

We define the origin of the plane containing the triangle to be at $\bar{P}_0$, and $\bar{u} \parallel (\bar{P}_1 - \bar{P}_0)$. Note, $(u_0, v_0) = (0, 0)$, $v_1{=}0$, $u_1{\neq}0$, and $v_2{\neq}0$. Let $\bar{P}_*$ be the point of interest on the triangle.

We can represent $\bar{P}_*$ by a ray from $\bar{P}_0$ through $\bar{P}_*$;

$$\bar{r}_*(\alpha) = \bar{P}_0 + \alpha(\bar{P}_* - \bar{P}_0) = \alpha\bar{P}_*, \quad \alpha \geq 0. \qquad (3)$$

We claim this representation of the triangle is equivalent to the baricentric representation; further we can extend the definition to arbitrary polygons possibly containing holes. We will now show the two representations are equivalent.

In baricentric coordinates we have $\bar{P}(\bar{\lambda}) = \lambda_0\bar{P}_0 + \lambda_1\bar{P}_1 + \lambda_2\bar{P}_2 = \lambda_1\bar{P}_1 + \lambda_2\bar{P}_2$, because $\bar{P}_0 = \bar{0}$. Thus,

$$\begin{bmatrix} u_1 & u_2 \\ v_1 & v_2 \end{bmatrix} \begin{bmatrix} \lambda_1 \\ \lambda_2 \end{bmatrix} = \begin{bmatrix} u_* \\ v_* \end{bmatrix},$$

but $v_1 = 0$,

$$\begin{bmatrix} u_1 & u_2 \\ 0 & v_2 \end{bmatrix} \begin{bmatrix} \lambda_1 \\ \lambda_2 \end{bmatrix} = \begin{bmatrix} u_* \\ v_* \end{bmatrix},$$

substituting we get,

$$\lambda_1 = \frac{u_*v_2 - v_*u_2}{u_1v_2}, \text{ and } \lambda_2 = \frac{v_*}{v_2}.$$

Now, define the equation of edge k as,

$$\bar{e}_k(\beta) = \bar{P}_k + \beta(\bar{P}_{k+1} - \bar{P}_k), \quad 0 \leq \beta \leq 1. \qquad (4)$$

Define $\bar{P}_e$ as the intersection of $\bar{r}_*(\alpha)$ and $\bar{e}_k(\beta)$. Then,

$$\bar{P}_e = \bar{r}_*(\alpha_e) = \bar{e}_k(\beta_e),$$

substituting and rearranging,

$$\alpha_e\bar{P}_* - \beta_e(\bar{P}_{k+1} - \bar{P}_k) = \bar{P}_k.$$

By Cramer's Rule,

$$\alpha_e = \frac{u_1v_2}{u_*v_2 - v_*(u_2 - u_1)}, \text{ and}$$

$$\beta_e = \frac{u_1v_*}{u_*v_2 - v_*(u_2 - u_1)}.$$

At α_e, $\bar{r}_*(\alpha_e) = \bar{P}_e = \alpha_e\bar{P}_*$, or $\bar{P}_* = \bar{P}_e/\alpha_e$. Substituting into the equation for edge 1 and rearranging,

$$\bar{P}_* = \frac{(1-\beta_e)}{\alpha_e}\bar{P}_1 + \frac{\beta_e}{\alpha_e}\bar{P}_2,$$

which has the same form as the expression in baricentric coordinates. We must now show the coefficients of $\bar{P}_1$ and $\bar{P}_2$ are λ_1 and λ_2 respectively.

$$\frac{1-\beta_e}{\alpha_e} = \frac{\dfrac{u_*v_2 - v_*u_2}{u_*v_2 - v_*(u_2 - u_1)}}{\dfrac{u_1v_2}{u_*v_2 - v_*(u_2 - u_1)}}$$

$$= \frac{u_*v_2 - v_*u_2}{u_1v_2} = \lambda_1,$$

$$\frac{\beta_e}{\alpha_e} = \frac{v_*}{v_2} = \lambda_2.$$

Extension to Convex Polygons To extend the interpolation algorithm from triangles to arbitrary convex polygons is straight forward; but it provides an interesting insight. Given a convex polygon chose some point, denoted $\bar{P}_c$, then calculate the surface normal there. The choice of $\bar{P}_c$ is arbitrary, but a good choice is the centroid of the polygon. $\bar{N}_c$, the normal at $\bar{P}_c$, can be taken to be the average of the normal at each of the vertices, the normal to the original surface at $\bar{P}_c$, or something completely different. (The first choice will lead the following algorithm to make the normal at any point on the interior of the polygon a function of the normal at each of the vertices.) We then define the ray from $\bar{P}_c$ through the point $\bar{P}_*$ as,

$$\bar{r}_*(\alpha) = \bar{P}_c + \alpha(\bar{P}_* - \bar{P}_c), \qquad (5)$$

in an analogous way to the definition of $\bar{r}_*(\alpha)$ for a triangle. We can now compute the intersection of the $\bar{r}_*(\alpha)$ and $\bar{e}_k(\beta)$.

$$\bar{P}_e = \bar{r}_*(\alpha_e) = \bar{e}_k(\beta_e)$$

implies,

$$\bar{P}_c + \alpha_e(\bar{P}_* - \bar{P}_c) = \bar{P}_k + \beta_e(\bar{P}_{k+1} - \bar{P}_k).$$

Rearranging and applying Cramer's Rule,

$$\alpha_e = \frac{u'_k \Delta v_k - v'_k \Delta u_k}{u'_* \Delta v_k - v'_* \Delta u_k}, \text{ and}$$

$$\beta_e = \frac{u'_* v'_k - v'_* u'_k}{u'_* \Delta v_k - v'_* \Delta u_k},$$

where $\bar{P}'_* = \bar{P}_* - \bar{P}_c$, $\bar{P}'_k = \bar{P}_k - \bar{P}_c$, and $\Delta\bar{P}_k = \bar{P}_{k+1} - \bar{P}_k$. It is interesting to note, the definition of equation (5) and the choice of $\bar{P}_c$ have the effect of triangulating the polygon, as shown in Figure 5 below.

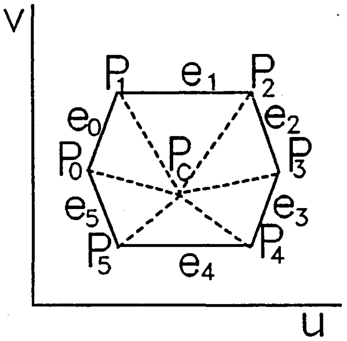

Figure 5: Triangulated polygon

The normal at the point $\bar{P}_*$ is given by an expression similar to (5)

$$\bar{N}_*(\alpha) = \bar{N}_c + \alpha(\bar{N}_* - \bar{N}_c). \tag{6}$$

However, unlike the expression for $\bar{P}_*$, $\bar{N}_*$ is unknown, in fact, it is the desired quantity. To solve for $\bar{N}_*$ we will write the expression for $\bar{N}_e$, the normal at $\bar{P}_e$, in terms of $\bar{N}_*(\alpha)$.

$$\bar{N}_e = \bar{N}_*(\alpha_e) = \bar{N}_c + \alpha_e(\bar{N}_* - \bar{N}_c). \tag{7}$$

But $\bar{N}_e$ along edge k at $\bar{P}_e$ is given, as in previous algorithms by,

$$\bar{N}_e = \bar{N}_k(\beta_e) = \bar{N}_k + \beta_e(\bar{N}_{k+1} - \bar{N}_k). \tag{8}$$

Equating equations (7) and (8) and solving for $\bar{N}_*$ gives,

$$\bar{N}_* = \bar{N}_c + \left[\frac{1}{\alpha_e}\right](\bar{N}'_k + \beta_e \Delta\bar{N}_k),$$

where $\bar{N}'_k = \bar{N}_k - \bar{N}_c$, and $\Delta\bar{N}_k = \bar{N}_{k+1} - \bar{N}_k$. The interpolated normals from our algorithm are identical to those interpolated using the baricentric coordinate parameters, for a given triangle.

Extension to Non-convex Polygons The extension of the algorithm to handle non-convex polygons, possibly containing holes, muddles the issue somewhat, and is more of an engineering solution than a clean mathematical one. With that caveat, let us consider Figure 6 below, a non-convex polygon containing a single hole.

The basic idea is to remember the edges whose intersection with $\bar{r}_*(\alpha)$ are closest to $\bar{P}_*$ on the positive and negative sides. That is, the edges where α_e is the least positive and the greatest negative are denoted $e+$ and e_-. In this case, $e+$ and e_- are edges e_0 and e_9 respectively, as they have the closest intersections to $\bar{P}_*$. The interpolation of $\bar{N}_*$ is a weighted average of the normals at the intersection points. The normals at the intersection points are interpolated from the normals at the edges' vertices. This procedure is analogous to Phong's, except we interpolate along $\bar{r}_*(\alpha)$, rather than the current scan line.

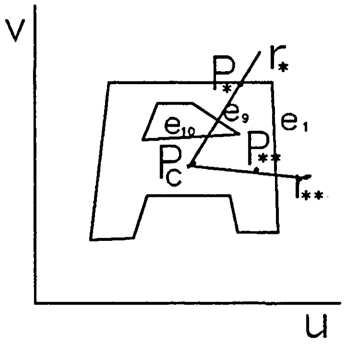

Figure 6: Non-convex polygon with a hole, $\bar{P}_c$ inside

It should be noted that if $\bar{P}_c$ is inside the polygon, it must be considered when determining the closest points to $\bar{P}_*$. If $\bar{P}_c$ is, as shown in Figure 7, outside of the polygon, then the value of $\bar{N}_c$ is not important because it will not be used. When $\bar{P}_c$ is inside, as in Figure 6, $\bar{N}_c$ will be used and can be computed as in the convex case. For example, in Figure 6, the normal at $\bar{P}_{**}$ would be a combination of $\bar{N}_c$ and $\bar{N}_{e_1}$, as in the convex case.

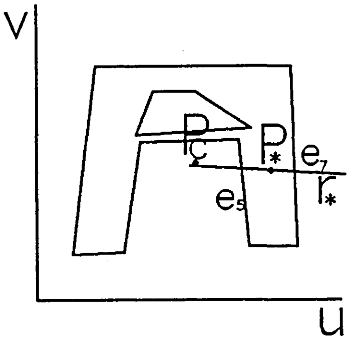

Figure 7: Non-convex polygon with a hole, $\bar{P}_c$ outside

Complexity The time and space complexity of our interpolation scheme is not significantly greater than that required to determine if $\bar{P}_*$ is inside the polygon. One well known method to determine if a point is inside a polygon is to intersect a ray, originating at the point, in a given direction, with each edge of the polygon. If the number of intersections is odd the point is inside, otherwise it is outside. If we rewrite equation (5) as $\bar{r}_*(\alpha) = \bar{P}_* + \alpha(\bar{P}_* - \bar{P}_c)$, then we count intersections, for inside / outside determination, when $\alpha \geq 0$. However, the edges whose intersections with $\bar{r}_*(\alpha)$ have the least positive and greatest negative values of

α, must be saved to use in the interpolation. If the greatest negative value of α is less than -1, then $\overline{P}_c$ is closer to $\overline{P}_*$ than any other edge's inside / outside test ray intersection point. In the original form of equation (5), we count intersections where $\alpha \geq 1$ for inside / outside determination, and use $\overline{N}_c$ if the greatest value of α that is less than 1 is also less than 0.

The intersection of the $\overline{r}_*(\alpha)$ and $\overline{e}_k$ can be made robust by writing $\overline{r}_*(\alpha)$ as an implicit function of u and v. An intersection occurs if the vertices of an edge are on opposite sides of the ray, or if one is on or near the ray, and the other is on a predetermined side, say positive. Edges with both vertices on the ray, or one on the ray and the other on the wrong side (negative), are not counted.[9]

The calculations can be sped up by precomputing and storing various values, such as $\overline{P'}_k$, $\overline{N'}_k$, $\Delta\overline{P}_k$, and $\Delta\overline{N}_k$, for $k = 0,\ldots,n$. Note, it is not necessary to retain the original values of P_k or N_k for the interpolation scheme.

Scan Line Coherent Version

The previous development assumed the polygon was randomly sampled and as such did not make use of any form of coherence from one point to the next. We will now present a development which uses the coherence of a polygon, along a scan line, so that the ray inside / outside test is not required to determine the edge k. The values of α_e and β_e will be computed incrementally, and the current edge k will be tracked around the polygon. The presentation here is for convex polygons; the extension for non-convex polygons is analogous to that for the point sampling version.

In the previous version the vertices of the polygons were represented in the (u,v) coordinates of the plane containing the polygon. Here we assume the polygons have been projected onto the image plane, and the vertices are represented in the (u,v) space of the image plane.

Define the inside / outside test ray in terms of the current pixel as,

$$\overline{r}_{i,j}(\alpha) = \overline{P}_c + \alpha(\overline{I}(i,j) - \overline{P}_c), \tag{9}$$

where i,j are the indices of the current pixel on the screen, and $\overline{I}(i,j) = (u(i),v(j))$ is the current point on the image plane.

When $\overline{I}(i,j)$ is on $\overline{e}_k$,

$$\overline{P}_e = \overline{I}(i,j) = \overline{P}_c + \alpha_{e_{i,j}}(\overline{P}_e - \overline{P}_c),$$

which implies $\alpha_{e_{i,j}} = 1$. In that case, solving equation (4) at $\overline{I}(i,j)$ for $\beta_{i,j}$ gives,

$$\beta_{i,j} = \frac{\overline{I}(i,j) - \overline{P}_k}{\Delta\overline{P}_k} = \frac{u(i) - u_k}{\Delta u_k}, \text{ or } \frac{v(i) - v_k}{\Delta v_k},$$

for $\Delta u_k \neq 0$, and for $\Delta v_k \neq 0$ respectively. As we step from pixel i to pixel $i+1$ along scan line j we would like to incrementally calculate $\alpha_{e_{i,j}}$ and $\beta_{e_{i,j}}$. Solving for them at $(i+1,j)$ we have,

$$\alpha_{e_{i+1,j}} = \frac{u'_k \Delta v_k - v'_k \Delta u_k}{u'(i+1)\Delta v_k - v'(j)\Delta u_k}, \text{ and} \tag{10}$$

$$\beta_{e_{i+1,j}} = \frac{u'(i+1)v'_k - v'(j)u'_k}{u'(i+1)\Delta v_k - v'(j)\Delta u_k}. \tag{11}$$

We can compute the difference $\Delta\alpha_{e_{i,j}} = \alpha_{e_{i+1,j}} - \alpha_{e_{i,j}}$, in general as the following.

$$\Delta\alpha_{e_{i,j}} = \frac{u'_k \Delta v_k - v'_k \Delta u_k}{u'(i+1)\Delta v_k - v'(j)\Delta u_k} - \tag{12}$$

$$\frac{u'_k \Delta v_k - v'_k \Delta u_k}{u'(i)\Delta v_k - v'(j)\Delta u_k}.$$

After some rearranging,

$$\Delta\alpha_{e_{i,j}} = \left[\frac{\Delta v_k (u'(i) - u'(i+1))}{u'(i+1)\Delta v_k - v'(j)\Delta u_k}\right]\alpha_{e_{i,j}}.$$

However, if we look at the difference of the numerators and denominators independently, we can do better. Let us denote the numerator of f as $n(f)$, and likewise the denominator as $d(f)$. By inspection of equation (12), $\Delta n(\alpha_{e_{i,j}}) = 0$, and $\Delta d(\alpha_{e_{i,j}}) = (u'(i+1) - u(i))\Delta v_k$. We can now write $\alpha_{e_{i+1,j}}$ as a function of the numerator and denominator of $\alpha_{e_{i,j}}$, as follows.

$$\alpha_{e_{i+1,j}} = \frac{n(\alpha_{e_{i,j}})}{d(\alpha_{e_{i,j}}) + (u'(i+1) - u'(i))\Delta v_k}. \tag{13}$$

Recall, $\alpha_{e_{i,j}} = 1$ when $\overline{I}(i,j)$ is on edge k, which occurs at the beginning of the each span, and $\Delta n(\alpha_{e_{i,j}}) = 0$. Therefore, $n(\alpha_{e_{i,j}}) = 1$, which implies,

$$\alpha_{e_{i+1,j}} = \frac{1}{\frac{1}{\alpha_{e_{i,j}}} + (u'(i+1) - u'(i))\Delta v_k}.$$

Recalling equation (6), we note that $\alpha_{i,j}$ is not required, only $1/\alpha_{e_{i,j}}$ is needed. Thus, let us define $\hat{\alpha}_{e_{i+1,j}}$ as $1/\alpha_{e_{i,j}}$, or

$$\hat{\alpha}_{e_{i+1,j}} = \hat{\alpha}_{e_{i,j}} + \Delta u(i)\Delta v_k.$$

Similarly, we will compute Δ's for the numerator and denominator of $\beta_{e_{i+1,j}}$ separately and combine the results at the end.

$$\Delta n(\beta_{e_{i,j}}) = (u'(i+1) - u'(i))v'_k.$$

Note $d(\beta_{e_{i,j}}) = d(\alpha_{e_{i,j}}) = \hat{\alpha}_{e_{i,j}}$. Finally,

$$\beta_{e_{i+1,j}} = \frac{n(\beta_{e_{i,j}}) + \Delta u(i)v'_k}{\hat{\alpha}_{e_{i+1,j}}}.$$

The normal at $\overline{I}(i+1,j)$ can then be calculated directly from equation (6).

If $\beta_{e_{i,j}}$ is not between 0 and 1, then $\overline{r}_{i,j}(\alpha)$ does not intersect edge k. If $\beta_{e_{i,j}} > 1$ then proceed to edge $k+1$, otherwise to edge $k-1$, and recompute $\alpha_{e_{i,j}}$ and $\beta_{e_{i,j}}$. It is possible to skip an edge entirely if it is very short compared to the step size. If $\hat{\alpha}_{e_{i,j}} = 0$ the ray is parallel to the edge, and computation must proceed to the next edge.

Complexity The number of computations above Phong's algorithm is a small constant per pixel. Instead of incrementally computing the interpolated normal from the interpolated edge normals, we incrementally compute $\hat{\alpha}_{e_{i+1,j}}$ and $\beta_{e_{i+1,j}}$. Computing α requires 1 add and 1 multiply, $(u'(i+1) - u'(i)$ is assumed to be calculated elsewhere). Unfortunately, β requires, 1 add, 1 multiply and 1 divide. From $\alpha_{e_{i+1,j}}$ and $\beta_{e_{i+1,j}}$, $\overline{N}_{i+1,j}$ is computed using 6 adds, and 6 multiplies, given $\overline{N}'_k$ and $\Delta\overline{N}_k$. Phong's algorithm requires 3 adds per pixel; a difference of 5 adds, 8 multiplies, and 1 division per pixel. For an image with 256K pixels, this would require, at most, about 4M extra operations. If not all of the pixels were covered the number would be further reduced. There is an additional cost when moving from one edge to the next, for which we have not accounted. However, even if it were to require a similar number of operations, current microprocessors could process the extra computations in about 10 to 15 seconds. Empirical studies are underway to quantify the differences.

Conclusions

We have examined two existing algorithms for the interpolation of intensities or normals across a polygonal surface. Both algorithms will "smooth" out most visual discontinuities in the rendering of the surface. However, the algorithms have two primary shortcomings; the inability to use the normals at more than four of a polygon's vertices, and the lack of invariance under a rotation about the image plane normal.

We have presented an algorithm which overcomes both of these objections. Rotation invariance is accomplished by always interpolating along a fixed ray, from a given point, $\overline{P}_c$, through the point of interest. By selecting $\overline{N}_c$ as the average of the normals at all of the vertices on the polygon, the interpolated normal becomes a function of the normals at all of the vertices on the polygon. The algorithm is well suited for visible surface algorithms which use random point sampling, that is, do not use coherence, such as ray tracing. It is, in the authors opinion, easier to implement and faster to execute, than a Phong model when using such a visible surface algorithm.

A method of incrementally calculating the interpolation parameters, for use with visible surface algorithms which use scan line coherence, has been derived. Analysis indicates that it does not use significantly greater resources than previous algorithms.

GUARDED HORN CLAUSES AND EXPERIENCES WITH PARALLEL LOGIC PROGRAMMING

Jiro Tanaka, Kazunori Ueda, Toshihiko Miyazaki, Akikazu Takeuchi,
Yuji Matsumoto, and Koichi Furukawa

ICOT Research Center
Institute for New Generation Computer Technology
1–4–28, Mita, Minato-ku, Tokyo 108 Japan

This paper tries to overview the various activities of ICOT related to Guarded Horn Clauses (GHC). We describe a new parallel logic language GHC, first proposed by Ueda[1,2]. The main features of this language are its simplicity and ease of implementation. The implementation of GHC and programming efforts in the language are also described. We also summarize the current status of Kernel Language Version 1 (KL1). KL1 is the language system for the PIM hardware[3]. The overall structure of KL1 and the work on its distributed implementation are described.

1. INTRODUCTION

The final goal of the Fifth Generation Computer Project is the development of a logic-based high-speed parallel computing system. Our objective is the design and development of a "logic programming language" which allows parallel execution. Kowalski[4] has pointed out that a set of Horn clauses also allows "parallel" execution as well as sequential execution. A lot of work has been devoted to the Or-parallel execution of Prolog programs. We consider that this approach may be useful for uncontrolled all-solution-search problems. However, it may be inadequate for solving parallel programs in general. What we want is a more expressive, general-purpose parallel programming language which includes important concepts such as processes, communication and synchronization.

2. PARALLEL LOGIC PROGRAMMING LANGUAGE

2.1 Design goals

The design requirements for our parallel logic programming language can be summarized as follows[1]:

- Parallelism. It must express parallelism "by nature." Sequential languages with parallel constructs added are inadequate. It should have as little sequentiality as possible in order to preserve parallelism inherent in a Horn-clause program.

- Expressiveness. It must be an expressive, general-purpose parallel programming language. In particular, it must be able to express important concepts in parallel programming such as processes, communication, and synchronization.

- Simplicity. We do not have much experience with parallel programming. Therefore, it must be a "simple" language and we must establish a foundation of parallel programming first.

- Efficiency. There are various typical parallel problems to be described in the language. It is important that we can execute such programs as efficiently as comparable programs written in existing parallel programming languages.

2.2 GHC

The languages we are interested in are the parallel logic languages such as Parlog[5] and Concurrent Prolog[6]. These languages seem to come closest to satisfying the above requirements. Although there are differences, the basic computation mechanisms of these languages are quite similar: Horn clauses with guards are used for defining predicates, goals are executed in parallel, and they have some synchronization mechanisms between goals.

In this section, we describe the new parallel logic language GHC, which was proposed by Ueda[1,2]. It inherits many features from Parlog and Concurrent Prolog. What is most characteristic about this language is that the guard is the only syntactic construct added to Horn clauses. In GHC, synchronization is realized by the suspension mechanism of guards.

A GHC program is a set of guarded Horn clauses of the following form:

$$H :- G_1, G_2, ..., G_m \mid B_1, B_2, ..., B_k.$$

The operator | is called a commitment operator. The part of a clause before | is called a guard, and the part after | is called a body. Note that a clause head is included in a guard.

CH2345-7/86/0000/0948$01.00 © 1986 IEEE

A goal clause has the following form:

$$:-\ B_1, ..., B_n. \qquad (n > 0)$$

This can be regarded as a guarded Horn clause with an empty guard.

The semantics of GHC is quite simple. Informally, to execute a program is to refute a given goal clause by means of input resolution using the clauses constituting the program. This can be done in a fully parallel manner under the following rules.

(a) Unification invoked in the guard of a clause cannot instantiate the caller of that clause. If this happens, unification suspends until that caller is instantiated by some other goal. This provides the basic synchronization mechanism of GHC.

(b) When the guard of a clause succeeds, it is first checked that no other clause has been selected for the same goal. If confirmed, that clause is "committed" exclusively for subsequent execution of the goal.

(c) Unification invoked in the body of a clause cannot instantiate the guard of that clause until that clause is committed.

It must be stressed that under the rules stated above, anything can be done in parallel: Conjunctive goals can be executed in parallel; candidate clauses for a goal can be tested in parallel; head unification can be done in parallel; head unification and the execution of guard goals can be done in parallel. However, it is even more important to stress the fact that we can also execute a set of tasks in an arbitrary order as long as it does not change the meaning of the program.

2.3 Program examples

In this section we give program examples showing how GHC programs are described.

Binary Merge

```
merge([A|Xs], Ys,     Zs) :- true |
          Zs=[A|Zs1], merge(Xs, Ys, Zs1).
merge(Xs,     [A|Ys], Zs) :- true |
          Zs=[A|Zs1], merge(Xs, Ys, Zs1).
merge([],     Ys,     Zs) :- true |
          Zs=Ys.
merge(Xs,     [],     Zs) :- true |
          Zs=Xs.
```

The goal merge(Xs, Ys, Zs) merges two streams Xs and Ys (implemented as lists) into one stream Zs. This is an example of a nondeterministic program. Note that no binding can be exported from the guard; the binding to Zs must be done in the body.

Generating Primes

```
primes(Max, Ps) :- true |
          gen(2, Max, Ns), sift(Ns, Ps).
gen(N, Max, Ns) :- N =< Max |
          Ns=[N|Ns1], N1 := N+1,
          gen(N1, Max, Ns1).
gen(N, Max, Ns) :- N >  Max | Ns=[].
sift([P|Xs], Zs) :- true |
          Zs=[P|Zs1], filter(P, Xs, Ys),
          sift(Ys, Zs1).
sift([],     Zs) :- true | Zs=[].
filter(P, [X|Xs], Ys) :- X mod P=:=0 |
          filter(P, Xs, Ys).
filter(P, [X|Xs], Ys) :- X mod P=\=0 |
          Ys=[X|Ys1], filter(P, Xs, Ys1).
filter(P, [],     Ys) :- true | Ys=[].
```

The goal primes(Max, Ps) returns through Ps a stream of primes up to Max. The stream of primes is generated from the stream of integers by filtering out the multiples of primes. For each prime P, a filter goal filter(P, Xs, Ys) is generated which filters out the multiples of P from the stream Xs, yielding Ys.

3. SEQUENTIAL IMPLEMENTATION

Even though our final target of GHC is parallel implementation, sequential implementation of GHC is nevertheless important. Our experience with Concurrent Prolog shows that interpretive execution of this type of language can be very slow[7]. For this reason, we have concentrated our efforts on implementing GHC "compilers."

GHC and Prolog have lots of similarities, so translation of the former to the latter is much simpler than direct compilation to a machine language. We decided to compile GHC programs to DEC-10 Prolog programs since we already have a DEC-10 Prolog compiler which translates a Prolog program to the machine language. The GHC source programs are ultimately compiled into machine code.

The basic technique for compiling a parallel logic programming language to Prolog is given in Ueda's paper[8]. We have already developed two GHC compilers using that technique[9], one developed by Miyazaki and the other developed by Ueda. These compilers have the following features in common.

(1) They both use techniques similar to Concurrent Prolog Compiler[8] which compiles a Concurrent Prolog program to DEC-10 Prolog.

(2) Both systems evaluate the guards of candidate clauses sequentially. Or-parallel execution of candidate clauses is not performed. The body of a clause is evaluated only after that clause is selected.

(3) Since they are both implemented on top of Prolog, there exists an interface to Prolog. The goal prolog(X) calls X as a Prolog goal.

The differences between the two can be summarized as follows:

(a) Ueda's Compiler[8]. This compiler works on the subset of GHC containing no user-defined goals in guards of clauses. We call this subset "Flat GHC" (FGHC) since there are no nesting guards. In this case, run time check of variables is not needed. This compiler does not distinguish "failure" from "suspension," i.e., "failures" are treated as "suspensions." These simplifications make the execution speed of this compiler very fast (approximately 11KLIPS for "append" program on DEC-2065).

(b) Miyazaki's Compiler. This compiler works on the full set of GHC, i.e., we can call user-defined goals from the guard of a clause. In this case, we need run time check of variables. We have realized this by using the "address-comparison method." Execution speed is slower than Ueda's compiler. This compiler distinguishes between "failure" and "suspension."

Although compilation to Prolog provides an offhand way to execute GHC programs, we also need more direct implementation for more realistic applications. Compilation of FGHC programs into the VAX-11/780 machine code has also been attempted. We have started to build a compiler of FGHC into the VAX machine code. Mock-up object code has been tested and timed. The full compiler system is being written in FGHC, C and VAX-11/780 assembly languages.

4. GHC PROGRAMMING

At this stage, it is very important for us to gain experience in parallel programming. Various application efforts based on GHC are currently under way. These works can be summarized as follows:

(1) All-solution-search transformation [10]

We are developing a program transformation technique to transform Horn clause programs into deterministic GHC programs. It can be viewed as a way to provide GHC with the all-solution-search ability. This technique is applicable to a non-trivial class of programs and the transformed program can be executed quite efficiently. The technique is also important in that it exploits And-parallelism for parallel search as well as Codish's work[11].

(2) Process fusion[12]

The language features of GHC encourages the stream-oriented programming where computation is expressed as processes communicating with one another. In general, each process is designed to compute a relatively simple and small task. However, the resulting programs, if naively implemented, may generate too many small processes which may cause inefficiency because of excessive interprocess communication. Process fusion aims to reduce the number of processes by fusing communicating processes. This is analogous to loop fusion in procedural languages. Development of the program transformation method is currently proceeding based on the fold/unfold method of Burstall and Darlington [13].

(3) Parallel parser[14]

The aim of this research is to develop a parsing system which is naturally implemented in a parallel logic programming language. In our framework, a grammar rule written in DCG [15] is compiled into a program of a parallel logic programming language such as Guarded Horn Clauses or Parlog. Words in a given sentence are defined as processes, consecutive pairs of which are connected by streams. Completed subtrees are also represented as processes and partially constructed parse trees are expressed as data structures produced and put into streams by such processes. Parsing proceeds as dynamic construction of such processes and data. Although the construction of the parse trees proceeds from bottom to top, we also utilize top-down predictions implemented as filtering processes. these processes filter out subtrees that are inconsistent with the predicates. The system is most appropriately compared with Martin Kay's Chart Parsing, in that inactive arcs correspond to processes and active arcs are represented as data passed through streams. The important feature of our method is that the grammar rules and the dictionary are completely compiled into a program in the target parallel logic programming language and the system does not need an additional program to interpret the grammar and the dictionary. The derived program has neither side-effects nor duplicate computation.

(4) Algorithmic debugging[16]

Another research effort is devoted to the development of a debugger for GHC. It has been said that debugging parallel programs is a very hard task compared with debugging sequential programs. The reasons is that 1) conceptually several computations are executed in parallel, 2) these computations may interact with each other, and 3) there are new kinds of bugs such as deadlocks. Usually a program is debugged by examining its execution trace. The execution trace of a parallel program is, however, messy since traces of several computations are interleaved. Even if the execution trace is separated into several traces using, say windows, that is not sufficient for debugging. In general, we must distinguish between debugging and understanding program behavior. In the case of debugging, what is required is to find the location of the bug. Monitoring of program behavior will help finding a bug, but it forces a programmer to understand the program behavior. It would be better if a programmer could debug a program only with more abstract knowledge such as input and output specifications of component modules. We have defined abstract semantics of GHC programs and are developing an algorithmic debugger for GHC. The debugger is based on Shapiro's idea of algorithmic debugging[17] and reduces the number of queries based on the "divide and query" strategy. Lloyd and Takeuchi formally examined the properties of the debugger[18]. For simplicity the current version of our algorithmic debugger only deals with the body of GHC clauses

(5) Propositional temporal logic prover[19]

Temporal Logic is an extension of the first order logic including the notion of time. It deals with logical descriptions and reasoning on time. A propositional temporal logic prover based on the omega-graph refutation procedure has been developed in GHC.

Omega-graph refutation is a procedure to decide the validity of a temporal formula. It negates a given formula, computes the initial node formula of the negated formula, constructs the corresponding omega-graph, and checks the existence of a loop called an "omega-loop." If the loop is found, then the given formula is proved to be invalid.

In our implementation, an omega-graph is constructed incrementally from the initial node formula by successive node expansions. It is represented by the network of communicating processes which spawn brother processes as the graph is expanded. New methods have also been implemented for the detection of an omega-loop where the network of processes finds loops by sending and receiving messages.

We have implemented an appropriate mechanism which checks whether access to the unconstructed part of the network is attempted and forces the process to suspend. Therefore, an omega-loop detection can be performed in parallel with omega-graph construction. It has helped to reduce execution time drastically.

5. KERNEL LANGUAGE VERSION 1

In this section we summarize the current status of Kernel Language Version 1 (KL1). KL1 is originally the language for the PIM hardware. The prototype development of PIM-D (Parallel Inference Machine based on Dataflow mechanism) and PIM-R (Parallel Inference Machine based on Reduction mechanism) has been done[3]. KL1 is expected to operate as the interface between PIM hardware and software to be developed for the parallel high-speed logic-based system.

The first conceptual specification of KL1 was made in 1984[20]. We have stated that KL1 should be based on Concurrent Prolog[6] adding set-abstraction, meta-inference and module facilities.

Based on this conceptual specification, lots of energy has been put into the detailed specifications of KL1 and implementation of Concurrent Prolog [7]. This work clarified the problems existing in Concurrent Prolog regarding semantics and parallel execution . It forced us to revise the conceptual specification of KL1 [21].

After extensive investigations, we have decided to adopt Flat GHC (FGHC) as the core of KL1. Discussion on the detailed specifications of KL1 have also made it clear that we need to separate the language into several layers. Thus, KL1 now consists of three layers. These are shown in Figure 1.

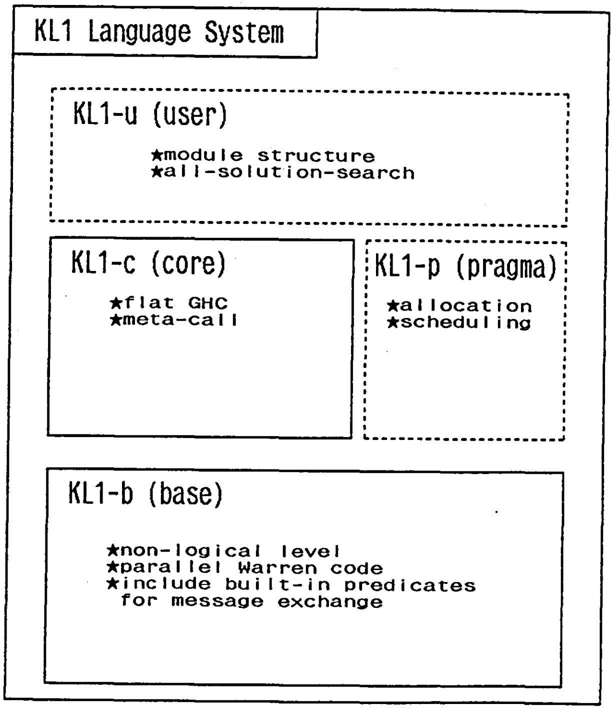

Figure 1 KL1 Language system

KL1-c is the core language of KL1. We assume KL1-c to be FGHC with meta-call predicates.

KL1-p is the pragma language which specifies how the program should be executed in a distributed/parallel environment. KL1-p is not a language as it stands. It is attached to KL1-c to specify process allocation and scheduling information.

KL1-u is the user language to be built on KL1-c and KL1-p. It has the module structure and all-solution-search predicates. KL1-u is in the design stage right now.

KL1-b is the machine language which hardware/ firmware will directly support. This level is not a logical level and it looks like the parallel version of Warren's abstract machine instruction set[22].

6. DISTRIBUTED IMPLEMENTATION

Much research on PIM hardware has been carried out from the "architectural" view point. However, we have noticed that there still exist lots of problems to be solved at the "software" or "firmware" level, such as (1) how to boot the system, (2) how to deliver object programs to each processing element (PE), (3) how to handle input/output and interrupts, and (4) how to balance the load between PEs.

To address these software problems arising from distributed environment, we have decided to start a "Multi-PSI" project. Multi-PSI hardware is simply built up by connecting 6 - 16 Personal Sequential Inference (PSI) machines[23] by high speed grid-network.

6.1 The multi-PE model

We take the multi-PE system where dozens of PEs are grid-network connected as our starting point. There are many design choices. Lots of intensive discussions on these issues have been held inside ICOT. The decisions we have made so far are as follows:

(1) PEs must be connected in a way which allows easy expansion of their number. Our system needs to work even if we have hundreds of PEs.

(2) Each Processing Element (PE) has its local memory. It has no shared memory nor global address space. In our system, PEs communicate by message exchange.

(3) We have employed And-parallelism, since we believe that it plays a more basic role than Or-parallelism in the distributed environment. Each PE executes a program independently or cooperatively.

The conceptual figure of the multi-PE model we assume is shown in Figure 2.

This multi-PE model has the following features.

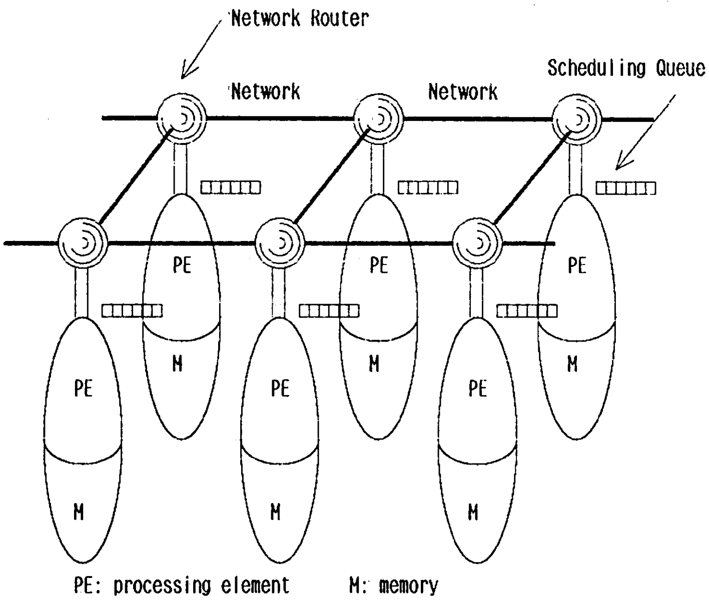

Figure 2 Multi-PE Model

(1) The program, i.e., the collection of clauses, is loaded to every PE at the beginning. A more realistic assumption such as "lazy" fetching of program code may be needed at a later stage.

(2) First, a goal is put into one PE. This automatically starts the computation. Each PE executes the goals sent from other PEs besides processing local goals. When there are no goals left to be processed on any PE, computation terminates.

(3) Each PE has one scheduling queue. Each PE repeats dequeuing a goal from the scheduling queue and reducing it to the resulting goals. These goals are enqueued to the scheduling queue or sent to an other PE.

(4) Since each PE has an independent address space, unification of two variables existing in different PEs makes it necessary to span inter-PE reference chains. Each PE has a variable management table for that purpose.

(5) Unification in one PE may generate various messages to be sent to other PEs. Examples of such messages are "get_value," "unify," and "unify_channels."

6.2 Multi-PE simulator

We have implemented a software simulator of the multi-PE system [24]. The simulator is based on the work by Miyazaki and Murakami [25]. Our system simulates the execution of pre-processed FGHC programs in a multi-PE environment. It is written in Prolog and consists of processes and a network manager as shown in Figure 3.

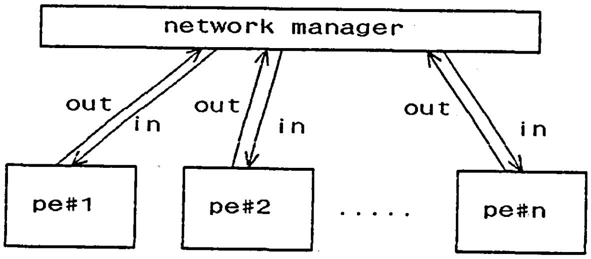

Figure 3 Multi-PE simulator

Each PE checks whether there is a message from its input channel. If so, messages are added to the scheduling queue. Then it executes the first goals in the queue. If there is a message to be sent, the message is put to the output channel. The network manager takes care of message exchange between PEs. Messages inside output channels include the sender's address. The network manager delivers the message to the specified input channel.

Since our system does not have the global address space, sending a goal which includes variables to other PEs requires a somewhat complicated mechanism. In our implementation, each PE has a variable management table to keep track of inter-PE references.

6.3 Implementation on PSI[26]

Implementation of FGHC on one PSI machine was a more realistic starting point to the "Multi-PSI" project. The PSI is a personal workstation and its design concept is very similar to a LISP machine. Conventional techniques have been adopted and ESP[27], the object-oriented extension of Prolog, is firmware supported.

The compiler which translates an FGHC program to Warren-like abstract machine instruction sequences[22] and the emulator of that abstract machine instruction set have already been implemented. Our Warren-like instruction set also includes the primitives for distributed execution. The emulator was written in ESP and was realized using "heap" on PSI machine.

The current version only executes a program on one PSI machine. The execution speed is approximately 0.9 KLIPS on a naive reverse program. We are now devoting a lots of energy to the extension of this work to the Multi-PSI system. ICOT has already finished the design of the connecting hardware. The actual hardware of Multi-PSI Version 1 will be completed by the end of April 1986.

7. SUMMARY

We described the various activities at ICOT related to Guarded Horn Clauses (GHC). The language features of GHC, its implementation efforts and its applications were described. We also summarized the current status of KL1 and efforts aimed at its distributed implementation. These are on-going activities and must be extended in various directions.

8. ACKNOWLEDGMENTS

These research activities have been carried out as a part of the Fifth Generation Computer Project. We would like to thank our colleagues, Kazuo Taki and Takashi Chikayama, for their useful comments and suggestions. We also would like to thank Kazuko Takahashi and Tadashi Kanamori at the Central Research Laboratory, Mitsubishi Electric Corp., for their GHC programming efforts. Thanks go also to Kazuhiro Fuchi, the Director of ICOT for giving us the opportunity to pursue this research.

Abstract

We have proposed a new parallel inference mechanism called the KABU-WAKE method, and have built an experimental OR parallel inference system based on this method. This paper evaluates use of the KABU-WAKE mechanism in practical applications. Tests on our experimental system using a restricted bottom-up parser show that the KABU-WAKE method is very effective for large problems that contain a lot of parallelism. This paper also describes two difficulties of the KABU-WAKE method made evident through analysis of the status of each processor element during the processing of a problem with a low performance improvement ratio. We also estimated the performance improvement ratio expected with 100 processor elements. This research was sponsored by MITI as a part of the FGCS project.

1. Introduction

AI research is now flourishing. In this field, a problem with one of the important features can be solved by traversing a search tree using trial and error methods. A logic program can also be executed using parallel processing, such as OR parallel, AND parallel, or AND-STREAM parallel processing. OR parallel processing is suitable for nondeterministic algorithms and we therefore think it is well suited to a search-type problem described above.

We proposed a new parallel inference mechanism, called the KABU-WAKE method. We built an experimental OR parallel inference system implementing this method [1], [2]. We ran a simple game problem, the N-Queen problem, on the experimental system to evaluate our method [3], [4]. At present, we are evaluating our method for two practical applications, both of which are parser programs with restricted grammars. We have already presented an evaluation of one of the applications-- a top-down parser for the Japanese language. The algorithm produced a top-down parsing tree from a sentence [6]. This paper evaluates the KABU-WAKE method using a bottom-up parser for the Japanese language. The algorithm makes a parsing tree from terminal symbols at the bottom [5]. By analyzing the status of each Processor Element (PE) during processing, we will explain 1) why the performance improvement ratio (how much performance improves over performance with 1 PE) with fewer than 12 PEs was high using a large problem, 2) why the performance improvement ratio was low using a problem that cannot achieve a high performance improvement ratio with 12 PEs, and 3) estimate the performance improvement ratio expected with 100 PEs using a problem that achieved a high performance improvement ratio with fewer than 12 PEs. Chapter 2 discusses problems in parallel inference processing, and explains the features and principles of operation of the KABU-WAKE method. Chapter 3 outlines our experimental system. Chapter 4 discusses the results of executing the bottom-up parser program on our experimental system.

2. KABU-WAKE method

2.1 Problems in Parallel Inference Processing

Our original question is how to make an OR parallel processing inference system so that performance is proportional to the number of PEs. The following problems need resolution:

(1) Problems within each PE
- i. Reducing overhead for switching and scheduling tasks
- ii. Reducing the time for creating and dividing tasks

(2) Problems between PEs
- i. Achieving dynamic load balancing, because we do not know how much

CH2345-7/86/0000/0955$01.00 © 1986 IEEE

processing a program requires before it is executed.

ii. Reducing the number of subtask transfers

iii. Reducing the amount of time for each subtask transfer

The KABU-WAKE method solves most of these problems for certain applications, as we discuss in the next section.

2.2 Principles of Operation

This section discuss the operation principles of the KABU-WAKE method. Figûre 1-a is an example of a knowledge base written in Prolog. We have omitted the arguments of the predicates to simplify explanation. The arrows indicate the normal flow in a conventional sequential inference. Figure 1-b is a snapshot of processing using the KABU-WAKE method. The bold lines indicate the processing in PE 0, corresponding to the processing indicated by the arrows in Figure 1-a. If a request comes from PE 1, PE 0 divides its task at the node closest to the root of the search tree and transfers a portion to PE 1. If a request then comes from PE 2, PE 0 again divídes a part of the task in the same way. This method enables several PEs to solve one problem.

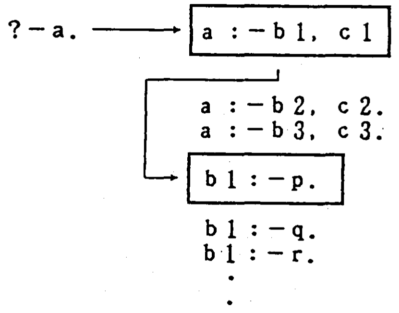

Figure 1-a

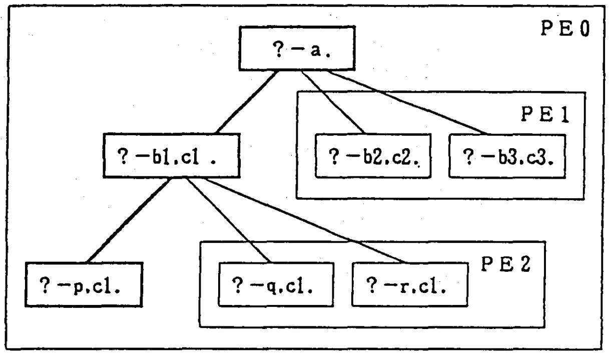

Figure 1-b

Figure 1 Basic KABU-WAKE mechanism

2.3 Features

The KABU-WAKE method has two principal features:

-- Each PE uses the same search strategy as is used by a conventional sequential processor to traverse a search tree, namely, a depth-first search.

-- A PE divides its task and transfers a portion of it only when requested by another PE.

These features have the following advantages:

(1) Low overhead in each PE

i. Each PE processes only one task.

--> There is no overhead for switching and scheduling tasks as in a multiple task environment.

ii. A task is divided at the node closest to the root of the search tree.

--> We think that each PE should divide a task into the largest possible subtasks.

iii. Each PE uses conventional sequential processing.

--> There is almost no overhead for parallel processing during execution in each PE [4]. Also, this method can use the high-speed techniques developed for conventional sequential processing, such as in compilers.

(2) Low overhead between PEs

i. A busy PE divides its task and transfers a portion only when requested by another PE.

--> When all the PEs are busy, there is no communication.

ii. A distributed processing method is used in which only idle PEs receive tasks.

--> Effective dynamic load balancing is possible.

(3) Easy implementation

i. The number of tasks does not exceed the number of PEs.

--> No mechanism is required to temporarily hold extra tasks for PEs.

3. Experimental System

3.1 System configuration

Figure 2 shows the system hardware configuration. The experimental system consists of 16 PEs (one for the man-machine interface) and two networks. These networks are used for different purposes, and were designed specifically for our method.

(1) PE

A PE performs inference processing. It gives part of it's task to another PE if a request comes during processing. A KABU-WAKE interpreter is installed in each PE. This interpreter is a conventional sequential interpreter with added control mechanisms [2],[4] to implement the KABU-WAKE method. Each PE has a copy of the entire database.

(2) CONTROL NETWORK

The control network is a communication route for requesting tasks. This network connects all PEs in a ring via control network adapters (CNAs). The clock frequency is 2 MHz. A packet, which indicates whether each PE is busy or idle, goes around the network [6] in 8-microsecond cycles.

(3) DATA NETWORK

The data network is a communication route for transferring tasks. It is a two-stage network made up of 4 x 4 switches. The communication method is DMA transfer of 8 bits in parallel. The transmission rate of the network hardware without overhead is about 400 KB/s, but it drops to 50 KB/s with the addition of the communication software overhead [6].

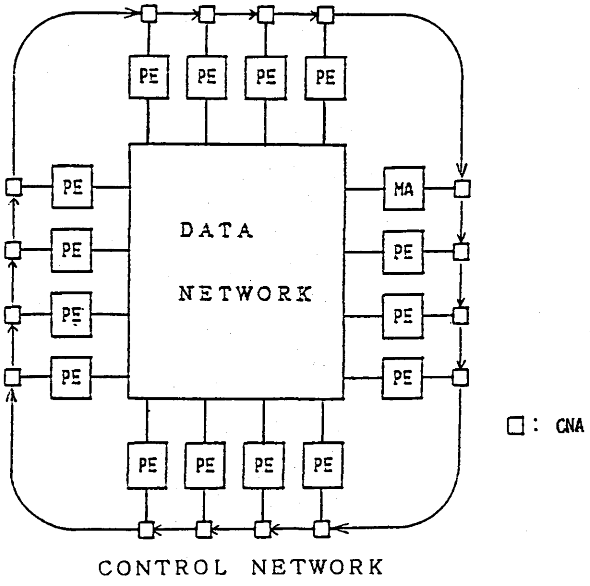

Figure 2 System configuration of experimental machine

3.2 Implementation

The following items need be implemented in our experimental system.

(1) Unbinding of variables

When a search tree is split, the status of the variables in the split tree must be as if all the processes located below the split portion of the search tree had failed and backtracked, i.e., unbinding. To speed up this unbinding operation, we reserved an area for each variable in which was stored the time at which it was bounded. Each time a subgoal is reached, a new level number, corresponding to the depth of subgoal, is assigned. For variables bound during the processing of that subgoal, the same level number as that of the subgoal is flagged. When a tree is split, we can determine whether binding should be released by comparing the level of the subgoal to be split with the variable's level number. In this method, the time required to release variables for splitting is proportional to the number of variables in the subgoal to be split. Using a trailing stack is another alternative, but we think the processing would take more time.

(2) Use of rule numbers

When a tree is split and transferred, it is transferred in the form of a subgoal. However, since some of the definitions for the subgoal are already being processed, the other PEs must start from subsequent definitions. We, therefore, we adopted a method in which a special predicate, called a rule number, is prepared and attached to the subgoal before transfer to indicate where to start execution.

(3) Control of request

Some tasks cannot be split when a request is received from another PE. If this is often the case, PE performance deteriorates. To handle this situation, we used a request reception flag to indicate whether a task can be split. This enables a PE to concentrate on a task without being disturbed by other PEs.

4. Evaluation

Let us now consider the results obtained by running the bottom-up parser on our experimental system. We will first present the results, then discuss them.

4.1 Results

4.1.1 Test programs

We entered three sentences into the bottom-up parser (44rules, 103facts). The characteristics of the three bottom-up parser programs corresponding to the three sentences entered are shown in Table 1. Here, the bottom-up parser is a Japanese-language parser; the algorithm makes a parsing tree from terminal symbols at the bottom. We define a execution time with 1 PE as the amount of processing time. The ratio of the amount of processing time in Sentence 1 to that in Sentence 2 is 1:8 and of Sentence 1 to Sentence 3 is 1:60. The amount of processing time required in Sentence 1 is about 1.3 times as much as in 7-Queen.

Table 1 Logical characteristics of bottom-up parser programs

ITEM PROGRAM	Average number of parallel degrees *1	Number of inference levels
Sentence 1	45	1294
Sentence 2	236	2081
Sentence 3	1427	2388

Notes

*1 : Average number of parallel degrees = ((total number of inferences) ⁄ (number of inference levels))

*2 : The three sentences entered are as blow :

Sentence 1

“wakai otoko wa kouen de akai boushi no onna no ko ga hon wo yomu nowo mita ”

(meaning) :

A young man saw a girl with a red hat reading a book at a park.

Sentence 2

“aoi fuku no wakai otoko wa kouen no ki no benchi de akai boushi no onna no ko ga atarashii ryouri no hon wo yomu nowo mita ”

(meaning) :

A man wearing blue clothes saw a girl with a red hat reading a new cookbook on a wood bench at a park.

Sentence 3

“akai fuku no wakai otoko wa watashi no machi no kouen no ki no benchi de akai boushi no onna no ko ga atarashii ryouri no hon wo yomu nowo mita”

(meaning) :

A young man wearing red clothes saw a girl with a red hat reading a new cookbook on a wood bench at a park in my town.

4.1.2 Performance improvement ratio

Figure 3 shows the relationship between the number of PEs and the performance improvement ratio due to parallel inference. It shows that in a large problem, such as Sentence 3, the performance improvement ratio is almost proportional to the number of PEs. As the amount of processing decreases (Sentence 3 -> Sentence 2 -> Sentence 1), the performance improvement ratio decreases. The ratio of Sentence 1 increases only until the number of PEs reaches 8, then it levels off.

4.2 Discussion

This section discusses the following three items.

(1) Performance improvement ratio of Sentence 3

Figure 3 shows that the performance improvement ratio of Sentence 3 is higher than that of Sentence 1 and 2. We will discuss the cause.

(2) Performance improvement ratio of Sentence 1

Figure 3 shows that the performance improvement ratio of Sentence 1 is low. We will discuss the cause, and describe several difficulties related to the KABU-WAKE method made evident through our analysis.

(3) Estimated performance improvement ratio of Sentence 3

One of the AI applications is a search problem; we think this type of problem requires a great deal of processing. We regard Sentence 3 as such a search-type problem and estimate the performance improvement ratio with 100 PEs.

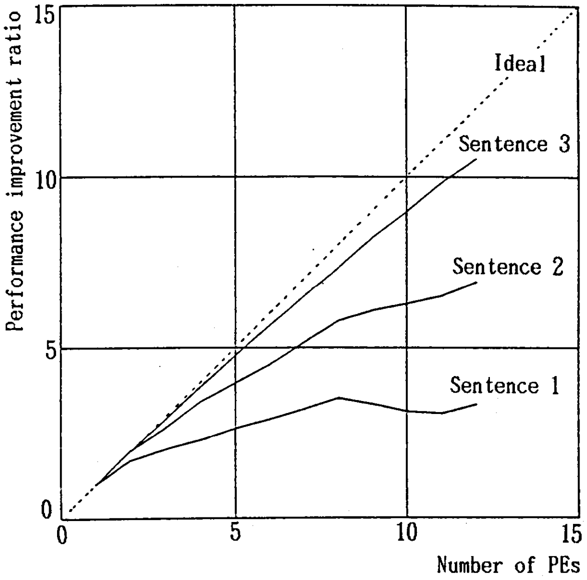

Figure 3 Performance improvement ratio due to parallel inference

4.2.1 Performance improvement ratio of Sentence 3

Figure 4 graphs the relationship

between the processing time (with 1 PEs) and the number of subtask transfers (with 12 PEs). In Figure 4, the xcoordinate is a logarithm of the processing time. Figure 4 indicates that the number of subtask transfers is almost proportional to the logarithm of the processing time, but not to the processing time itself. This means that, as the prcessing time increases exponentially, the number of subtask transfers increases linearly. That is, for similar programs, the longer the processing time, the less communication overhead. This is why the performance improvement ratio of Sentence 3 is higher than that of Sentence 1 and 2.

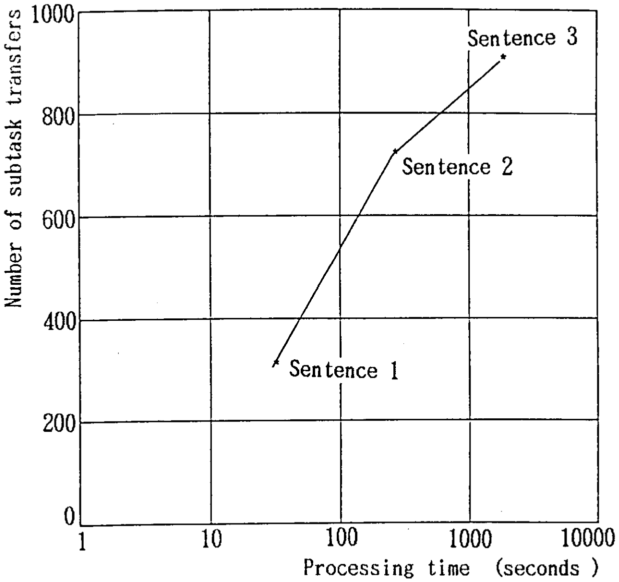

Figure 4 Relationship between processing time and number of subtask transfers (PEs =12)

4.2.2 Performance improvement ratio of Sentence 1

Table 1 shows that the average number of logical parallel degrees in processing by the KABU-WAKE method is 45. However, the performance improvement ratio of Sentence 1 does not reach 4, even when Sentence 1 is processed with 12 PEs.

<1> Results

The experimental results show that when the number of PEs is 12, the rate of processing items (busy, KABU-WAKE, idle) are as follows:

busy time: 30.6%,
KABU-WAKE time: 43%,
idle time: 26.4%

Busy time includes all of the inference processings. KABU-WAKE time includes all of the KABU-WAKE processings (explained later).

The ratio of processing time shows that KABU-WAKE time and idle time accounted for more than 70% of all the time used to process Sentence 1. These two factors (we call them overhead for parallel execution) prevent performance improvement.

<2> Analysis

To discover why the overhead for parallel execution such as both KABU-WAKE time and idle time are large, we discuss some factors which may cause the overhead.

There are two factors which may cause the overhead:

Factor 1: KABU-WAKE processing time per transaction
The time depends on what feature of KABU-WAKE processing is being used.

Factor 2: number of KABU-WAKE processings
The number depends on the nature of parallelism in the search tree of Sentence 1.

(1) Features of KABU-WAKE processing

Figure 5 details the KABU-WAKE processing time in the execution of Sentence 1. The KABU-WAKE processing time is 106 ms: 49 ms for Sender to transfer a subtask and 57 ms for Receiver to receive the subtask. While Sender does Split processing in the KABU-WAKE processing, the Receiver is idle (Wait in Figure 5), and the Wait time is 33 ms. This minimum time is needed for each KABU-WAKE processing. It takes 2 ms for the KABU-WAKE interpreter to process a inference, so the interpreter can process about 53 inferences during KABU-WAKE processing time and about 16 inferences during Wait time. The KABU-WAKE processing time per transaction was long.

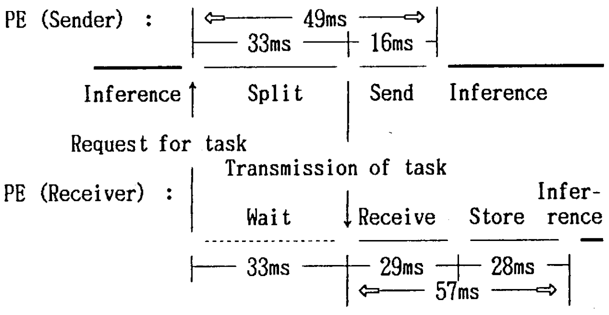

Figure 5 Details of KABU-WAKE processing time

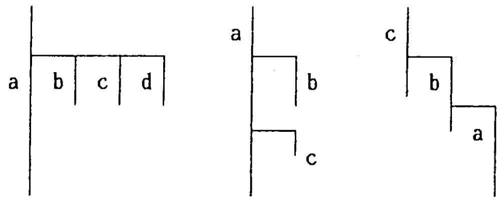
(2) Nature of parallelism in the search tree of Sentence 1.

Almost all the parallelisms are of the type shown in Figure 6, and almost all branches (b, c, and d in Figure 6) in the portions with such parallelisms have a number of inferences smaller than 60.



Almost all branches b, c, or d has a number of inferences smaller than 60.

Figure 6 Characteristics of a sabtask that to can be processed in parallel by a bottom-up parser

In the execution of Sentence 1 with 12 PEs, the transferred subtasks, consisting of fewer inferences than 24, is about 36% of all the transferred subtasks, and consisting of fewer than 60 is about 81%. It means that the number of KABU-WAKE processings was large because the transferred subtasks consisted of a small number of inferences. Further the beginning and the ending of execution was generally not good. Also because of the long KABU-WAKE processing time and the large number of transferred subtasks, there were many idle PEs that sometimes became busy. This cause a lot of idle time. Figure 7 shows the dynamic change of status of each PE during the processing of Sentence 1. In Figure 7, busy, KABU-WAKE, and idle states have the following meanings:

-- Much idle time occurred during the first and last thirds of the execution. This accounted for more than 90% of all idle time.
-- Communication was distributed uniformly from the beginning to the end of execution. In the first third, the number of subtask transfers was 112, in the second third, 108, and in the last third, 125.
-- All of the PEs processed the majority of inferences during the middle third of execution.

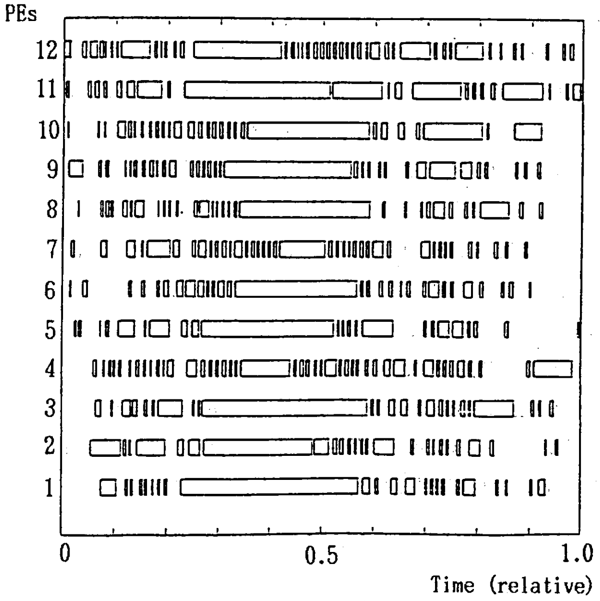


Figure 7 Change of status in each PE during processing of Sentence 1

The KABU-WAKE processing and the search tree of Sentence 1 have the above characteristics. When we return to the factors which cause overhead in parallel execution, the KABU-WAKE processing time per transaction was long and the number of KABU-WAKE processings was large. So, the overhead (KABU-WAKE time and idle time) took up more than 70% of all the time used to process Sentence 1.

Two difficulties in the KABU-WAKE method were revealed during analysis of the above experiment.

i. KABU-WAKE processing time per transaction is longer than it should be.

ii. The number of inferences which make up a transferred subtask have a large influence on the performance improvement ratio.

4.2.3 Estimated performance improvement ratio of Sentence 3

This section describes the estimated performance improvement ratio expected if Sentence 3 is processed with 100 PEs.

The following expression shows how the performance improvement ratio with 100 PEs is obtained.

$$\text{performance improvement ratio} = \frac{\text{(execution time with 1 PE)}}{\text{(execution time with 100 PEs)}}$$

The value of the execution time with 1 PE is based on actual measurement. During execution with 100 PEs, each PE does inference processing, does KABU-WAKE processing, or is idle. So, the execution time with 100 PEs is determined by the following expression.

```
execution time with 100 PEs =
     ((busy time) +
       (KABU-WAKE time) + (idle time))
     ---------------------------------
                   (100)
```

In the above expression, busy time is the sum of inference processing time from PE 1 to PE 100: we can regard the busy time as the execution time with 1 PE. The KABU-WAKE time is determined by the following expression.

```
KABU-WAKE time =
   ((KABU-WAKE processing time
              per transaction) *
      (number of subtask transfers))
```

Here, the value of the KABU-WAKE processing time per transaction is based on actual measurement of the execution of Sentence 3 with less than 12 PEs. To estimate the number of previous subtask transfers when Sentence 3 is processed with 100 PEs, we used the relationship between the number of PEs and the number of subtask transfers obtained by actually measuring the execution of Sentence 3 with less than 12 PEs. (In the KABU-WAKE method, the relation is linear [4],[6].) We estimated the idle time from the relationship between the number of PEs and the amount of idle time (shown in Figure 8) obtained by actually mesuring the execution of Sentence 3 with less than 12 PEs. Figure 8 indicates that the relationship is almost linear.

The above computations give an estimated performance improvement ratio of about 50 when Sentence 3 is processed with 100 PEs.

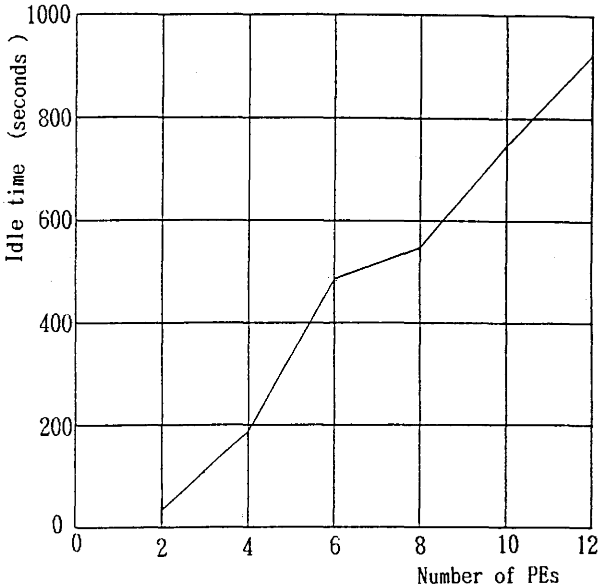

Figure 8 Relationship of number of PEs to idle time

5. Conclusion

We evaluated the KABU-WAKE method by running a bottom-up parser program with restricted a grammar on our experimental system. The results led us to the conclusions listed below.

(1) With the KABU-WAKE method, we can obtain a performance improvement ratio proportional to the number of PEs for large problems with a lot of parallelism. The method has the advantage for parallel inference that, as the amount of processing increases exponentially, the number of subtask transfers increases linearly.

(2) Difficulties in the KABU-WAKE method made evident through analysis of the cause of the low performance improvement ratio when 12 PEs were used is as follows:
  i. The KABU-WAKE processing time per transaction is longer than it should be.
  ii. The number of inferences which make up a transferred subtask greatly influences the performance improvement ratio.

(3) The estimated performance improvement ratio is about 50, when a problem that achieved a high performance improvement ratio with fewer than 12 PEs is processed with 100 PEs.

In our analysis described in 2, above, we saw that the KABU-WAKE processing time had a great deal of influence on the performance improvement ratio. We think it is important to reduce the KABU-WAKE processing time per transaction. For 2 i, above, we have built a KABU-WAKE compiler that reduces the KABU-WAKE processing time per transaction and are awaiting an evaluation of it. For 2 ii, as the KABU-WAKE processing time gets shorter, its influence on the performance improvement ratio becomes smaller. We are investigating other possible solutions to 2 ii that relate to the basic principles of the KABU-WAKE method.

We think that one of the practical applications in AI, the search problem, requires a large amount of processing with a large number of subtasks that can be processed using OR parallel. The KABU-WAKE method is very suitable for this type of application.

FGCS is attempting to develop an AND-STREAM parallel inference machine, which executes the GHC (Guarded Horn Clause) language [7]. From the point of view of GHC, OR parallel Prolog, that is pure Prolog, is a language that is used to describe special types of algorithms such as a search problem. Therefore, when we think of the GHC-oriented machine as a general purpose parallel inference machine, we can regard an OR parallel Prolog-oriented machine as a special-purpose parallel inference machine. As search problems appear in most AI applications, we think the OR parallel Prolog-oriented machine is quite valuable.

6. Acknowledgments

The authors would like to thank Mr. Tanahashi, Section Manager, and Mr. Sato, General Manager, for their unfailing encouragement and Mr. Yamada, Managing Director, for giving us the opportunity to conduct this research.

A Very Fast Prolog Compiler on Multiple Architectures

Toshiaki Kurokawa Naoyuki Tamura Yasuo Asakawa
Hideaki Komatsu

Science Institute, IBM Japan, Ltd.
5-19 Sanban-cho, Chiyoda-ku, Tokyo 102, JAPAN

Abstract

In this paper, we report on our experiment on Prolog compiler technology. Targeted properties of the compiler are efficiency and portability. The generated code so far attained is so efficient to gain more than 1 MEGA LIPS on IBM 3090.

One of the speciality of the compiler is in the intermediate Virtual Prolog Machine Code, which enhanced efficiency and portability. Another advantage of the compiler is to generate PL.8 code which can be used on multiple machines including the IBM 370 and IBM RT-PC.

We introduce some declarative extensions to the Prolog language, which is compatible with the language and is powerful enough to produce efficient code.

1 Our Goals and Approaches

The goals of our optimizing Prolog compiler technology development were the following:

1. Development of the technology to produce one of the world's fastest Prolog compiler.
2. Both efficiency and portability achieved in the same framework.
3. Conducting the feasibility study of the compiler technology in a reasonably short period.
4. Evaluation of various machine architectures from the standpoint of the Prolog compilation.

To achieve these goals we have employed the following techniques:

1. Extension of the Prolog language for the generation of efficient code, while maintaining compatibility.
2. Adoption of the Virtual Prolog Machine scheme as the intermediate stage of the compilation process for effective optimization.
3. Use of the machine independent and efficient system programming language, PL.8[1], as the object code.

In this paper, we present the newly introduced declarations, an overview of the compilation and an evaluation of the compiler.

We have omitted arguments about Prolog such as in [6], and assumed the readers have some familiarity with Prolog language and programming[3].

2 Prolog Language Extensions

There are two extensions newly introduced to Prolog language: *notrail* and *type*. Both are declarations which can be attached to any predicate. So far, *mode* declaration in DEC-10 Prolog[2] is the only declaration that is used for optimizing compilation.

- *Notrail* declaration indicates that the annotated predicate actually behaves rather as a function so that there is neither backtracking nor ambiguous head selection. This declaration usually follows the *usage* declaration explained below.
- *Type* is declared actually in part of the *usage* declaration where input/output *mode* is also declared for the predicate. With it, we can declare the data type of each argument, not of each variable. So far, we limit type categories among the built-in data types such as *atom, nil, list, integer, structure, variable*, and their combination.

For example, we can define the list concatenation program, *append*, that is deterministic and accepts two input lists (possibly *nil*) and produces one output list. It is actually the same as the well-known *append* predicate but is declared as Figure 1.[1]

```
<- usage append(in:(list+nil),
                in:(list+nil),
                out:(list+nil)).
<- notrail append(*,*,*).

append({},X,X).
append({A|X},Y,{A|Z}) <- append(X,Y,Z).
```

Figure 1: APPEND with declarations

The introduction of *type* annotations is natural, in the sense that most contemporary high-level programming languages, even Lisp, have type declarations. However, the *notrail* declaration is special to the Prolog language, and may need some explanations.

[1] Note that we use VM/Prolog[4] syntax. In DEC-10 Prolog[2], square brackets ([]) would be used to indicate list data instead of curly braces ({, }).

CH2345-7/86/0000/0963$01.00 © 1986 IEEE

This declaration is introduced mainly from the following two reasons:

1. For the compiler writer, it helps the decision to eliminate the trailing of variables. Without it, all variables have to be trailed, or at least checked whether they must be trailed or not, even if the execution is deterministic.
2. For the Prolog programmer, this declaration eliminates the use of the *cut* operation. It is commonly observed with a novice programmer that he either puts in too many cuts or forgets to puts in cuts at all. Most of the Prolog predicates tend to be deterministic, especially when Prolog is used for system programming.

The benefit of the deterministic declaration varies with machine architectures. For the ordinary commercially available machines such as IBM S/370 or IBM RT-PC[5], the gain is significant because the trailing operation requires more instructions compared with special Prolog machines such as Tick and Warren's Pipelined Prolog Machine[11].

We have also introduced two auxiliary declarations: *key* and *entry*. *Key* declaration can be used to specify the argument which will be indexed. *Entry* declaration is used to declare the entry point and an entry declaration is necessary for a compilation unit.

More complicated examples of these declarations are shown in appendix A, which is really used for benchmark tests. That original version is defined in Prolog contest[10].

3 Outline of The Compilation Process

As noted in our goals, our emphasis lies in its *optimization* and *portability*. We adopt a *virtual machine* as an intermediate stage of our compilation so that we can enhance both the optimization and the portability.

The virtual machine, which we have adopted, is based on Tick and Warren's machine[11]. However, considering from the viewpoint of optimizing Prolog compiler, the level of its instructions is too high. For example, its instruction "*get_list A1*" implies the following:

```
test the tag of register A1
if reference then
    do dereference
    and retry
if unbound variable then
    create a list cell
    bind it to the variable
    check whether trailing is necessary or not
    if necessary then do trailing
    set the address of the list cell to register S
    set write mode
if list then
    set the address of the list cell to register S
    set read mode
otherwise
    fail
```

As far as "*get_list A1*" is a primitive instruction and it can not be decomposed into lower level instructions, there is no opportunity for optimization even if it is known that A1 is always a list. Therefore, in our virtual machine many low level instructions are introduced, which basically correspond to each statement in above example. The optimizer in our compiler eliminates redundant type-checking and mode-checking at this level.

Another special point of our approach is the adoption of PL.8 as an object code.

PL.8 compiler provides a low-level optimization. For example, we need not care about the register allocation. It also provides the portability among S/370 and RT-PC.

The compilation process can be summarized in the diagram in Figure 2.

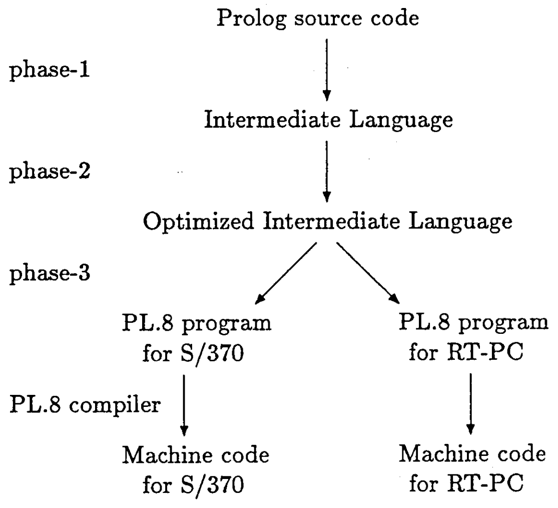

Figure 2: The outline of our compilation process

3.1 Phase-1

In this phase, Prolog program is translated to intermediate language, which is called *WIL*. This is considered as mapping process of Prolog language into the virtual machine. From this point of view, some optimization is done. For example,

- tail recursion optimization[12]
- decision of unification order using *mode* information
- detection of *unsafe variable* using *type* and *mode* information
- selection of the best code for builtin predicates using *type* information
- variable classification

Type and mode information is also generated so that optimization can be done effectively in the following phase.

In Figure 3, a part of output of phase-1, which is generate from *append*, is shown. It corresponds to the indexing part and unification of the first argument of the second clause in Figure 1. This will be expanded to low-level code before optimization process. Expansion is very simple and straightforward. An example of expanded code is shown in Figure 4.

```
asa3:
   assertion(type(a(1)) = list + {}
                         + ref( \= undef));
   select type(a(1)) of {
     ref( \= undef) -> {
        deref(a(1));
        goto(asa3) };
     {} -> goto(asa1);
     list -> goto(asa2);
     otherwise -> failure};
 ..............................
asa2:
   get_list(a(1))
        where trail = no &
              type(a(1)) = list + {}
                         + ref( \= undef) &
              deref = no;
   unify_variable(x(1),0);
   unify_variable(x(2),1);
 ..............................
```

Figure 3: A part of output of phase-1 for *append*

3.2 Phase-2

In this phase, the intermediate code is translated into a graph for optimization. The optimization consists of following two steps:

1. tracing the graph to infer the behavior of the intermediate code by *semantic definition of the intermediate language WIL*
2. modifying the graph by *graph reduction rules*

This optimization process is repeated several times and after that the optimized graph is translated back to the intermediate code. Roughly speaking, by this optimization,

- redundant case instructions
- never-selected case entries
- unreachable instructions

are eliminated. Detailed discussions about this optimization techniques will be found in our accompanying paper [8], especially from the *knowledge-based* viewpoint.

Figure 5 shows the result of optimization of the code shown in Figure 4.

```
asa3 :
    case type(a(1)) of {
        ref( \= undef) ->
            goto(tn82);
        {} ->
            goto(asa1);
        list ->
            goto(asa2);
        atom + int + struct + ref(undef) ->
            goto(tn81)
    };
tn82 :
    deref(a(1));
    goto(asa3);
.......................
asa2 :
    case type(a(1)) of {
        ref ->
            goto(tn64);
        list ->
            goto(tn62);
        {} + atom + int + struct ->
            goto(tn60)
    };
tn64 :
    get_list_w(a(1));
    setmode(write);
tn56 :
    case mode of {
        write ->
            goto(tn58);
        read ->
            goto(tn57)
    };
tn58 :
    unify_variable_w(x(1),0);
tn53 :
    case mode of {
        write ->
            goto(tn55);
        read ->
            goto(tn54)
    };
tn55 :
    unify_variable_w(x(2),1);
tn52 :

      unify_variable_r(x(2),1);
........................
```

Figure 5: Output of phase-2

3.3 Phase-3

The code obtained in phase-2 is machine independent. In phase-3, the code is translated into PL.8 program. During this translation information which depends on the target machine is used to optimize the following:

- design of tag
- primitive operations
- the order of case entries

Figure 6 is an example of PL.8 code generated for S/370 from the code shown in Figure 5.

3.4 PL.8 compiler

As described in [1], PL.8 compiler does many kinds of optimization. For example, register allocation, dead code elimination, code motion, value numbering, dead store elimination, straightening, and so on. Off course, those are also effective in our case. These are done in global viewpoint.

PL.8 compiler can also do optimization which is considered in Warren's "Abstract Prolog Instruction Set"[13] level. Value numbering and register allocation algorithm used in PL.8 compiler can do same optimization shown in Figure 7[2].

4 Evaluation

The compiler itself is written entirely in high-level programming languages, namely, VM/Prolog and PL.8. Due to the quality of the debugging environment for VM/Prolog[9] and for PL.8, the prototype compiler has been developed in short term.

The compiler itself runs on VM/CMS on IBM S/370, producing code both for IBM S/370 and for IBM RT-PC.

```
asa3:
select;
when(  shiftr(a1,28)=4 )
goto tn62;
when( a1= ('30000000'xb^('OFFFFFFF'xb &0)) )
goto tn77;
otherwise
goto tn82;
end;
tn82:

 /*** DEREF(a1)***/
 a1 =
 ptr(
 a1
 ,memory)->w;
goto asa3;
........................
tn62:

 /*** G_LIST_R(a1)***/
 s = ('00000000'xb^('OFFFFFFF'xb &a1));
mode = rmode;

 /*** U_VAR_R(x1,0)***/x1=s->strfrm.w0;

 /*** U_VAR_R(x2,1)***/x2=s->strfrm.w1;

........................
```

Figure 6: Output of phase-3(for S/370)

Although full facilities of Prolog are not yet implemented, enough facilities are realized to handle list processing and arithmetics. With these functions, we can measure LIPS[3] values that are presented in Table 1. We also measured the performance by some more complicated programs such as the classical "eight-queen problem", which is shown in appendix A. The measured execution times are shown in Table 2.

As our current prototype compiler have several points to

```
get_list A1
unify_variable X4
unify_variable X5    -->  unify_variable A1
get_variable X6,A2   -->  (deleted)
get_list A3
unify_value X4
unify_variable X7    -->  unify_variable A3
put_value X5         -->  (deleted)
put_value X6         -->  (deleted)
put_value X7         -->  (deleted)
execute append/3
```

Figure 7: Example of-Warren's Abstract Prolog Instructions level optimization

[2] This example is found in [11] and [13].

[3] LIPS (Logical Inferences Per Second) is usually measured by a simple list manipulation program, *i.e.* a simple *append* or a naive *reverse*.

be tuned up, we can reasonably expect the final LIPS values better than those presented in Table 1. Note that the speed on IBM 3090 has exceeded one MEGA-LIPS, which is a good intermediate step to achieve the goals raised in Fifth Generation Computer Project [7]. Also note that in the figures for the IBM RT-PC, all system overheads are included. In other words, we measured real time performance in IBM RT-PC.

	RT-PC	3081K	3090
Without hints	56	611	1000
With hints	87	827	1420

Table 1: LIPS value measured on IBM S/370 and IBM RT PC. The unit is KLIPS. The benchmark program is *simple append* with 1000 elements. Hints mean *mode*, *type*, and *notrail* declarations.

	3081K		RT-PC	
	Without hints	With hints	Without hints	With hints
First	5	14	65	178
All	92	232	1066	2860

Table 2: Execution time of 8-queen problem. The unit is millisecond. Hints mean *mode*, *type*, and *key* declarations.

Table 3 shows the effectiveness of the optimizations which are done in phase-2 and in PL.8 compiler. From this table it is found that the optimizer in PL.8 compiler does the optimization considered in Warren's Instruction level, shown in Figure 7. But it is also found that optimization in low-level virtual machine instructions is also effective and combination of these two level optimization is very effective.

Table 4 shows the effectiveness of newly introduced declarations. According to this table, *mode* declaration, only itself is little useful for optimization. Combination of *mode* and *type* declaration, we call it *usage* declaration, is very effective. *Notrail* declaration is also effective, especially for RT-PC, which is the so-called workstation and which memory is much slower than host-class machines.

5 Concluding Remarks

It is not an easy task to conclude in this kind of evolutionary activities. However, it should be noted that our main emphasis lies in the technology development, not in the product development. In other words, when one tries to make a product-level Prolog compiler based on our technology, he or she may have to trade off efficiency for functionality.

Our prototyping is, in analogy to physics, an experiment conducted only to prove the correctness or feasibility of our approaches. We conducted an extensive review on similar works, and as far as we know, our compiler has achieved the highest performance for Prolog compilation.

	3081K		RT-PC	
	Without hints	With hints	Without hints	With hints
No optimization	1	1.06	1	1.09
Prolog only	1.68	1.92	1.62	1.86
PL.8 only	1.64	1.85	1.68	1.74
Prolog+PL.8	3.30	4.47	2.80	4.35

Table 3: Effect of optimization: relative values of LIPS in case of append. Hints mean *mode*, *type*, and *key* declarations.

	3081K		RT-PC	
	Without notrail	With notrail	Without notrail	With notrail
None	1	1.08	1	1.15
Mode only	1.03	1.26	1.04	1.30
Type only	1.07	1.16	1.23	1.36
Mode+Type	1.24	1.40	1.47	1.97

Table 4: Effect of declaration: relative values of LIPS in case of append. Optimization is done both in phase-2 and PL.8 compiler.

A RELATIONAL DATABASE MACHINE BASED ON FUNCTIONAL PROGRAMMING CONCEPTS

Yasushi KIYOKI, Kazuhiko KATO and Takashi MASUDA

Institute of Information Sciences and Electronics
University of Tsukuba
Sakura, Niihari, Ibaraki 305, Japan

ABSTRACT

We present a novel approach to a relational database machine for processing knowledge bases. This approach is based on functional programming concepts in order to manage processor resources and memory resources with the theoretical neatness of functional computation. By using demand-driven evaluation as a driving method of functional computation, parallelism can be exploited in executing relational operations (relational database operations) and inference operations based on unification. Furthermore, these operations can be executed avoiding the complexity of resource management within a restricted resource environment. This approach is implemented under a multiprocessor architecture combined with a demand-driven evaluation mechanism. In this paper, we define the basic primitives which are used to implement demand-driven evaluation and function application. We also present a basic algorithm and a system architecture for executing basic operations for knowledge bases by using a demand-driven evaluation mechanism. To ascertain feasibility of our approach, a relational operation system has been implemented on the basis of the approach.

1. Introduction

The relational model [4] has received much attention as a promising data model for implementing database systems with theoretical basis. Furthermore, it has been recognized that the model is significant for implementing knowledge base systems based on mathematical logic, and it has been studied how relational database concepts can be applied to mathematical logic [6].

It is known that basic operations in such knowledge base systems are relational operations and inference operations based on unification. The important feature of these operations is that they deal with a vast amount of data represented as relations.

We consider the basic operations within the framework of functional programming concepts. Functional programming [2] include many attractive concepts, and its fundamental concepts are summarized as follows:

(1) The value of a function expression depends only on its textual context, not on computational history. This notion is referred to as referential transparency.

(2) Functional computations are free of side effects. The parameter passing mechanisms call-by-value, call-by-name and call-by-need have the same semantics.

(3) Functional programs often contain implicit and easily detected parallelism [5].

In this paper, we present a novel approach to a relational database machine for processing knowledge bases. In this approach, functional programming concepts are applied to both relational and inference operations in order to exploit parallelism in a natural way and to manage processor resources and memory resources with the theoretical neatness of functional computation.

In [16], relational operations have been described in a dataflow language based on data-driven evaluation [1]. Processing of relational operations has been considered as stream processing in the data-driven evaluation including the eager and lazy evaluations. Furthermore, in [17], an advanced stream-oriented algorithm which exploits parallelism inherent relational operations has been presented in detail.

In the approach presented in this paper, demand-driven evaluation is used in computing functions of relational and inference operations.. A relational operation, such as the selection operation or the join operation, is defined as a function, and operand relations of the relational operation are manipulated as arguments of the function. The arguments corresponding to operand relations are evaluated as streams of tuples by using the demand-driven evaluation mechanism. By using this evaluation mechanism in functional computation, it becomes possible to execute both relational and inference operations in parallel within restricted computing resources. In this approach, the stream-oriented algorithm [17] can also be realized within the framework of demand-driven evaluation.

In this paper, we also discuss how relational database concepts can combine with inference operations based on unification. In our approach, a set of fact clauses in Horn clauses is represented as a relation, and the fact clauses are manipulated by using functional computation.

The relational database machine proposed in this paper exploits parallelism inherent in knowledge base processing, and makes it possible to execute basic operations for knowledge bases within a restricted resource environment.

2. Approach to Functional Computation

In our approach, each process of relational and inference operations is described on the basis of functional programming concepts. In order to realize several driving methods of functional computation, basic primitives are defined. The basic primitives sup-

CH2345-7/86/0000/0969$01.00 © 1986 IEEE

port various kinds of parameter passing mechanisms required in functional computation.

2.1 Demand-driven Evaluation in Functional Computation

The methods of driving functional computation are classified [20],[21] as follows:

(1) Demand-Driven Evaluation,
(2) Data-Driven Evaluation, and
(3) Sequential Evaluation.

We employ demand-driven evaluation in executing relational operations and in executing inference operations, in order to execute those operations in parallel within a limited resource environment. Demand-driven evaluation generally introduces a fair amount of overhead in issuing demands. However, the demand-driven evaluation allows better control of parallelism, more selective evaluation, and a natural way of handling a large amount of data within a limited resource environment. The advantage of demand-driven evaluation includes the potential for eliminating a vast amount of computation by evaluating only what is necessary for computing the result. Since relational operations and inference operations generally require to manipulate a large amount of data, the potential inherent in demand-driven evaluation is effectively utilized. In executing these operations, granularity of data which is transferred by a single demand can make large. Therefore, when compared with the total amount of data transferred by a single demand, the overhead caused by the demand transfer is insignificant.

In this approach, the following parallelisms inherent in functional computation are exploited:

(1) parallel evaluation for arguments of a function,
(2) parallel execution between a function which generates its return value as a stream [10] and a function which consumes the stream as an actual argument. That is to say, stream-oriented parallel processing between a function of stream-producer (producer function) and a function of a stream-consumer (consumer function).

To exploit the parallelism of (1), demands are simultaneously issued from a consumer function to producer functions which generate actual arguments of the consumer function. Consequently, the independent operations can be executed in parallel.

The parallelism of (2) is exploited between a producer function and a consumer function. In data-driven evaluation, to exploit the parallelism, it is necessary for the consumer function to begin the computation eagerly before the producer function completes producing all intermediate results [1]. To extract the parallelism in demand-driven evaluation, it is necessary for the producer to begin the computation eagerly before the demand arrives from the consumer. In our approach, parallelism is exploited by pre-issuing a demand to the producer function before the consumer function begins computation. When the producer function receives a demand pre-issued from the consumer function, the producer function begins computation. In producing a stream, the producer function does not produce every stream element by a single demand. The producer generates some fixed amount of stream elements by a single demand. After the producer function completes producing the fixed amount of stream elements, it suspends computation and waits for the subsequent demand. As a result, the stream-oriented parallel processing [17] between the producer and consumer functions can be performed within the framework of demand-driven evaluation.

In this approach, each relational operation or each inference operation is defined as a function. Several arguments of the function correspond to operand relations of an operation, and such a argument is evaluated as a stream of tuples in a relation.

To implement demand-driven evaluation, call-by-name or call-by-need is employed as a parameter passing mechanism. That is, an argument of a function is not evaluated until a reference to the argument is encountered in the execution of the function body. In call-by-name, if a formal argument is encountered more than once, the corresponding actual argument is reevaluated each time it is encountered in the function body. In this case, the actual argument can be deleted after a reference to it is completed. Therefore, if call-by-name is employed in evaluating the argument corresponding a stream of tuples, relational and inference operations can be performed within limited memory resources. However, when the same argument is encountered more than once in the function body, it must be reevaluated, that is, the function which generates the stream corresponding to the actual argument must be recomputed. We call this parameter passing mechanism "recomputation mechanism."

On the other hand, in call-by-need, a formal argument is evaluated only once when the first reference is encountered. The evaluated actual argument is used in the other references to the argument. In this parameter passing mechanism, the actual argument must be retained until every reference to it completes. If the actual argument is huge like a stream of tuples in a relation, it seems that memory could be swamped. However, recomputation of the same function is unnecessary. This mechanism is referred to as "caching mechanism"[11]. The decision of a parameter passing mechanism is important in functional computation of relational operations or inference operations, because actual arguments of functions, which are relations, are generally very large. If recomputation mechanisms are used in evaluating every argument, computations may increase drastically. On the other hand, if caching mechanisms are used, the memory overflow may cause heavy overhead. In our approach, both recomputation and caching mechanisms are supported and are used together.

2.2 Basic Primitives

Our approach to parallel processing for relational and inference operations is based on the following strategy:

(1) Each operation for processing knowledge bases is defined as a function. A query is decomposed into several function applications. The relationship between operations, that is the relationship between a producer function of a stream and a consumer function of the stream, can be decided at compile time for a query.

(2) Referential transparency is ensured among functions. A function is allocated to one of the multiple processors connected to a communication network. As a result, parallelisms based on demand-driven evaluation are exploited among functions. Independent functions are evaluated in parallel. Furthermore, stream-oriented parallelism between a producer function of a stream and a consumer function of the stream is also exploited under demand-driven control. If another function is called in the function during computation of the function body, it can be allocated to another processor and these functions can be executed in parallel within the framework of demand-driven evaluation.

(3) An individual function is compiled so as to maximally extract the ability of the processor architecture to which the function is allocated. If a sequential processor is used to compute the individual function, the function is compiled into the sequential object codes. For example, if data-driven-processor is used to compute the individual function, the function is compiled into single-assignment codes.

In this subsection, the basic primitives for realizing demand-driven evaluation and for realizing function application are presented. The basic primitives are implemented at the architecture level of each processor in the relational database machine shown in Section 4.

channel(type, granularity, parameter_passing_method)

The primitive "channel" specifies a channel between a producer function instance of a stream and a consumer function instance of the stream. This primitive returns the identifier "cid" of the channel as a return value. The channel is used to communicate a stream between two function instances. The channel corresponds to a buffer which stores elements of a stream. As the properties of a channel, "type," "granularity" and "parameter_passing_method" are specified. Here, "type" indicates the data type of an element of a stream, and "granularity" indicates a amount of data transferred by a single demand. The buffer size of the channel is decided according to granularity. And, "parameter_passing_method" indicates "recomputation" or "caching" alternatively as the parameter-passing mechanism for a formal argument corresponding to a stream.

new(f, pid, cid, parameters)

This primitive creates a function instance of a function specified by "f." Here, "pid" is the identifier of the processor to which the function instance is allocated, and "cid" indicates the output channel for the stream returned from the function instance. The formal arguments (arguments of input streams and the other arguments) of the function are specified in "parameters." The function instance does not begin computation until a demand is issued to it from the consumer function of its output stream.

When a query is decomposed into relational operations or inference operations, function instances corresponding to those operations are created by using the primitive "new" and they are connected to channels by using the primitive "channel." When a function instance requires to call another function or the function itself (recursive call) during the execution of the function body, these primitives are specified in the definition of the function body.

pre-demand(cid)

This primitive is used to issue a first demand from a consumer function of a stream to the producer function of the stream. The channel for passing stream elements is indicated as "cid." This primitive is one of the basic primitives which implement demand-driven evaluation. By pre-issuing a first demand, the producer function can begin computation eagerly. As a result, parallelism is exploited between the consumer function and the producer function.

get1(cid)

This primitive accesses an element of a stream in the buffer of the input channel indicated by "cid" and returns the element as the return value. If the buffer is vacant, this primitive issues a demand to the producer function of the stream, then waits until the buffer is refilled with stream elements. Each element is deleted from a buffer once it is accessed by this primitive.

get2(cid)

When this primitive is used, the double buffering mechanism must be supported in the channel indicated by "cid." While the producer function stores stream elements in one area of the buffer, the consumer function can access a stream element stored in the other area by using this primitive. When one area of the buffer is vacant, this primitive pre-issues a demand to the producer function to have the area refilled. Then, it begins to access a stream element in the other area. Each element is deleted from a buffer once it is accessed by this primitive.

put1(d)

This primitive stores a stream element, which is indicated by "d," as a return value of a function in the buffer of the output channel. When the buffer is filled with stream elements, that is, when the amount of data indicated as granularity is generated, the execution of this primitive is suspended until the subsequent demand arrives.

put2(d)

When this primitive is used, the double buffering mechanism must be supported in the output channel. While the consumer function accesses a stream element stored in one area by using the primitive "get2(cid)," the producer function can simultaneously stores a stream element indicated by "d" as a return value in the other area of the buffer by the primitive put2(d). When the area of the buffer is filled with stream elements and when the subsequent demand is received, this primitive begins to store a stream element in the other area of the buffer. Otherwise, it waits until the subsequent demand is received.

The primitives "get1(cid)" and "put1(d)" are used when two function instances which communicate via the channel "cid" are allocated to the same processor. On the other hand, the primitives "get2(cid)" and "put2(d)" are used when two function instances which communicate via the channel "cid" are allocated to different processors. When "get2" and "put2" are used between two function instances, the stream-oriented parallelism is exploited between these function instances.

If another function is called in the function body, a new function instance is created by using the primitive "new" in the function body. Furthermore, new channels are specified by using the primitive "channel" to pass streams as actual arguments and to receive a stream as a return value . In this case, the stream elements are passed to the new instance via channel "cid" by primitive **"send1(cid)"** or **"send2(cid)."** The primitives "send1" and "send2" are used as "put1" and "put2," respectively. However, in "send1" and "send2," the channel identifier ("cid") is explicitly specified to pass stream elements to the new function instance. The output stream of the new function instance, that is the return value, is received by a primitive **"receive1(cid)"** or **"receive2(cid)."** The primitives "receive1(cid)" and "receive2(cid)" are used as "get1" and "get2," respectively.

mark_end_of_stream()
This primitive writes "EOS" into the end of an output stream as an identifier indicating the end of the stream.

check_end_of_stream(cid)
This primitive detects the end ("EOS") of a stream. It returns a logical value "TRUE" if the end of the stream is detected. Otherwise, it returns "FALSE."

2.3 Functional Computation

The amount of data propagated by a single demand is referred to as "granularity." As described in 2.2, granularity is indicated as a property of the channel. When a relational operation is described as a function, three kinds of granularity can be specified as follows:

(1) tuple-level granularity
(2) page-level granularity
(3) relation-level granularity

In tuple-level granularity, although the size of the buffer between the producer and the consumer can be minimized, many demands may be issued to the producer function. This may cause heavy communication overheads [3]. In relation-level granularity, the whole intermediate data, that is the complete intermediate relation, is produced by a single demand. In this granularity, the buffer of a channel is required to store the whole intermediate relation. Furthermore, the stream-oriented parallelism between producer and the consumer functions is not exploited.

In each granularity, it can be specified whether stream-oriented parallel processing is performed between the producer function and the consumer function. When a formal argument corresponding to a stream is encountered more than once in a function body, one of the parameter passing mechanisms ("recomputation" or "caching") is indicated as the property of the channel.

In the following, several function definitions of relational operations are presented. The following programs abstractly show compiled object codes of functions by using the notation of the C language. In our approach, if a sequential processor is used to execute a function, the function is compiled into sequential object codes including basic primitives. The basic primitives are implemented at the architecture level in the processor.

(1) page-level granularity without stream-oriented parallelism

Stream elements (tuples of a relation) can be transferred via the limited size of buffer. The size of buffer is referred to as "granularity" and it is equal to the "page size." When the program of a function "selection" receives a demand from another function, "get1(cid)" issues a demand to the producer function of a stream, and then waits for a page of stream elements. When the page of stream elements is stored in the input buffer, the "selection" function begins to compute the selection operation and stores the resulting elements in the output buffer of the output channel by the primitive "put1(d)" until the output buffer is filled. In this case, according to granularity, several demands are issued to the function producing the stream elements.

Program 1

```
define_function selection(relation, a)
stream relation;
item a;
{
    tuple tu;
    while (!check_end_of_stream(relation)) {
         tu = get1(relation);
         if (selection_test(tu, a))
              put1(tu);
    }
    mark_end_of_stream();
}
c1 = channel(tuples, INPUT_BUFFER_SIZE,
            RECOMPUTATION or CACHING);
/* specification of channel for output stream */
c2 = channel(tuples, OUTPUT_BUFFER_SIZE,
            RECOMPUTATION OR CACHING);
/* specification of channel for input stream */
new(selection, pid, c2, c1, a);
/* creation of function instance */
```

(2) page-level granularity with stream-oriented parallelism

In demand-driven evaluation, a demand is issued to the producer function when the actual argument is encountered. However, in order to perform stream-oriented parallel processing between consumer and the producer functions, the demand must be pre-issued from the consumer function to producer function. It is achieved by using the primitives as shown Program 2. In the function "selection," the primitive "pre-demand" pre-issues a first demand to the producer function of the input stream, and then the execution of the selection operation begins. At the same time, the producer function begins function computation by the pre-issued demand, and stores a resulting page into the output buffer. In function "selection," a demand is pre-issued again to the producer function by the primitive "get2(cid)," and begins computing the selection operation to the page. As the result of the pre-issued demand, the page is stored by the primitive "put2(d)" in the producer function.

In this function, demands are always pre-issued by "pre-demand" or "get2(cid)." This stream-oriented parallelism is exploited by supporting the double buffering mechanism in the buffer of a channel between the consumer function and the producer function of its actual argument.

Program 2

```
define_function selection(relation, a)
stream relation;
item a;
{
    tuple tu;
    pre-demand(relation); /* pre-issuing a demand */
    while (!check_end_of_stream(relation)) {
         tu = get2(relation);
         if (selection_test(tu, a))
              put2(tu);
    }
    mark_end_of_stream();
}
c1 = channel(tuple, INPUT_BUFFER_SIZE,
            RECOMPUTATION or CACHING);
c2 = channel(tuple, OUTPUT_BUFFER_SIZE,
            RECOMPUTATION or CACHING);
new(selection, pid, c2, c1, a);
```

(3) page-level granularity with stream-oriented parallelism (Several references to same argument are encountered.)

In the function "selection," a reference to the input stream is encountered only once. When references to the input stream are encountered more than once in a function body, it is required to reproduce the same stream by recomputation or to retain the whole stream by caching. For example, binary relational operations, such as the join or union operations, require to refer to the same input stream (the stream of the inner relation) more than once [17]. Therefore, recomputation or caching is specified alternatively as the property of a channel. In the case of recomputation, function computation can be performed within the limited memory resource. In the case of caching, the retained stream data may cause memory overflow. The function "join" is shown in Program 3. In this function, tuples in the outer-relation page are sorted on the joining attribute, and then each tuple in the inner-relation page is joined with tuples of the outer-relation page by using binary search algorithm.

Program 3

```
define_function join(relation_1, relation_2,pagesize)
stream relation_1; /* stream of outer-relation */
stream relation_2; /* stream of inner-relation */
int pagesize;      /* size of outer-relation page */
{
   tuple in1[pagesize], in2;
   int i;
   pre-demand(relation_1);
   pre-demand(relation_2);
   while (!check_end_of_stream(relation_1)) {
     for (i = 0; (i < pagesize) &&
           !check_end_of_stream(relation_1); i++)
           in1[i] = get2(relation_1);
      sort(in1); /* sorting of outer-relation page */
          while (!check_end_of_stream(relation_2)) {
           in2 = get2(relation_2);
           if (!check_end_of_stream(relation_1) &&
               check_end_of_stream(relation_2))
              /* pre-issuing a demand to request
              re-reference to the stream of
              inner-relation */
             pre-demand(relation_2);
                if (binary_search(in1, in2))
                 put2(concatenate(in1, in2));
                /* comparing an inner-relation tuple
                   (in2) with outer-relation tuples
                   (in1) by binary search algorithm */
                /* concatenating tuples if joining
                   condition is satisfied */
          }
       }
       mark_end_of_stream();
}

c1 = channel(tuple, BUFFER_SIZE_1,
               RECOMPUTATION or CACHING);
/* channel for input stream of outer-relation */
c2 = channel(tuple, BUFFER_SIZE_2,
            RECOMPUTATION or CACHING);
/* channel for input stream of inner-relation */
c3 = channel(tuple, OUTPUT_BUFFER_SIZE,
            RECOMPUTATION or CACHING);
/* channnel for output stream */
new(join, pid, c3, c1, c2, BUFFER_SIZE_1);
```

(4) relation-level granularity

When the producer function is required to be reduced completely by a single demand, "complete_reduction" is specified as granularity. In this granularity, operand source relations or intermediate relations may overflow the limited size of buffer. Furthermore, stream-oriented parallelism is not exploited between producer and consumer functions. To realize relation-level granularity, the function "selection" shown in Program 2 is used, and "complete_reduction" is specified as granularity in the primitive "channel" as follows:

```
c1 = channel(tuple, COMPLETE_REDUCTION, RECOMPUTATION
or CACHING);
c2 = channel(tuple, COMPLETE_REDUCTION, RECOMPUTATION
or CACHING);
new(selection, pid, c2, c1, a);
```

3. Relational Operations and Inference Operations

Functional programming concepts can be applied to various kinds of applications. In this section, we discuss an approach to processing relational and inference operations in knowledge base systems. A basic algorithm of stream-oriented parallel processing for relational operations is discussed in [17] in detail. In this section, the algorithm for relational operations is briefly reviewed, and the stream-oriented algorithm for inference operations is presented.

3.1 Relational Operations

When a function of a relational operation receives a demand from the consumer function, it begins accessing tuples in its input buffer, then executes the relational operation until it completes the production of one resulting page of tuples in the output buffer. The output buffer is then regarded as the input buffer for the consumer function. An individual function instance of a relational operation is not required to create a whole intermediate relation by a single demand. Each function instance creates only one page of tuples specified as granularity. Individual buffers do not require the capacity to store an entire intermediate relation. In this algorithm, if a producer function and a consumer function are allocated to different processors, it is assumed that the double buffering mechanism is supported in every buffer. That is, while the consumer function gets tuples in one area of its input buffer, the producer function can store tuples in the other area of the same buffer at the same time.

Just before a consumer function begins accessing tuples in one of two areas of its input buffer, it pre-issues a demand to the producer function to make the other area of the input buffer refilled with the subsequent page.

As a result, stream-oriented parallel processing is performed between the producer and consumer functions. By using demand-driven evaluation, unary relational operations (the selection, restriction and projection operations), and binary relational operations (the join, union, intersection, difference and Cartesian-product operations) can be concurrently executed within a limited memory resource environment. In particular, this algorithm shows attractive advantages in executing the join, union and Cartesian-product operations, which are the most time-consuming and the most memory-consuming operations.

3.2 Inference Operations

The combination of logic programming concepts with relational databases often appears as a promising approach to knowledge base processing [6],[18]. In our approach, sets of Horn clauses are combined with relational databases. Inference operations based on unification are executed within the framework of functional programming concepts.

Three ways to combine logic programming concepts with relational databases can be considered as follows:

(1) A logic program is used as a high-level query for a relational database system. In this way, a query written in a logic program is translated into a sequence of relational operations (relational database operations), and the sequence of relational operations are executed by a relational database operation system.

(2) Relations in a relational data base are regarded as sets of Horn clauses. An inference system operates unification for relations. That is, the relational database is regarded as a part of sets of Horn clauses, and inference operations are executed in relational databases. Such a database is generally referred to as a deductive database [6]. A relation is regarded not only as a set of tuples but also as a set of fact clauses. The relational database is regarded as the collection of relations and the collection is defined as the extensional database [6]. Relations are used to store fact clauses, and rule clauses are referred to as the intensional database [6]. That is, fact clauses are distinguished from rule clauses, and they are stored as relations. That is, elementary information is classified into rules and facts. Sets of facts are represented explicitly as a relational database.

(3) As in (2), a relational database is also used to represent logic programs. However, not only a fact clause but also a rule clause are represented as a tuple [22]. Inference operations are executed in a relational database with the rule and fact clauses. This way is effective when the rule base is huge. This is because the rule base can be managed within the framework of the relational database management.

We realize two ways of (1) and (2). That of (3) is not supported. Usually, the size of a fact base determines the number of concurrent activities that can be carried out by the parallel machine. Hence, ways (1) and (2) are oriented toward knowledge base management applications.

In way (1), a query described in a logic program is translated into a sequence of relational operations. The sequence is executed by using the parallel processing scheme based on the functional programming concepts as described in Subsection 3.1.

To support way (2), the mechanism for executing unification of a goal clause with fact clauses is also implemented on the basis of functional programming concepts. The resolutions for rule clauses are performed by a rule reduction system. A query represented as a goal is reduced into AND-literals. Each AND-literal is referred to as a subgoal. A goal is reduced into AND-literals in the rule reduction system until each subgoal requires to be unified with fact clauses. A set of fact clauses are represented as a relation. A predicate name of a fact clause corresponds to a relation name. The facts which have the same predicate name are represented as a set of tuples in a relation. AND-literals reduced from the goal clause are unified with fact clauses in relations. AND-literals can be processed independently as long as no variables are shared among literals. As a result, AND-parallelism is exploited. Between AND-literals sharing free variables, binding environments of variable/value are transferred in the form of a stream.

In our approach, each AND-literal inputs a binding environment and returns a new binding environments as presented in [7] and [8]. In [7] and [8], binding environments are propagated within the framework of the data-driven evaluation. In [7], the eager and lazy evaluations are used to control the stream of binding environments. In our approach, demand-driven evaluation is used for processing fact clauses. The process of solving each literal in AND-literals is regarded as a function that returns a stream of binding environments. Each binding environment represents an alternative solution to the goal clause. Like relational operations, inference operations for a relational database are also performed on the basis of functional programming concepts. If AND-literals are sharing free variables, the input and output of binding environments among those AND-literals are performed using the stream-oriented scheme based on demand-driven evaluation.

For example, a goal clause " <- L1,L2,L3 " is constructed as three function nodes. The output of a function node is served as the input to another. It is clear that the activation of a literal does not have to wait for complete intermediate solutions to be generated by execution of the preceding function node. Therefore, stream-oriented parallel processing can be performed among these functions. In each function node, a literal is unified with fact clauses in a corresponding relation. Each function node is executed on the basis of demand-driven evaluation by using the following algorithm.

(1) When an inference function node receives a

demand from the consumer node, it repeatedly executes (2) and (3) until one page of new binding environments is created and stored in the output buffer.

(2) A single page of binding environments is accessed in one area of the input buffer. At this time, the other area of the input buffer becomes available and a demand is pre-issued to the producer node to refill the area with the subsequent page. As a result, stream-oriented parallel processing is performed between this node and the producer node.

(3) The search and unification to fact clauses represented in the operand relation are executed using the binding environments in the page that has just been accessed in (2), and new binding environments are created and stored in the output buffer. If the output buffer is filled with a page of new binding environments, execution is suspended and the node waits for the next demand from the consumer node, otherwise, (2) and (3) are executed repeatedly. If the page being manipulated is the last one of the binding environments served by the producer node, the execution of this inference node is terminated.

4. System Architecture

In this section, a relational database machine architecture based on functional programming concepts is presented. In this architecture, a sequential processor is used for computing an individual function. The overview of the multiprocessor architecture is shown in Fig. 1. Each processor (RKU or QRU) supports the basic primitives defined in Section 2. The processor includes an internal memory, and the processors are connected via a high-speed interconnection network. The relations in the database are distributedly stored in disk devices. The disk devices are connected to the processors via Staging Buffers. The three-level memory hierarchy employed in this architecture. As discussed in [9], [12], [13], [15] or [19], the three-level memory hierarchy is effective in manipulating relational operations.

Although a sequential processor is currently used to compute an individual function, advanced processors as discussed in [14] and [15] can be attached to each processor in future.

The total internal memory of each processor is not large enough to store a whole source relation or a whole intermediate relation in general. In this architecture, an operand source relation is staged up into a staging buffer as a stream of tuples, using the demand-driven evaluation.

The system consists of the following components:

QRU : QRU decomposes a query into a sequence of relational operations or into a goal clause which consists of AND-literals. QRU is regarded as a rule reduction system. In manipulating a query as a goal clause, the query is reduced into AND-literals until each literal requires to be unified with fact clauses. A query is reduced by unifying with rule clauses in the rule base. QRU allocates each relational or inference operation as a function instance to one of RKU's, and specifies the channels between function instances.

RKU : RKU's carry out relational operations and inference operations on the basis of functional programming concepts. Each RKU supports the basic primitives for realizing demand-driven evaluation and function application, and executes relational or inference operations as functions discussed in Sections 2 and 3. One or more operations can be allocated to each RKU by QRU. If several operations are allocated to a single RKU, they are executed as coroutines within the framework of demand-driven evaluation. This allocation enables the machine to execute a query within the limited number of processors. The execution sequence of the operations allocated to a single RKU is controlled by a scheduler. The scheduler gives control to one of the operations, when the operation has already received a demand and its operand pages have already been prepared in the internal memory. The function node to which control is given executes the operation to the data in the input buffer until the output buffer is filled (put-wait) or the operation to the data stored in the input buffer completes (get-wait). Then, the node suspends execution of function computation and returns control to the scheduler.

Communication Network : Stream data (the sequence of tuples or the sequence of binding environments) and demands are transferred via the Communication Network. Information for allocating function instances and for specifying the channels among function instances is also transferred between QRU and RKU's. The transfers of stream data and demands between processors are managed by Communication Processing Units connected to every processor.

Data Staging Network : Source relations are transferred from disk devices to Staging Buffers via the Data Staging Network. A source relation is stored to

one of the Staging Buffers which is connected to a single RKU. This network supports the allocation of source operand relations to the staging buffer.

5. Experimental Implementation

For simulation experiments of the relational database machine, we have implemented the basic primitives in software, and have developed a relational operation system as described in Sections 2 and 3 on the Sun-2 workstation [23]. Although this system is currently running on a single processor, it can simulate parallel processing environments based on demand-driven evaluation. Each relational operation is defined as a function and executed within the framework of demand-driven evaluation. In this section, experimental results of query execution are shown. The relational operation system can realize various environments of demand-driven evaluation.

5.1 Environments of the Experiment

The query chosen for presenting several environments of demand-driven evaluation is shown in Fig. 2. The query includes four selection operations, three join operations and a projection operation. The cardinality (the number of tuples) of each relation, the tuple length, selection selectivity factors and join selectivity factors are set as shown in Table 1. It is assumed that five processors (RKU's) are used to execute the query. Relational operations are allocated to processors as shown in Fig 2.

The following environments are assumed in the experiments.

(1) The transfer of stream elements is exclusively performed between two processors. While two processors are communicating via the Communication Network, no other processors can use it. The transfer of demands can be simultaneously performed among every processors. The data transfer rate is set to 16.6 milliseconds for a 2k-byte data.

(2) The elements of a stream corresponding to each source operand relation have been already stored in Staging Buffers. Tuples of a source relation are staged up to the Staging Buffer as a stream. Each operand relation is stored in the Staging Buffer connected to the processor which manipulates the operand relation.

5.2 Experimental Results

The query was executed in four environments shown in Table 2. These environments are realized by using basic primitives and by specifying the properties of channels as discussed in Section 2. Experimental results of Environment-1, Environment-2, Environment-3 and Environment-4 are shown in the time charts in Fig. 3, Fig. 4, Fig. 5, and Fig.6, respectively.

In Environment-1, stream-oriented parallelism is not exploited. On the other hand, in Environment-2, parallelism is exploited and performance of query processing is improved. In Environment-3, recomputation is performed in node-7 of the selection operation. In this environment, although recomputation causes heavy overhead, it enables the relational operation system to perform a query even in a case where the whole relation to be processed is not stored in the internal memory of the processor. In comparing Environment-2 with Environment-4, parallelism in Environment-2 is higher than that in Environment-4. In Environment-4, since the relation-level granularity is employed, the stream-oriented parallelism is not exploited. However, the parallelism is exploited by evaluating formal arguments of a function in parallel.

Response times were measured by varying granularity settings in Environment-2 as shown in Fig. 7. In this experiment, only the sizes of inner relation pages in executing the join operations are varied, and the granularity for streams of outer relations is set to the relation-level granularity. The granularity is set to the same value in every join operation in a query. For small granularity, response time is long. This is because demands are issued many times and the number of communication times of stream data increases in the small granularity case. For large granularity, the response time is long.

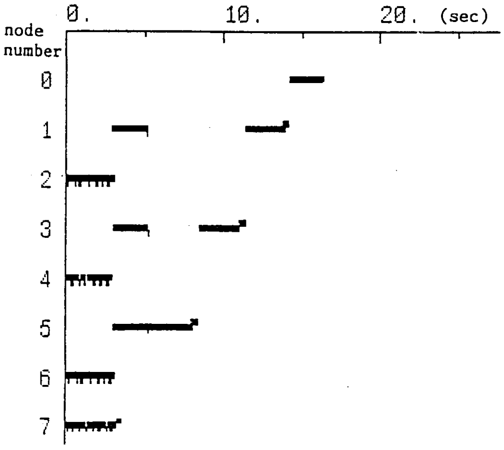

Fig. 6 Time chart (Environment-4)

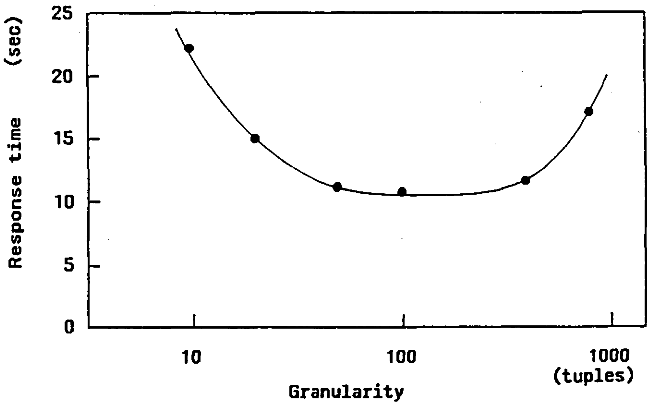

Fig. 7 Response time in various granularity settings

This is because stream-oriented parallelism is not exploited. In the case of large granularity, larger memory space is required in order to store a larger page. Optimal granularity is dependent not only on hardware performance, such as communication speed of the Communication Network, the size of available memory space or processing power of each processor, but also on contents of manipulated data. The proper page-level granularity exploits the highly parallelism within a limited memory resource environment.

5. Conclusions

We have presented a novel approach to a relational database machine for processing knowledge bases. The principle purpose of the approach is to concurrently perform both relational operations and inference operations within the limited resource environment in knowledge base systems. This approach is based on functional programming concepts in order to manage computer resources with the theoretical neatness of functional computation. By using demand-driven evaluation as a driving method of the functional computation, parallelism can be exploited in knowledge base processing. In this paper, we have defined the basic primitives which are used to implement demand-driven evaluation and function application. We have also presented a basic algorithm and a system architecture for executing relational and inference operations by using a demand-driven evaluation mechanism.

In this paper, we have also discussed how the relational database concepts are combined with logic programming concepts. For processing a set of fact clauses, we have presented an algorithm based on stream-oriented parallel processing.

We have developed the relational operation system based on the proposed approach. Currently, we are designing the inference operation system for fact clauses, and also designing the architecture in more detail.

ABSTRACT

We have developed a knowledge-based expert system for hardware logic design that designs CMOS circuits from a concurrent algorithm written in the occam *high-level programming language. This work was done as part of the activities of the Fifth Generation Computer Systems (FGCS) Project of Japan. Our system aims at supporting the entire design process from a specification to completed CMOS circuits by incorporating the designers' expertise into the computer and utilizing it effectively. Prolog was selected as the implementation/knowledge-representation language. This paper gives examples of the knowledge provided for this system, emphasizing the functional design phase which is heavily dependent on the designers' expertise. This paper also describes how Prolog was used to express this knowledge, and how the inference engine was created. While constructing this system, we also evaluated the effectiveness of Prolog as the implementation language for a new generation of CAD systems.*

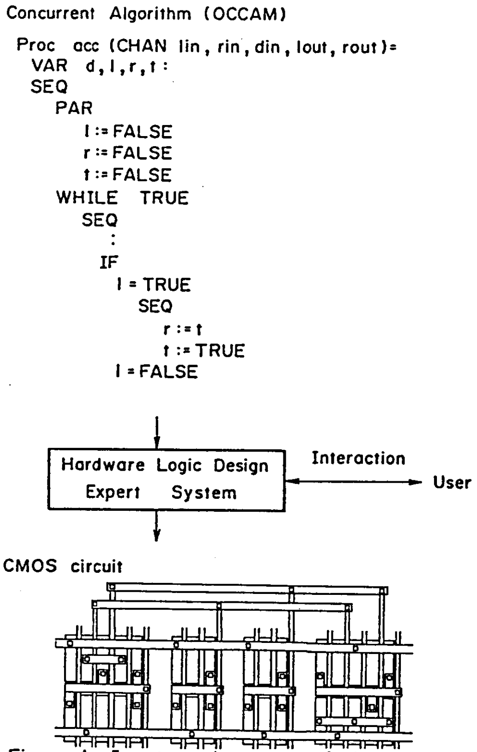
1. INTRODUCTION

The *FGCS* Project has been concerned with research into knowledge-based systems. We chose hardware logic design as an application for the following three reasons. First, the application must be an area in which human expertise plays a significant role. At present, reliable and efficient hardware logic design can only be done by skilled designers. Therefore, this area is a suitable testing ground for the use of expert knowledge. Secondly, because hardware logic design is synthesis-oriented, which is quite unlike any successfully developed analysis-oriented system such as MYCIN, there are many unknown factors to investigate. Lastly, since much must be considered in hardware logic design, a wide range of knowledge is required.

The implementation language is Prolog, which is also used as the underlying knowledge-representation language. Knowledge representation is an important issue. Hardware logic design employs various areas of knowledge, and design data must be represented as well. In addition, human designers switch from one representation to another in the course of their work. For these reasons, we have not adopted any particular existing tool for knowledge representation.

2. SYSTEM OVERVIEW

Our system aims at supporting the entire design process from a specification to completed CMOS circuits by incorporating the designers' expertise into the computer [1][2][3]. This system designs CMOS circuits that conform to the input specification through the interaction with the user, as shown in Figure 1. The input specification is a concurrent algorithm described in occam[4] which is a programming language characterized by its treatment of concurrency. The input specification is based on software concepts, such as variables and procedure calls, but not hardware concepts, such as registers and clocks. Therefore, with occam, a designer can create a concurrent algorithm without being familiar with hardware details.



Concurrent Algorithm (OCCAM)

```
Proc acc (CHAN lin, rin, din, lout, rout)=
  VAR d,l,r,t :
  SEQ
    PAR
      l := FALSE
      r := FALSE
      t := FALSE
    WHILE TRUE
      SEQ
       :
        IF
          l = TRUE
            SEQ
              r := t
              t := TRUE
          l = FALSE
```

Figure 1. Input and output of the system

CH2345-7/86/0000/0979$01.00 © 1986 IEEE

Given a concurrent algorithm, the system performs functional design using designer's expertise and interacting with the user to determine the hardware behavior. The hardware concepts, such as registers and clocks, first emerge in this intermediate design stage. Next, the system designs CMOS circuits to achieve the hardware behavior determined by the functional design process. The system outputs the CMOS cells in the library and CMOS functional cells, and their connections. Another program should be used for placement and routing of these cells on a chip.

Our system consists of a functional design phase and a circuit design phase, as shown in Figure 2. Because the system is divided into these two phases, the system is able to flexibly cope with different semiconductor technologies. The functional design phase, the first half of the design process, determines the application of hardware concepts in the implementation of a concurrent algorithm in **occam**, and produces the finite-state machine description in DDL[5] using designers' expertise related to the functional design for hardware. Although hardware behavior is determined at this step, it is independent of the semiconductor technology being employed. The circuit design phase, the second half of the design process, transforms the finite-state description into the desired CMOS circuits. To achieve this, the translator subsystem extracts and rearranges information required for the circuit design from DDL. The functional cell design subsystem designs combinational circuits, and the functional block design subsystem allocates cells in the library to functional blocks such as registers and memories. In the circuit design phase, technology-dependent knowledge related to circuit synthesis is used.

3. DESIGN EXAMPLE

This section discusses how the system works, taking a pattern matcher proposed by M.J.Foster and H.T.Kung[6], as an example. Figures 3 and 4 show the outline of the pattern matcher. This pattern matcher checks whether a given pattern, which is a fixed length vector of characters, is embedded in a given text string, which is an endless string of characters, as shown in Figure 3.

Let us denote the input string stream as $s_0s_1s_2\ldots$, the input finite pattern stream as $p_0p_1p_2\ldots p_k$, and the output result stream as $r_0r_1r_2\ldots$. Characters in the two input streams may be compared for equality, with the wild card character X matching any character in an input stream. The output bit r_i is to be set to 1 if the substring $s_{i-k}s_{i-k+1}\ldots s_i$ matches the pattern, and 0 otherwise. For example, in Figure 4 the pattern AXC matches substrings $s_0s_1s_2$, $s_3s_4s_5$, and $s_4s_5s_6$ (ABC, AAC, and ACC, respectively).

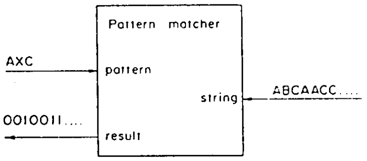

Figure 3. Data to and from the pattern matcher

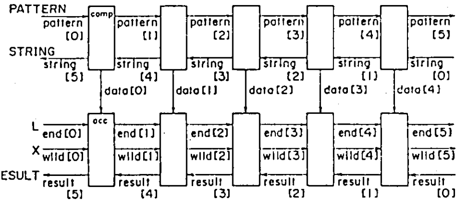

Figure 4. Dataflow of the pattern matcher

3.1 Design Specification

The concurrent algorithm of the pattern matcher, which is input to this system, is described in **occam**, as shown in Figure 6.

The **occam** program consists of three declaration parts, (A),(B), and (C), and a description of parallel processes, (D). The declaration parts are as follows.

(A) declares channel vectors. A channel vector is a set of channels, these being used for communication between concurrent processes. For example, pattern[6] means that there are six channels named pattern, and they are numbered from 0 to 5, as shown in Figure 4.

(B) declares a single comparator process. PROC gives the name *comp* to this process, and identifies five formal parameters, the internal channels, *pin*, *sin*, *pout*, *sout*, and *dout*, as shown in Figure 5. When the named process is substituted for the subsequent process (D), the formal parameters are replaced by the actual parameters. Process *comp* is a sequential process, which consists of two processes. One is the initialization (B-1), and the other is an endless

Figure 6. Algorithm for the pattern matcher in OCCAM

iterative process, WHILE TRUE. The iterative process contains a sequential process, which consists of two processes. The first two are output and input processes (B-2). The last process compares the characters in the pattern with those in the text string and outputs a Boolean value, TRUE or FALSE (B-3).

(C) declares a single accumulator process. The process named *acc* contains seven formal parameters, as shown in Figure 5. The variable *d* stands for the current comparison result of the comparator, *xnew* and *xold* for the don't care bit, *lnew* and *lold* for end of pattern, *rnew* and *rold* for final result of matching, and *t* for temporary result of matching. Process *acc* is a sequential process, which consists of two processes. One is the initialization of variables (C-1). The other is an iterative process, similar to process *comp*. The iterative process includes a sequential process, which consists of two processes. The first includes output and input processes (C-2). The second is a conditional process (C-3). When the end of pattern is reached, an accumulator uses the value *t* (current temporary result) as the final result, and then resets *t* to TRUE. Otherwise, it maintains a temporary result *t*, which is set by the logical expression $t := t \wedge (xnew \vee d)$. $\wedge$ and $\vee$ stand for boolean AND and OR, respectively. Thus if the current temporary result *t* is TRUE, and *xnew* or the current comparison result *d* is TRUE, then the new temporary result will be set to TRUE.

(D) indicates a 2x5 array of concurrent processes, as shown in Figure 4. The cells at the top are the comparators; the pattern flows from left to right and the string flows from right to left. The bottom cells, accumulators, receive the results of the comparison from above. They maintain partial results, and shift completed results from right to left. Two bits associated with the pattern flow through the accumulators from left to right. One bit is the end of pattern, L . The other is the wild card character, X.

3.2 Functional Design Phase

In the functional design phase, the finite-state machine description in DDL is produced from a given concurrent algorithm. Functional design can be thought of as that phase of the design that determines which hardware concepts to apply to the implementation of the concurrent algorithm and describes how the hardware should behave. This phase is one of the most knowledge-intensive parts, and its performance depends heavily on the knowledge which is used. This phase continues with the following procedures through the interaction with the user, as shown in Figure 7.

(1) Analysis of the structure of the occam specification. Taking the concurrent descriptions into account, it analyzes the occam construct(WHILE, SEQ, IF, etc.) and creates an outline of the hardware control mechanism (state transitions).

(2) Implementation of variables described in occam, using hardware elements(registers, terminals, etc.). Because the occam specification does not provide information about the number of required bits, the system queries the user. However, the system automatically infers that the number of bits for a variable is one if all of its sources turn out to be Boolean values ("TRUE","FALSE", or the evaluation of a logical expression).

(3) Compression of the operation sequences. This is an

Figure 8. Final DDL description

attempt to transform some occam sequential processes into DDL register transfer operations executed in parallel, which improves the performance of the generated hardware.

(4) Implementation of the communication between processes described in occam("?" for inputting a value from a channel, "!" for outputting a value to a channel). Basically the communication is implemented by hand shaking. Signal lines through which data is transferred and signal lines used for synchronization are provided.

After implementing occam primitive operations as DDL hardware operations and generating partial DDL descriptions, the system puts these partial descriptions together to complete the final DDL description, as shown in Figure 8.

3.3 Circuit Design Phase

The translator subsystem transforms the DDL finite-state machine description into information to be used by the circuit design process. It gathers and edits conditions for terminal connection, register transfer, and state transition operations. Then the translator subsystem organizes the data in frame-like structures, classified into twelve categories: system, clock, automaton, input signal, output signal, terminal, memory, register, state, decoder, arithmetic expression, and logical expression.

The DDL code shown in Figure 8 contains three register transfer operations of register "r" in automaton "acc". These operations provide the following information:

1) $| * \ acc\_init \ * | \quad r \leftarrow 0.$

2) $| * \ acc\_idle \ \& \ send1 \ * | \quad r \leftarrow rin.$

3) $| * \ acc\_state1 \ \& \ l \ * | \quad r \leftarrow t.$

where the states whose identifiers are modified by "acc" belong to the automaton "acc". "| * * | ..." stands for an if-clause. Based on the above information, the input circuit of register "r" is designed, as shown in Figure 9.

The automaton design subsystem implements automata having the appropriate states using flip-flops. It designs a control circuit around these flip-flops according to information on state transitions provided by the translator subsystem. Figure 10 shows the resulting circuit design for a pattern matcher that consists of a pair of the comparator and the accumulator.

The size of a combinational circuit that can be created using a single CMOS cell is limited by CMOS technology. Signal delay depends mainly on the number of FETs inserted in series between the power supply line and output line. Therefore, the circuit decomposition subsystem decomposes the combinational circuits so that the number of FETs in series does not exceed the limit imposed by signal delay considerations. The combinational circuit around register "r" is decomposed into four parts as shown in Figure 9.

The functional cell design subsystem implements the decomposed combinational circuits as functional CMOS cells. The optimal layouts of the functional CMOS cells are obtained by a heuristic algorithm[7]. However, if the designer is required to use NAND or NOR gates, then the partial combinational circuit (iv) in Figure 9 results in mediocrity as shown in Figure 11(a). In this case, we take advantage of the property of CMOS functional cells that physically adjacent gates can be connected by a diffusion area. As a result, the optimal layout is obtained as shown

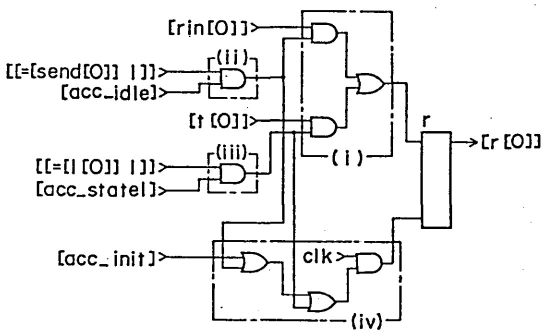

Figure 9. Input circuit of register r

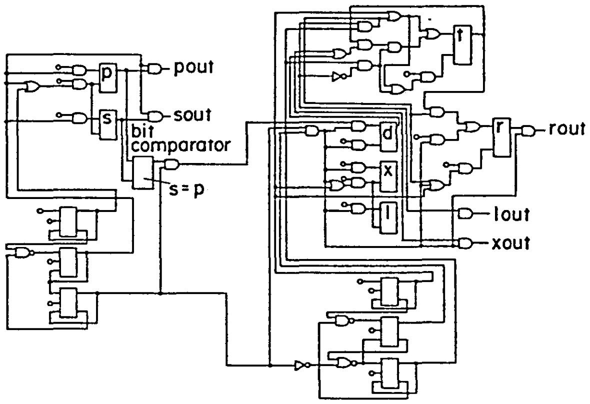

Figure 10. Logic diagram of pattern matcher

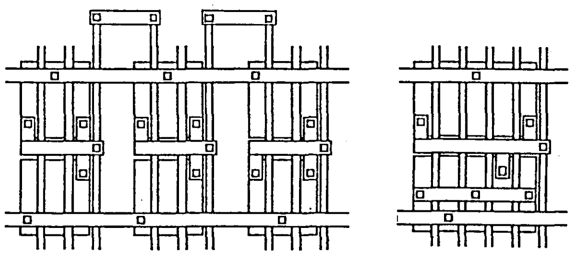

(a) NAND gates (b) Functional cell

Figure 11. Implementation of the circuit (iv) in Figure 9.

in Figure 11(b). Note that the optimal array is almost 50% smaller than the basic conventional array.

The functional block subsystem allocates cells in the library to functional blocks, such as registers, memories, decoders, and adders. Since functional cells and cells in the library are of the same height and have the same power connections and standardized connection points, they can be laid out by an existing physical design CAD system.

4. INFERENCE MECHANISM AND KNOWLEDGE

The functional design is heavily dependent on the designers' own expertise. It is difficult to automate the functional design by conventional algorithmic CAD techniques. We automated the functional design by incorporating the designers' expertise into the computer.

This section discusses how the inference mechanisms were created and gives examples of the designer's expertise provided for the functional design phase. We also evaluate the effectiveness of Prolog as an implementation/knowledge-representation language for a knowledge-based logic design system.

4.1 Characteristics of Functional Design

We must consider several points when performing functional design by a knowledge-based approach. The designer gradually refines the design while checking the specifications and clarifying the entire circuit. At each design step, the designer evaluates the design development and makes appropriate decisions. Therefore, it is extremely important in design to always have a clear understanding of the relationship among design objects. The knowledge-representation framework should reflect this fact. A good method must be provided for referring to the relations among design objects.

Another important issue is controlling the order of design jobs. With several similar jobs, which is placed first is significant, because one job may make another job unnecessary or at least make it easier. Therefore, the implementation language should be able to easily express the control of design jobs.

4.2 Inference Mechanism

4.2.1 Forward chaining

Forward chaining is used as the basic inference mechanism. Logic design is a process of incremental refinement. Incremental refinement comes from successive design decisions; every time a decision is made, the current design development is changed. Design development is represented as the information in the working memory. Chainging the current design development is performed by updating the information in the working memory.

Forward chaining seems to be able to simulate the incremental refinement design process. When the conditions set forth by the premise section of a forward chaining rule are satisfied, the conclusion section is activated and the working memory is updated. Then another rule is activated, referring to the updated working memory. Processing continues in this manner. We use the assert(addition of fact) and retract(deletion of fact) predicates of Prolog for updating the working memory. The working memory consists of design information, which is represented by about 40 types of Prolog fact. As the design process continues, the working memory is gradually filled with design information.

Figure 12 shows the general format of the forward chaining rule. When conditions 1, ..., n are satisfied in the premise section, actions 1, ..., m are activated in the conclusion section. The working memory is updated while causing side effects by the assert and/or retract predicates.

```
(Process):-
   (Condition 1),        --------┐
        .                        |
        .                        ├-- Premise  section
                                 |
   (Condition n),        --------┘
   (Action 1),           --------┐
        .                        |
        .                        ├-- Conclusion  secion
                                 |
   (Action  m).          --------┘
```

Figure 12. General format of the forward chaining rule

```

     (Condition 1), -------┐
          :                ├-- Premise  section
     (Condition n), -------┘
```

Figure 13. General format of the backward chaining rule

4.2.2 Backward chaining

Backward chaining is used for checking various conditions. In checking the conditions set forth in the premise section of a forward chaining rule, only reference to the working memory is required in some cases. In other cases however, several inference steps are required. When a specified condition is checked, the backward chaining rule whose conclusion section matches the specified condition is fired. Then, the various conditions set forth by the premise section of the fired rule are checked. Backward chaining is already implemented as the execution mechanism of Prolog.

Figure 13 shows the general format of the backward chaining rule. The head of the Prolog clause contains the conclusion, while the body contains the premise section. When conditions 1, ..., n are satisfied in the premise section, condition 0 is concluded. In backward chaining, the invocation of rules does not affect the working memory.

4.3 Knowledge Representation

In this section, specific knowledge examples of the functional design phase are presented to show how Prolog is used to express designer's expertise. Functional design can be regarded as the process that determines hardware concepts according to specifications in occam. Thus, the knowledge used in this process primarily associates specifications described as software with hardware concepts.

4.3.1 Knowledge for implementing a variable with hardware elements

Figure 14 shows the knowledge used to implement a variable used in occam descriptions with hardware elements. This is a forward chaining rule for implementing a occam variable *Var* and states that:

IF:

(1) There exists the input sources to the *Var* from the external processes through the channel, and

(2) input sources are all Boolean values, and

(3) there exists assigned sources to the *Var*, and

(4) assigned sources are all Boolean values, and

(5) other conditions are satisfied,

THEN:

(6) Store in the working memory the information stating that variable *Var* is to be implemented as a 1 bit register.

```
implement_variable (Var,_):-
   input_source (Var, Input_sources),               ----- (1)
   truth_value (Input_sources),                     ----- (2)
   assigned_source (Var, Assigned_sources),         ----- (3)
   truth_value (Assigned_sources),                  ----- (4)
        :
        .                                           ----- (5)
   assert (implementation (Var, 1, register,...)).  ----- (6)
```

Figure 14. Knowledge for implementing a variable with hardware elements (Forward chaining rule)

This predicate is activated with the variable name used in occam as its first argument. If conditions(1)–(5) are all satisfied, fact(6), stating that *Var* must be implemented as a 1 bit register, is written into the working memory. This rule is used to implement, for example, variable t in Figure 6.

input_source(*Var*, *Input_sources*) is a procedure call. What it means becomes clearer, according to the declarative reading of Prolog clauses; it reads "input source of *Var* is *Input_sources*".

4.3.2 Knowledge for compressing sequential operations

Figure 15 shows the knowledge used to check whether the sequential operations described in occam can be transformed into hardware operations executed in parallel, which would improve the performance of the generated hardware. This is a backward chaining rule and states that:

IF:

(1)(2) Both are store-type operations such as assignment processes, and

(3) they are processed one after another, and

(4) the variables into which the sources are to be stored are different, and

(5)(6) both variables are to be implemented as registers, and

(7) the variable in the first operation is not referred to in the source of the second operation,

THEN:

two operations in a sequence are compatible, or can be executed simultaneously.

This predicate is activated with two operations in **occam** as its arguments. Backward chaining is performed as follows. The conditions *store_operation* and *implementation* are resolved only by referring to the working memory, but the condition *referred_to* activates other rules. When conditions (1)–(7) are all satisfied, the compatibility check is successful.

Using this rule, the **occam** sequential process within the dashed box in Figure 6 is compressed into parallel register transfer operations in DDL, shown within the dashed box in Figure 8. Here, it is noted that the variables *rold* and *rnew* are implemented as a single register r, using the knowledge related to merging two registers into one.

The rule "*compatible*" expresses the relationship between two operations, and Prolog predicates provide a natural means of expressing such relations.

```
compatible (Operation 1 , Operation 2):-
 store_operation (Operation 1, Var 1, assign, Source 1 ,....) ---- (1)
 store_operation (Operation 2, Var 2, assign, Source 2,....) ---- (2)
 followed_by (Operation 1, Operation 2),                      ---- (3)
 Var 1  \== Var 2,                                            ---- (4)
 implementation (Var 1 , _, register,....),                   ---- (5)
 implementation (Var 2, _, register,....),                    ---- (6)
 not (refered_to (Var 1, Source 2)).                          ---- (7)
```

Figure 15. Knowledg for compressing sequential operations (Backward chaining rule)

4.3.3 Knowledge involving local job control

Figure 16 illustrates another forward chaining rule for implementing a variable in **occam** with hardware elements. In particular, this rule changes the order of design jobs locally. The idea of the predicate *implement_variable* is as follows; when no clues are provided regarding the number of bits for a variable, and a "similar" variable exists, try to determine the number of bits for the "similar" one first and use the result. Here, a "similar" variable is defined as one that stores the same type of data. To prevent falling into a loop while a decision about a specific variable is postponed, the list of all postponed variables is stored as the second argument of the predicate, *implement_variable*. This rule states that:

IF:

(1) There exists a variable which looks similar to *Var*, and

(2) the implementation of *Another_var* has not been postponed, and

(3) *Var* is added to the list of postponed variables and *Another_var* is implemented first, and

(4) the number of bits of *Another_var*, *Bit_width* is confirmed, and

(5) other conditions are satisfied,

THEN:

(6) Store in the working memory the information stating that the variable *Var* is to be implemented as a *Bit_width* bit register.

```
mplement_variable (Var, Task_list):-
 looks_similar (Var, Another_var ),                            ---- (1)
 not (member ( Another_var, Task_list)),                       ---- (2)
 implement_variable (Another_var,[Var | Task_list]),          ---- (3)
 implementation (Another_var, Bit_width, .... ),               ---- (4)
                 .
                                                               ---- (5)
                 .
 assert (implementation (Var, Bit_width, register,..)).        ---- (6)
```

Figure. 16. Knowledge involving local control (Forward chaining rule)

For example, this rule is applicable to variables *rold* and *t* which appear in PROC acc in Figure 6. The following assignment processes concern variable *rold* and *t*.

$$rold := t$$

$$t := TRUE$$

$$\vdots$$

$$rold := rnew$$

$$t := t \wedge (xnew \vee d)$$

The system attempts to implement variable *rold* first, but this design job is postponed because there are no clues to the number of bits. Next, the system tries to implement the similar variable *t*. In this case, *t* takes only Boolean values (TRUE or FALSE). Therefore, the system implements variable *t* as a one-bit register. After the implementation of variable *t*, it becomes clear that the variable *rold* should have only one bit, because *rold* has the same number of bits as *t*. In this way, the regular flow of control is altered by changing the order of jobs locally.

4.4 Effectiveness of Prolog

We evaluated the effectiveness of Prolog as an implementation/knowledge-representation language for a new generation of CAD systems.

While constructing this system, we confirmed that the following Prolog characteristics are useful in the construction of a knowledge-based expert system for logic design.

(1) The "predicate represents inter-object relationship" characteristic of Prolog is very efficient for expressing

relationships among hardware concepts, and software concepts.

(2) The characteristic that Prolog code can be declaratively read gives us a better understanding of the rules represented in Prolog.

(3) Controlling the order of design jobs, which requires complex operations for procedural programming languages, is facilitated by using the Prolog execution mechanism.

5. SYSTEM IMPLEMENTATION AND PERFORMANCE

This system was developed using C-Prolog and runs on the VAX-11/780. The C-Prolog interpreter of the VAX-11/780 runs at approximately 1 kLIPS. Table 1 lists the program sizes of various subsystems and the execution times of the two hardware design examples (CPU time of VAX-11/780). Design example 1 applies to the pattern matcher. Design example 2 applies to the simple microprocessor. The input **occam** specifications were about 40 and 50 lines, respectively. The functional design phase took 37 seconds of CPU time to generate the DDL description of the pattern matcher and 13 seconds for the microprocessor. The circuit design phase created the CMOS circuit of the pattern matcher in 11.6 minutes and that of the microprocessor in 13.3 minutes. These circuits correspond to approximately 350 gates for the pattern matcher and 1000 gates for the microprocessor.

6. CONCLUSIONS

We discussed a knowledge-based expert system for hardware logic design implemented in Prolog, with an emphasis on the inference mechanism and knowledge representation of the functional design phase.

Areas requiring further research are as follows.

First, the working memory needs to be appropriately structured. The working memory currently used in this system is a flat-type that consists only of Prolog facts. All procedure calls that deal with the working memory (Prolog's assert and retract predicates are used to update the data) are contained in rules. As a result, the procedure calls makes rule expression too complicated. The use of ESP[8] is a possible solution to the problem of structuring the working memory and separating these procedure calls from rules. ESP provides us with time-dependent states and a frame-like structure while retaining essential logic programming language features.

Secondly, the current system does not have a rule-interpreter on Prolog. As previously mentioned, the local control flow can be modified by changing the local job sequence without a rule-interpreter. However, global job control seems to be required to avoid waste design jobs and to increase the performance of the system. We are planning to introduce a meta-rule interpreter to achieve global control.

Lastly, expert system capability largely depends on the amount of stored knowledge. To improve this, expert knowledge must be repeatedly extracted and stored in the knowledge-base. Therefore, we believe that research into knowledge acquisition is necessary.

ACKNOWLEDGEMENTS

This work is based on the results of the R & D activities of the Fifth Generation Computer Systems Project. The authors would like to thank Dr. K. Furukawa and Mr. Y. Iwashita of ICOT (Institute for New Generation Computer Technology) for their encouragement and support.

ABSTRACT

The research activities on natural language processing of the FGCS Project are presented. Linguistic phenomena are formalized in terms of complex structures and constraints on them. The logic programming paradigm is adopted for implementing natural language processing systems because the basic operation for the complex structures is isomorphic with respect to unification. DUALS (Discourse Understanding Aimed at Logic-based System), CIL (Complex Indeterminate Language), and JPSG (Japanese Phrase Structure Grammar) are being developed using the unification-based approach. The large-scale machine readable and understandable dictionaries are also being developed.

1. Introduction

In our daily life, we communicate with one another mainly by means of speech and writing in natural languages. We get a lot of information from books and papers. Communication between human and computer should also be performed in the medium of natural language. The ability of computers to understand natural language will increase their accessibility and flexibility. The Japanese fifth generation computer project aims to develop such intelligent computer systems.

The special characteristic of the Japanese language, i.e., the use of a great many Chinese characters, has made Japanese text input and processing difficult for a long time. Recently, however, Japanese language processing technology has advanced a lot as evidenced by Japanese word processors and commercial machine translation systems. These technologies combined with artificial intelligence are expected to provide new Japanese information processing technology and a new computer culture.

ICOT began research and development of the Fifth Generation Computer Systems (FGCS) in 1982. Natural language processing technology is one of the most important research themes for the FGCS Project because it is a fundamental technology for knowledge information processing and it is used for the research and development of knowledge-base, intelligent-interface and various basic application systems, such as machine translation systems.

The results of research in the initial stage have led us to the conclusion that the logic programming framework is the most suitable for implementing natural language processing systems [6]. The linguistic phenomena in natural language can be formalized in terms of the complex structures of the grammatical features and the constraints on them, as is seen in the feature set of Generalized Phrase Structure Grammar (GPSG) [7], the functional structure of Lexical Functional Grammar (LFG) [11] and the "dags" of PATR-II [20]. The basic mechanism of logic programming is unification in Horn clause logic. Definite Clause Grammar (DCG) [18] is one of the bridges connecting the natural language processing and logic programming. Most of our research activities can be regarded as the improvement and the extension of DCG. GALOP (BUP) [12] is a bottom-up left corner parser which overcomes the drawbacks of top-down parser for DCG. A parallel model of DCG is also being developed [13]. CIL (Complex Indeterminate Language) [15,16] was developed to express and operate the complex features. CIL is an extension of

CH2345-7/86/0000/0987$01.00 © 1986 IEEE

Prolog. The newly introduced "partially specified term" of CIL is suitable for representing the complex features because an extended unification is defined on two partially specified terms. The declarative constraints can be written using the freeze mechanism of CIL. Our approach for semantic analysis, which also deals with pragmatics, is based on situation semantics [1] theory. In this approach, the semantic analysis process corresponds to constructing the relations between situations, and it is implemented as an algebra of events. The merging of events is one of the basic operations and it has an isomorphic structure with respect to unification. Therefore, the basic operations in both syntactic and semantic analyses are isomorphic with respect to those of logic programming, which makes logic programming compatible with natural language processing. DUALS (Discourse Understanding Aimed at Logic-based Systems) is its application system for discourse understanding which reads stories and answers questions on the stories. JPSG (Japanese Phrase Structure Grammar) [9] is a GPSG-based grammar theory for Japanese language whose basic operation is unification. The unification-based parser for JPSG has been developed. We developed some application systems, in order to verify and evaluate this fundamental technology mentioned above. Finally, the processing of large-scale language data is another important aspect of natural language processing. Dictionaries include much information about syntax and semantics which will be utilized for designing the lexicon and the knowledge-base in natural language processing systems. The following three types of machine readable and understandable dictionaries will be developed in the subproject which started in April 1986:

(1) Basic Word Dictionaries:
Four machine readable master dictionaries with 200,000 entries in each dictionary.

(2) Concept Classification Dictionary:
A systematic dictionary for 400,000 concepts including a general thesaurus.

(3) Concept Description Dictionary:
A knowledge database containing semantic descriptions of 400,000 concepts.

These systems mentioned above are implemented on the personal sequential inference machine PSI [17]. The programs are written in its programming language ESP [4]. This paper describes the main research activities and plans for natural language processing of the FGCS Project -- CIL, DUALS, JPSG, and Machine Readable and Understandable Dictionaries.

2. CIL (Complex Indeterminate Language)

2.1 Partially Specified Term

CIL is an extension of Prolog which was designed for the system description language of DUALS. CIL has the freeze predicate, which was originally introduced in Prolog-II [5], as a primitive predicate for realizing various lazy evaluation controls.

CIL introduces a new type of object called "partially specified term" ("partial term" for brief), which is influenced mainly by the notion of assignment developed in the situation theory of [2,3].

CIL = Prolog + Partial Term + Freeze.

We understand partial term as an abstraction from the following data structures, which are widely seen in programming languages, grammar formalisms, etc.:

-- Herbrand term in first order logic.
-- Association list and property list in LISP.
-- Frame and unit in knowledge representation.
-- Record in programming languages.
-- Record in relational data base theory.
-- Assignment in Barwise's situation theory.
-- Category as complex feature in GPSG and functional structure of LFG.

A partial term is written in CIL like this:

{a1/b1, ..., an/bn} n>= 0

where each ai is a ground term and bi is any term, possibly a partial term. The ordinal unification is extended to the partial terms. For example the extended unifier works like this:

```
    unify({a/1, b/2}, {b/X, c/3})
  = {a/1, b/2, c/3},
```

unifying X to be X = 2.

CIL can represent a semantic network even including cycles by using partial terms. For instance, the CIL unifier solves the system of three equations A = B, A = {a/B}, and B = {a/A}, giving A = B = {a/A}, a singleton graph with a self-loop with an edge labelled a. As is easily seen, CIL unification is close to that over infinite trees in Prolog-II. The domain of CIL can be defined formally to be a set of infinite trees.

2.2 Reserved Forms in CIL

The current CIL syntax is an extension of the syntax of DEC-10 Prolog. The following symbols ':', '?', '@', '#', '??', '!' appearing in terms are reserved for the CIL system as follows:

(1) A term of the form X!a is equivalent as a term to the value of the slot of X whose name is a. That is,

```
{al/bl, ..., ai/bi, ..., an/bn}!ai = bi.
```

(2) A term of the form X:C with terms X and C is called a description. C should be an executable form. This term is read "X such that C".

(3) A literal of the form p(...X?...) is equivalent to the literal freeze(X,p(...X...)).

(4) CIL includes convenient forms of term which are defined as follows:

```
@p  <=> X:p(X?), where p is a predicate
        symbol of arity 1 and X is a new
        variable.
V@p <=> V:p(V?), where p is like the
        above.
V#T <=> V:(V=T).
V?? <=> X:(X?=V), where X is a new
        variable.
```

2.3 Situation Semantics in CIL

Although the current CIL is not a full implementation of situation theory yet, it is already useful because of the introduction of partial terms and extended unification over them. Partially specified terms have general and natural descriptive power to represent various data structures of objects necessary for situation theory. The most difficult and basic problem which remains open for CIL, however, is to develop some ideas for designing a control library for constraint description. We think that the problem corresponds directly to the implementation of the constraints of situation theory.

3. DUALS (Discourse Understanding Aimed at Logic-based Systems)

DUALS is an experimental discourse understanding system developed to build a computational model for discourse understanding. The semantic framework is situation semantics in which the sentence meanings are represented as relations between situations. DUALS aims at dealing with the following items within this framework.

1) Primitives for discourse understanding
   (a) Anaphora
   (b) Speech act
   (c) Attitude verb
   (d) Tense
   (e) Quantifier
   (f) Conditions
   (g) Coordination
2) Plan-goal
3) Type description
4) Predicates for manipulating situations

The latest version of DUALS was implemented in CIL. It reads a story written in Japanese language and answers various type of questions about it. The system has the following characteristics:

(1) The semantic structure is constructed with the objects used in situation theory, such as individuals, assignments, relations, locations, conditions, events, parameters, and so on.

(2) Syntax analysis is performed by the parser based on the concurrent process model called SAX (Sequential Analyzer of syntaX and semantics) [13]. There are about 250 grammar rules. Constraints between

situations representing sentence meaning are generated in the form of partially specified terms of CIL by the syntax analysis module.

(3) Anaphora processing algorithm, i.e. the identification of pronouns and zero-pronouns (ellipses) is based on Kameyama's model [10].

(4) Plan-goal-based discourse structures are obtained by the discourse processing module. The rules to construct the discourse structures are described as constraints between events.

(5) The sentence generation module generates the surface sentences from internal meaning structures using grammar rules.

Our technical approach to implementation is to build a package for extended unification in logic programming. An interesting problem, and a more theoretical challenge, is determining what kinds of unification are needed as primitives for implementing situation semantics.

4. JPSG (Japanese Phrase Structure Grammar)

Grammar is an important component of a system for natural language understanding. JPSG is a new Japanese grammar theory for Japanese language based on GPSG. GPSG is suitable for implementation in the logic programming paradigm because it is a natural language syntax theory based on context free grammar (CFG) and its basic computational mechanism is unification. Besides, GPSG has the following features:

(a) Syntactic categories are defined as a complex feature set.

(b) Only phrase structure is used to represent grammatical information.

(c) Metarules for phrase structure rules are introduced.

(d) Constraints on features are described in the syntactic principles, which make phrase structure rules general.

(e) Syntax and semantics are closely related.

Since the Japanese language has a word order variation called "scrambling", GPSG cannot handle it feasibly. In order to handle the "scrambling", the subcategorization feature (SUBCAT) whose value is a set of syntactic categories, is introduced in JPSG. This is an extension of HPSG [19].

Currently, the grammar formalism of JPSG is completed for basic Japanese syntax with the following characteristics:

(1) Syntactic categories are defined as a feature set. Some feature examples are as follows:

PAS -- This indicates the passivizability of a verb. The value is '+' or '-'.

POS -- This indicates a part of speech. The value is one of {V, N, P,...}.

GR -- This indicates a grammatical relation. The value is one of {SBJ, OBJ}.

SUBCAT -- This is the set of syntactic categories which a head category demands as its complements.

SLASH -- This is the set of the missing categories. This feature is used in the same way as in GPSG.

(2) The following phrase structure rule is sufficient for basic Japanese syntax:

(2.1) M --> D H

Rule (2.1) states that mother category (M) dominates one daughter category (D) on the left and one head category (H) on the right. This simplification of the rule is achieved by describing the constraints on the features in syntactic principles.

(3) Since a new SUBCAT feature is introduced, SUBCAT feature principle (SFP) is extended like that of HPSG. SFP describes the inheritance of SUBCAT values as follows:

"The SUBCAT of M is identical to that of H minus D."

For example, if the category of D is N[OBJ] and SUBCAT of H is {N[SBJ], N[OBJ]}, then SUBCAT of M will be {N[SBJ]}. N[OBJ] represents the object noun phrase. The absence of order between the elements of SUBCAT makes it easy to deal with "scrambling" [8].

(4) Most of the syntactic principles used in GPSG are also used in JPSG such as HEAD feature

convention (HFC) and FOOT feature principle (FFP). A set of certain features is called "HEAD features", for example, the POS feature. HFC is a constraint stating that "HEAD features of M are identical to those of H in (2.1)". SUBCAT and SLASH are called FOOT features. FFP is a principle about the inheritance of FOOT features stating that "FOOT feature of M is identical to the union of that of D and H in (2.1)".

(5) A lot of grammatical information is contained in a dictionary.

The basic operation used in JPSG is "unification" because in the syntactic principles mentioned above, the phrase "be identical to" can be replaced by "can be unified to". The parser for JPSG is being developed in CIL. JPSG and CIL are compatible because the syntactic category as feature set corresponds to a partially specified term and syntactic principles correspond to Horn clauses.

5. Machine Readable and Understandable Dictionaries

We presented the unification-based approach for natural language processing and its applications in previous sections. On the other hand, processing of large-scale language data is another important aspect of natural language processing.

This research aims at developing a large-scale database for various natural language processing and speech processing application systems. The language database will be composed primarily of three machine-readable dictionaries: a large-scale basic dictionary as the master dictionary; a concept classification dictionary including a thesaurus; and a concept description dictionary containing descriptions of the meanings of concepts. Application systems utilizing these dictionaries will be developed including machine translation systems and speech recognition systems.

5.1 Basic Word Dictionaries

The term "basic word" means words used in everyday speech, general technical terms, proper nouns, and so on. Machine-readable master dictionaries will be developed containing these basic words. These are the dictionary types:

(1) Japanese
(2) English
(3) Japanese-English
(4) English-Japanese

Each dictionary will include about 200,000 entry words. These dictionaries will be developed in accordance with the specifications already established [14].

5.2 Concept Classification Dictionary

This dictionary will contain specifications of the relations between concepts and indicate exactly how specific concepts are classified in the concept world. Classification bases for the concept world are 'super-sub', 'whole-part', 'composition-element' and other similar relations. The multiple inheritance mechanism will be used as well. The standard thesaurus will form a part of this dictionary. At least 400,000 concepts will be included.

5.3 Concept Description Dictionary

This dictionary will contain the meaning of each individual concept classified in the concept classification dictionary. The combination of the concept classification and the concept description will form the knowledge base for the "general world", and will be utilized in semantic and discourse analysis.

5.4 Application systems

Machine translation systems and speech recognition systems will be developed using these dictionaries.

6. Conclusion

This paper described the research activities on natural language processing within the Japanese Fifth Generation Computer System project. Having finished the initial stage, the project is now at the end of the first year in the four-year intermediate stage. Natural language understanding includes a lot of difficult issues that remain unsolved, especially in discourse understanding. Nevertheless, fruitful results and new ideas have been obtained over the four years of research to date by concentrating on the logic programming framework as discribed in this paper. The last four years has convinced us that the logic programming approach is very promising for implementing natural language processing systems. In the intermediate stage, we will continue this approach to build the subsystems that will be integrated to form the total knowledge information processing system in the final stage.

7. Acknowledgement

This research is being carried out by the Second Research Laboratory of ICOT in very close cooperation with seven manufactures. Many fruitful discussions were held in meetings of the following working groups -- NLS (Natural Language processing System, Head: Prof. Tanaka of Tokyo Institute of Technology), JPS (Japanese Phrase Structure grammar, Head: Prof. Gunji of Osaka Univ.), MRD (Machine Readable Dictionaries, Head: Prof. Ishiwata of Ibaraki Univ.). Finally, the authors would like to thank the director K. Fuchi, ICOT Research Center for providing us with the opportunity for this research.

Abstract

The verification system Argus/V for proving properties of Prolog programs is outlined by contrasting verification with testing in logic programming. Specifications in Argus/V are given by a class of first order formulas, including goals for normal execution. Contrary to the specifications considered in the usual framework of verification, our specification states a partial property of the program than states what the progrom does as a whole. Though verification in Argus/V does not guarantee the correctness of the program at one stroke, the more properties of the program we prove, the closer the program is to what we intend. Verification in Argus/V is done using inference rules devised for verification, extension of these for usual execution. Execution in Prolog, on which testing is based, is a special case of the inferences in our verification. These two features of Argus/V show that both testing and verification are methods located on a continuous axis to confirm that the program is as we intend it.

Keywords : Verification, Testing, Theorem Proving, Prolog.

Contents

1. Introduction — Testing and Verification —

It is said that Prolog is a higher-level programming language than conventional languages, because operations in Prolog are further distanced from machine structure and closer to purely symbolic manipulation. Though such machine-independent human-oriented characteristics would seem to make programming easier, we still write incorrect Prolog programs quite frequently. For example, we might write the following incorrect program to reverse a list.

```
reverse([ ],[ ]).
reverse([X|L],M) :- reverse(L,N),append(N,X,M).
```

Figure 1. Incorrect Program for Reversing Lists

How can we determine whether the program is what we intend in our mind ? There are two well-known approaches, which give completely different impressions.

One approach is *testing*. Appropriate data is supplied to the program and it is run in order to see whether it shows unexpected responses or behavior. In general,*the more data for the program we test, the better we can determine how close the program is to what we intend it to be.* But testing is considered a rather naive and informal method, and troublesome to the human programmer.

Another approach is *verification*. A specification, that shows *what* the program does as a whole, is given and proved logically with respect to the program, that shows *how* the desired resuls are computed. Verification is considered a rather formal method, to confirm the correctness of the program at one stroke, possibly mechanically.

These approaches seem to be fundamentally separated in conventional programming. How do things stand in logic programming ? In order to answer the question and make the motivation of our verification method understandable, we review what we are doing in testing in Section 2 and the paradigm of logic programming in Section 3. Then an outline of our verification system Argus/V is given in Section 4. In particular, we emphasize the characteristics of specifications and the use of extended execution. In Section 5, we discuss the similarities between testing and our verification with respect to two features, that is, both approaches confirm the correctness of programs gradually and both approaches are based on execution.

2. Testing of Prolog Programs

Let us test the *reverse* program in Figure 1. *Tracer*, one of the testing tools of DEC10 Prolog system [23], responds as follows.

```
| ?- reverse([2,1],M).
   (1) 0 Call : reverse([2,1],_40) ?
   (2) 1 Call : reverse([1],_105) ?
   (3) 2 Call : reverse([ ],_117) ?
   (3) 2 Exit : reverse([ ],[ ])
   (4) 2 Call : append([ ],1,_105) ?
   (4) 2 Call : append([ ],1,1)
   :
```

Figure 2.1. Example of A Testing of Prolog Program

A goal in the trace holds, when the goals (with "Call") below the goal hold. By observing the behavior in the trace and finding the goal contradicting the programmer's intention, the programmer can correct the program in Figure 1 as follows.

```
reverse([ ],[ ]).
reverse([X|L],M) :- reverse(L,N), append(N,[X],M).
```

Figure 2.2. Correct Program for Reversing Lists

After all, *testing is confirming whether there is any difference between the model the programmer has in his/her mind and the actual behavior of the program.*

3. Logic Programming Paradigm Revisited

Now, let us recall the paradigm of logic programming, the central idea of the Japanese Fifth Generation Computer Systems project. *The execution of a Prolog program is the construction of a logical proof* ([1],[9],[10],[15],[20]). For example, the execution of *?-reverse*$([2,1],M)$ is the construction of a proof of $\exists M reverse([2,1],M)$. In general, we have the following inference rule for each definite clause "B :- $B_1, B_2, \ldots, B_m$", where σ is an m.g.u. of A and B. (It is read the formula below the line holds when the formulas above the line hold.)

$$\text{execution} \qquad \frac{\sigma(B_1 \wedge B_2 \wedge \cdots \wedge B_m)}{A}$$

Figure 3.1. Inference Rule for Execution

The proof of a given formula we would like to prove is constructed from the bottom. (See the Figure 3.2 below.) The tracer in Section 2 shows the proof upside-down from left to right.

$$\dfrac{\text{reverse([ ],[ ])}\wedge\text{append([ ],1,1)}}{\qquad\qquad\dfrac{\text{reverse([1],1)}\wedge\text{append(1,2,?)}}{\text{reverse([2,1],?)}}}$$

Figure 3.2. Proof Tree Corresponding to Execution

According to the paradigm, the behavior on which we focus our attention in testing is how the proof of formulas of the form $\exists Y_1, Y_2, \ldots, Y_m\ (A_1 \wedge A_2 \wedge \cdots \wedge A_k)$ is constructed.

4. Verification of Prolog Programs

4.1. Specification of Prolog Programs

The most prominent feature of logic programming languages is, of course, the close relation to logic, the origin of the name. For example, Prolog is very close to, actually a sublogic of, first order logic, long used as one of the most common specification languages. This close relation between programming languages and specification languages prompts reexamination of the nature and the role of specifications and verification.

Specification and verification are still necesary.

Some people think that Prolog programs are formulas of first order logic, rendering independent specification and verification redundant. We agree that in some cases a specification can be a Prolog program as it is, and we cannot write any other simpler specifications of some programs. But, as can be easily seen, Prolog programs are not always specifications. Many computation mechanism have been devised to increase efficiency. Moreover, even if a Prolog program is a description of our intention in logical formulas, it is written from one point of view, which might be erroneous. Confirmation that the program is what we intend must be effected from another point of view by testing or verification [7].

Specifications verified might be partial.

It has often been said that specifications are sometimes as large as programs themselves. The specifications considered so far are usually *total*, that is, they must contain all the information about what the program does as a whole. Such specifications are necessary for program synthesis, because specifications for synthesis usually have to contain all the information for the program to be constructed. The close relation between Prolog and first order logic suggests the possibility of relaxing this restriction on verification. The specifications in our verification system might be *partial*, that is, they are not necessarily the total description of what the program does as a whole, because the program itself may be a part of its own specification. For example, the following property ***reverse-reverse***

$\forall$ X,Y (reverse(X,Y) $\supset$reverse(Y,X))

is also satisfied by the identity relation ***id*** defined by

id(X,X).

Hence, even if we have proved the ***reverse-reverse*** property with respect to the program at hand, we can't conclude that our program is the correct ***reverse***. It is a fortunate situation when we are able to write down the total specification. But we usually content ourselves with a set of partial specifications. *The more properties of the program we verify, the closer the program is to what we intend.* After all, *verification is confirming whether there is any difference between the model the programmer has in his/her mind and the actual properties of the program.* Our verification is much closer to testing in its nature and functioning.

Specification Formulas and Goal Formulas

Now we introduce the class of first order formulas used for specification in Argus/V.

We generalise the distinctions of positive and negative goals. The *positive* and *negative subformulas* of a formula $\mathcal{F}$ are defined as follows (see [24],[21],[22],[25]).

(a) $\mathcal{F}$ is a positive subformula of $\mathcal{F}$.

(b) When $\neg\mathcal{G}$ is a positive (negative) subformula of $\mathcal{F}$, then $\mathcal{G}$ is a negative (positive) subformula of $\mathcal{F}$.

(c) When $\mathcal{G}\wedge\mathcal{H}$ or $\mathcal{G}\vee\mathcal{H}$ is a positive (negative) subformula of $\mathcal{F}$, then $\mathcal{G}$ and $\mathcal{H}$ are positive (negative) subformulas of $\mathcal{F}$.

(d) When $\mathcal{G} \supset \mathcal{H}$ is a positive (negative) subformula of $\mathcal{F}$, then $\mathcal{G}$ is a negative (positive) subformula of $\mathcal{F}$ and $\mathcal{H}$ is a positive (negative) subformula of $\mathcal{F}$.

(e) When $\forall X \mathcal{G}$ or $\exists X \mathcal{G}$ is a positive (negative) subformula of $\mathcal{F}$, then $\mathcal{G}_X(t)$ is a positive (negative) subformula of $\mathcal{F}$.

Example 4.1.1. Let $\mathcal{F}$ be

∀ B,U,A_1,V,A (reverse(B,[U|A_1])∧append(A_1,[V],A) ⊃
∃ A_2 (reverse(B,A_2)∧append(A_2,[V],[U|A])))

Then $\exists A_2(reverse(B, A_2) \wedge append(A_2, [V], [U|A]))$ is a positive subformula of $\mathcal{F}$, while $reverse(B, [U|A_1])$ is a negative subformula of $\mathcal{F}$.

Let $\mathcal{F}$ be a closed first order formula. When $\forall X \mathcal{G}$ is a positive subformula or $\exists X \mathcal{G}$ is a negative subformula of $\mathcal{F}$, X is called a *free variable* of $\mathcal{F}$. When $\forall Y \mathcal{H}$ is a negative subformula or $\exists Y \mathcal{H}$ is a positive subformula of $\mathcal{F}$, Y is called an *undecided variable* of $\mathcal{F}$. In other words, free variables are variables quantified universally, and undecided variables are those quantified existentially when $\mathcal{F}$ is converted to its prenex normal form.

Example 4.1.2. Let $\mathcal{F}$ be

∀ B,U,A_1,V,A (reverse(B,[U|A_1])∧append(A_1,[V],A) ⊃
∃ A_2 (reverse(B,A_2)∧append(A_2,[V],[U|A])))

Then B, U, A_1, V and A are all free variables, while A_2 is an undecided variable.

A closed first order formula S is called a *specification formula* (or *S-formula* for short) when

(a) no free variable in S is quantified in the scope of quantification of an undecided variable in S and

(b) each undecided variable appears only in some positive conjunction of atoms $A_1 \wedge A_2 \wedge \cdots \wedge A_k$ in S.

In other words, S-formulas are formulas convertible to prenex normal form $\forall X_1, X_2, \ldots, X_n \; \exists Y_1, Y_2, \ldots, Y_m \mathcal{F}$ and each Y_i appears only in some positive conjunction of atom in $\mathcal{F}$. Note that S-formulas include both universal formulas $\forall X_1, X_2, \ldots, X_n \mathcal{F}$ and usual execution goals $\exists Y_1, Y_2, \ldots, Y_m \; (A_1 \wedge A_2 \wedge \cdots \wedge A_k)$.

Example 4.1.3. Let S be

∀ B,U,A_1,V,A (reverse(B,[U|A_1])∧append(A_1,[V],A) ⊃
∃ A_2 (reverse(B,A_2)∧append(A_2,[V],[U|A])))

Then S is an S-formula, because free variables B, U, A_1, V and A are quantified outside $\exists A_2$, and A_2 appears only in the positive conjunction $reverse(B, A_2) \wedge append(A_2, [V], [U|A])$. An execution goal

∃ C append([1,2],[3],C)

is also an S-formula.

A formula G obtained from an S-formula S by leaving free variable X as it is, replacing undecided variable Y with $?Y$ and deleting all quantifications is called a *goal formula* of S. Note that S can be uniquely restorable from G. In the following, we use goal formulas instead of original S-formulas. Goal formulas are denoted by F, G, H.

Example 4.1.4. An S-formula

∀ B,U,A_1,V,A (reverse(B,[U|A_1])∧append(A_1,[V],A) ⊃
∃ A_2 (reverse(B,A_2)∧append(A_2,[V],[U|A]))

is represented by a goal formula

reverse(B,[U|A_1])∧append(A_1,[V],A) ⊃
reverse(B,?A_2)∧append(?A_2,[V],[U|A]).

An execution goal

∃ C append([1,2],[3],C)

is represented by a goal formula

append([1,2],[3],?C).

Let S be a specification in an S-formula, M_0 be the minimum Herbrand model [10] of P and P^* be the completion [8] of P. We adopt a formulation as follows : Model-theoretically speaking, verification of S with respect to P is showing $M_0 \models S$. Proof-theoretically speaking, it is proving S from P^* using first order inference and some induction. (Of course, the proof-theoretical formulation is weaker than the model-theoretical formulation. See Section 4.4 for induction.)

4.2. Inference Rules for Verification

Though we have pointed out the similarity between testing and our verification, it is meaningless to just rephrase the definition of verification. The current Prolog interpreter can't execute our S-formulas directly. Now we present the method and the mechanism of our verification (cf. [3],[13],[14],[28]). Our inference rules for verification consist of *extended execution* and *computational induction*. Extended excution is an extension of usual execution and consists of case splittings (∧-deletion,∨-deletion and ⊃-deletion), definite clause inference (DCI), "Negation as Failure" inference (NFI) and simplification. We omit discussion of the case splitting rules in what follows, because they are not used very frequently. See [Kanamori and Seki 1985], [Kanamori 1986] for details.

Using intuitive notations, DCI, NFI and simplification are depicted as inference rules as follows. In the followings, we use $\mathcal{F}_{\mathcal{G}}(\mathcal{H})$ for replacement of *all* occurrences of a formula $\mathcal{G}$ in a formula $\mathcal{F}$ with $\mathcal{H}$ and $\mathcal{F}_{\mathcal{G}}[\mathcal{H}]$ for replacement of an occurrence of a formula $\mathcal{G}$ in a formula $\mathcal{F}$ with $\mathcal{H}$. See the following explanation for the meaning of other notations.

DCI
$$\frac{\sigma(G_A[B_1 \wedge B_2 \wedge \cdots \wedge B_m])}{G_+[A]}$$

NFI
$$\frac{\tau_1(G_A[\wedge_{i=1}^{m_1} B_{1i}]) \quad \cdots \quad \tau_k(G_A[\wedge_{i=1}^{m_k} B_{ki}]) \quad G_A[false]}{G_-[A]}$$

simplification
$$\frac{\sigma(G)_A(true) \quad \sigma(G)_A(false)}{G}$$

Figure 4.2. Main Inference Rules for Verification

4.3. Extended Execution

The execution of positive goals is generalized using polarity.

Definite Clause Inference(DCI)

Let A be a positive atom in a goal formula G and "B :- $B_1, B_2, \ldots, B_m$" be any definite clause in P. When A is unifiable with B by an m.g.u. σ without instantiation of free variables, a new OR-goal $\sigma(G_A[B_1 \wedge B_2 \wedge \cdots \wedge B_m])$ is generated. ($B_1 \wedge B_2 \wedge \cdots \wedge B_m$ is *true* when $m = 0$.) All new variables introduced are treated as fresh undecided variables.

Example 4.3.1. Let S be

∀ A,B,C,U ((reverse(C,B)⊃reverse(B,C))⊃
(reverse(A,[U|B])⊃reverse([U|B],A))).

Then the goal formula of S is

(reverse(C,B) ⊃reverse(B,C)) ⊃
(reverse(A,[U|B]) ⊃reverse([U|B],A))

We can apply DCI to *reverse*$([U|B], A)$ and it is replaced with *reverse*$(A, ?D) \wedge$ *append*$(?D, [U], B)$. Note that the variable in the body is treated as an undecided variable $?D$.

Example 4.3.2. When S is an existential formula of the form $\exists Y_1 Y_2 \cdots Y_m (A_1 \wedge A_2 \wedge \cdots \wedge A_k)$, i.e., of the form of usual execution goals, the goal formula of S is $?\text{-}A_1, A_2, \ldots, A_k$. (The juxtaposition delimited by "," denotes conjunction and $?\text{-}G$ denotes the goal formula obtained by replacing every variable Y in G with $?Y$.) Then usual execution is applied to $?\text{-}A_1, A_2, \ldots, A_k$. The figure below shows an example, where *common* and *reverse* are defined by

common(X,L,M) :- member(X,L),member(X,M).
member(X,[X|L]).
member(X,[Y|L]) :- member(X,L).

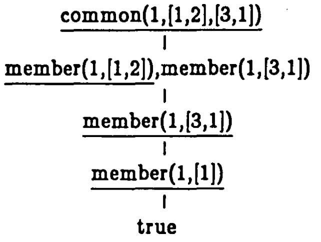

Figure 4.3.1. DCI for Usual Positive Goals

We also generalize the execution of negative goals using polarity.

"Negation as Failure" Inference(NFI)

Let A be a negative atom in a goal formula G. We generate new AND-goals $\tau(G_A[B_1 \wedge B_2 \wedge \cdots \wedge B_m])$ for every definite clause "B :- $B_1, B_2, \ldots, B_m$" in P, whose head B is unifiable with A, and an AND-goal $G_A[\textit{false}]$. ($B_1 \wedge B_2 \wedge \cdots \wedge B_m$ is *true* when $m = 0$.) All new variables introduced are treated as fresh free variables. (Note that A always includes only free variables and τ may be any m.g.u. without restriction.)

Example 4.3.3. Let S be

∀ A,B,C,U ((reverse(A,C)⊃reverse(C,A))⊃
(reverse([U|A],B)⊃reverse(B,[U|A]))).

Then the goal formula of S is

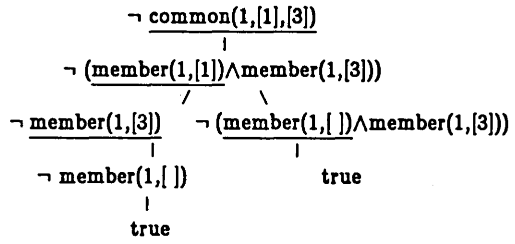
(reverse(A,C) ⊃reverse(C,A)) ⊃
(reverse([U|A],B) ⊃reverse(B,[U|A]))

We can apply NFI to *reverse*$([U|A], B)$. In the first goal,the atom is replaced with *reverse*$(A, D) \wedge$*append*$(D, [U], B)$. Note that the variable in the body is treated as a free variable D. The last goal obtained by replacing the atom with *false* is trivially *true*.

Example 4.3.4. Let S be a specification of the form $\neg A$ where A is a ground atom. Suppose there exist k definite clauses whose heads are unifiable with A by m.g.u.s $\tau_1, \tau_2, \ldots, \tau_k$. When NFI is applied to A, we have $k + 1$ AND-goals

$\neg\tau_1(B_{11} \wedge B_{12} \wedge \cdots \wedge B_{1m_1})$,
$\neg\tau_2(B_{21} \wedge B_{22} \wedge \cdots \wedge B_{2m_2})$,
$\vdots$,
$\neg\tau_k(B_{k1} \wedge B_{k2} \wedge \cdots \wedge B_{km_k})$,
$\neg$*false*.

The last goal formula is trivially *true*. Other goal formulas are of the form $\forall X_1, X_2, \ldots, X_n \neg(A_1 \wedge A_2 \wedge \cdots \wedge A_m)$, because variables introduced from the bodies of the definite clauses are free variables in the generated goal formulas. We can continue applying NFI by selecting atoms in each body of the goal formula. When a selected atom has no unifiable head, the only goal formula generated is the last one, which is always *true*. When all goal formulas are reduced to *true*, $\neg A$ is proved. This is exactly the "Negation as Failure" rule in the usual sense [8],[15]. The figure below shows an example.



¬ common(1,[1],[3])
¬ (member(1,[1])∧member(1,[3]))
¬ member(1,[3])
¬ (member(1,[ ])∧member(1,[3]))
¬ member(1,[ ])
true
true

Figure 4.3.2. NFI for Usual Negative Goals

We sometimes simplify goal formulas by assuming that some atom is *true* or *false* (cf.[22]).

Simplification

Let G be a goal formula. When $A_1, A_2, \ldots, A_m$ are positive atoms and $A_{m+1}, A_{m+2}, \ldots, A_n$ are negative atoms unifiable to A by an m.g.u. σ without instantiation of free variables ($0 < m < n$), we generate new AND-goals $\sigma(G)_A(\textit{true})$ and $\sigma(G)_A(\textit{false})$.

In the following examples, both σ are $<>$ and undecided variables are not instantiated. For more general simplifications with instantiation of undecided variables, see Figure 4.3.3.

Example 4.3.5. Let G be a goal formula

(add(X,Y,Z) ⊃add(Y,X,Z)) ⊃
(add(X,Y,Z) ⊃add(Y,s(X),s(Z)))

of an S-formula

∀ X,Y,Z ((add(X,Y,Z) ⊃add(Y,X,Z)) ⊃
(add(X,Y,Z) ⊃add(Y,s(X),s(Z)))).

Because $\sigma =<>$ is a substitution without instantiation of free variables and unifies the positive atom *add*(X, Y, Z) and the negative atom *add*(X, Y, Z), we generate new AND-goals

(true ⊃add(Y,X,Z)) ⊃(true ⊃add(Y,s(X),s(Z))) ,
(false ⊃add(Y,X,Z)) ⊃(false ⊃add(Y,s(X),s(Z))) ,

i.e., *add*$(Y, X, Z) \supset$*add*$(Y, s(X), s(Z))$ and *true*. This inference corresponds to generating

$(Y+X)+1=Y+(X+1)$

from

$X+Y=Y+X \supset (X+Y)+1=Y+(X+1)$

in functional programs, i.e., using the equation $X+Y = Y+X$ in the premise and throwing it away. This is called *cross-fertilization* in the Boyer Moore Theorem Prover (BMTP) [5].

Example 4.3.6. Let G be a goal formula

$(\text{reverse}(A,C) \supset \text{reverse}(B,A)) \supset$
$\quad (\text{reverse}(A,C) \wedge \text{append}(C,[U],B) \supset \text{reverse}(B,[U|A]))$

of an S-formula

$\forall\, A,B,C,U\ ((\text{reverse}(A,C) \supset \text{reverse}(C,A)) \supset$
$\quad ((\text{reverse}(A,C) \wedge \text{append}(C,[U],B)) \supset \text{reverse}(B,[U|A])))$.

Because $\sigma = <>$ is a substitution without instantiation of free variables and unifies the positive atom $reverse(A,C)$ and the negative atom $reverse(A,C)$, we generate new AND-goals

$(\text{true} \supset \text{reverse}(C,A)) \supset$
$\quad (\text{true} \wedge \text{append}(C,[U],B) \supset \text{reverse}(B,[U|A]))$,
$(\text{false} \supset \text{reverse}(C,A)) \supset$
$\quad (\text{false} \wedge \text{append}(C,[U],B) \supset \text{reverse}(B,[U|A]))$,

i.e., $reverse(C,A) \supset (append(C,[U],B) \supset reverse(B,[U|A]))$ and *true*. This inference corresponds to generating

$\text{reverse}(C)=A \supset \text{reverse}(\text{append}(C,[U]))=[U|A]$

from

$\text{reverse}(\text{reverse}(A))=A \supset$
$\quad \text{reverse}(\text{append}(\text{reverse}(A),[U]))=[U|A]$

in functional programs, i.e., replacement of the special term $reverse(A)$ with a variable C. This is called *generalization* in BMTP [5].

The Figure 4.3.3. below is one of the sequences of the applications of extended execution. A goal in the sequence holds, when the goals below it hold, like the goals in Figure 2.1.

$\text{reverse}(M,[X|L_1]) \wedge \text{append}(L_1,[Y],L) \supset \underline{\text{reverse}([Y|M],[X|L])}$
$\quad \Downarrow$ DCI with $<>$
$\text{reverse}(M,[X|L_1]) \wedge \text{append}(L_1,[Y],L) \supset$
$\quad \text{reverse}(M,?L_2) \wedge \underline{\text{append}(?L_2,[Y],[X|L])}$
$\quad \Downarrow$ DCI with $<?\overline{L_2 \Leftarrow [X|?L_3]}>$
$\underline{\text{reverse}(M,[X|L_1])} \wedge \text{append}(L_1,[Y],L) \supset$
$\quad \underline{\text{reverse}(M,[X|?L_3])} \wedge \text{append}(?L_3,[Y],L)$
$\quad \Downarrow$ simplification with $<?L_3 \Leftarrow L_1>$
$\underline{\text{append}(L_1,[Y],L)} \supset \underline{\text{append}(L_1,[Y],L)}$
$\quad \Downarrow$ simplification with $<>$
true

Figure 4.3.3. Example of Verification of Prolog Programs

4.4. Computational Induction

Because we have adopted the model-theoretical formulation in 4.1, we need to use some kind of induction in order to make our proof system as strong as possible to approximate the model-theoretic formulation.

The following induction scheme is used for induction on natural numbers [6].

$$\frac{Q(0) \qquad \forall X\ (Q(X) \supset Q(X+1))}{\forall X\ (\text{number}(X) \supset Q(X))}$$

Figure 4.4.1. Induction Scheme for Natural Number

Note that the *number* predicate is defined in Prolog as in Figure 4.4.2 and the induction formulas above the line in Figure 4.4.1 is exactly what are obtained by replacing *number* in Figure 4.4.2 with Q.

```
number(0).
number(X+1) :- number(X).
```

Figure 4.4.2. Prolog Programs Defining Natural Number

Similarly, the induction scheme for *reverse* is obtained by replacing *reverse* in Figure 2.2. with Q. This is de Bakker and Scott's computational induction for Prolog ([2],[9],[11],[12],[29]).

$$\frac{Q([\,],[\,]) \quad \forall L,M,N,X\ (Q(L,N) \wedge \text{append}(N,[X],M) \supset Q([X|L],M))}{\forall L,M\ (\text{reverse}(L,M) \supset Q(L,M))}$$

Figure 4.4.3. Induction Scheme for *reverse*

Example 4.4. When the induction scheme above is applied to *reverse-reverse*, i.e.,

$\text{reverse}(L,M) \supset \text{reverse}(M,L)$

the following two induction formulas are generated.

$\text{reverse}([\,],[\,])$
$\text{reverse}(N,L) \wedge \text{append}(N,[X],M) \supset \text{reverse}(M,[X|L])$.

In general, the goals we are going to prove are not necessarily of the form $p(X_1,X_2,\ldots,X_n) \supset Q(X_1,X_2,\ldots,X_n)$. Moreover, more than two induction schemes might be suggested. In order to manage such situations, we have a device to generate and manipulate induction schemes based on an equivalence-preserving program transformation [27]. See [Kanamori and Fujita 1986] for details.

4.5. Argus/V Verification System

The Argus/V verification system has the module structure depicted below. A given specification is first converted to its goal formula, then passed through the four modules in Figure 4.5.

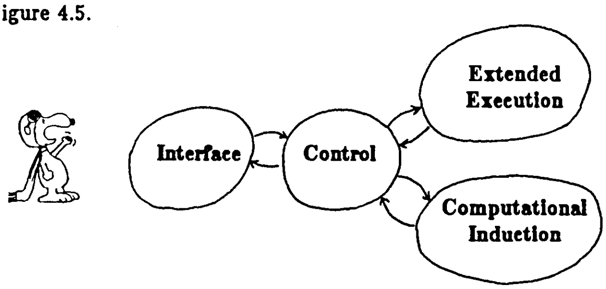


Figure 4.5. Argus/V Module Structure

Because we have additional and generalized inference rules for verification, we need a procedure to select the inference rules to be applied. When and how extended execution and computational induction are applied is controlled by many BMTP-like heuristics [5]. This can be considered a kind of meta-inference [4],[26]. See [Kanamori and Horiuchi 1985] for the use of type inference in Argus/V.

5. Discussion — Testing and Verification —

As shown in Section 4, verification in Argus/V is very close to testing not only in its nature and the role it plays but also in the methodology and its mechanism. In fact, testing is a special case of verification in Argus/V in which the specifications are ground goals or existentially quantified atoms. The difference is that verification in Argus/V is more general than testing. For example, testing can confirm *reverse-reverse* for only lists with specific lengths, while verification in Argus/V proves it for lists of any length. In a sense, testing deals with the superficial observable *directly*, while verification penetrate the interior observable only *indirectly*. In other words, "our *prover* is a *prober*."

6. Conclusions

We have given an outline of the Argus/V verification system for proving properties of Prolog programs by contrasting verification with testing in logic programming. The first version of Argus/V was developed between April 1984 and March 1985. It consists of about 7000 lines in DEC-10 Prolog and takes about 9.5 seconds (CPU time of DEC2060 with 384 kw main memory) to prove *reverse-reverse* automatically. More than 50 theorems have already been proved automatically and the number is increasing.

Acknowledgements

The Argus/V verification system is a subproject of the Fifth Generation Computer System(FGCS) "Intelligent Programming System". The authors would like to thank Dr.K.Fuchi (Director of ICOT) for the opportunity of doing this research and Dr.K.Furukawa (Chief of ICOT 1st Laboratory) and Dr.T.Yokoi (Chief of ICOT 2nd Laboratory) for their advice and encouragement.

A 32-BIT CMOS MICROPROCESSOR WITH SIX-STAGE PIPELINE STRUCTURE

H.Kaneko, Y.Miki, S.Nohara, K.Koya, and M.Araki

Microcomputer Product Div. NEC corp.
1753 Shimo-numabe, Nakahara, Kawasaki City, 211 JAPAN

Abstract

32-bit microprocessors are the key devices which carry high data processing capability, that was obtained by earlier general purpose computer systems and mini-computer systems, in much lower cost. Earlier 32-bit microprocessors were limited to adopt excellent architecture and design using appropriate hardware by number of devices could be fabricated on a chip. Complex functions such as Virtual Memory management and Floating-Point operations had to be obtained by multi-chip configuration in an earlier microcomputer system.

V60 is a 32-bit CMOS microprocessor with the Virtual Memory management facility and Floating-Point arithmetic operations based on IEEE-754 Floating-Point standard on a single chip, and adopts six-stage pipeline structure constructed with six independent pipeline stages.

We obtained a peak performance of 3.5 Million Instructions Per Second (MIPS) execution speed at 16MHz clock rate, and integrated 375,000 transistors on a single chip using a state of the art double-metal layer CMOS process technology based on 1.5um design rule.

1.Introduction

Advantages in VLSI fabrication technology have made it possible to design highly integrated VLSI microprocessors. We are now in a technology region that some hundreds of thousands of circuit devices can be integrated on a tiny chip with reasonable cost[1,2]. The progress, in general, brings three benefits to general-purpose microprocessor designers; multiple 32-bit internal data paths; functionality integration such as pipelined structure; higher performance by short clock cycle.

1.1 32-bit Microprocessors

Microprocessors have been used in a variety of application area, from small control systems to large computing systems, since they were introduced to marketplace in 1971.

The number of devices on a microprocessors have increased about one hundred-times in this 15 years. In addition, the speed of expansion in application range does not seem to be decreased. Also the machine cycle of them have speeded up about 30 times.

The internal data-processing ability has been expanded from 4, 8, and 16 to 32-bit, because of the requests to provide the strong data-processing power and large address space.

For 32-bit microprocessors, the main application area seems to be in data-processing because of their excellent ability that obtained by general-purpose computer and mini-computer systems for information data-processing. Fundamental requests from such application area will include high-level languages support, Operating-Systems support, and application programs support.

To provide high-performance of the 32-bit microprocessors, they operate at shorter operation clock rate (more than 12MHz) than earlier microprocessors.

On the other hand, a large amount of the address space increases the main memory devices and goes to the expense the high-speed main memory systems (more than 1MB) fitted with the machine cycle of the 32-bit microprocessors.

But, the real mission of the 32-bit microprocessors to supply the low-cost information processing systems but the high-ability of their data-processing.

1.2 Design Limitations for Microprocessors

There are two physical limitations to design the microprocessors.

One of those is cost-performance trade-off problem. It decreases the yield of chips on a silicon wafer by throwing much number of the transistors into a chip. In the worst case, the chip designers can not get a properly working chip from a silicon wafer. It is given up to employ a large amount of hardware circuits or high-level hardware techniques for the reasonable chip cost. Consequently this problem limits an architecture designer for the microprocessors to implement his ideal architecture on a chip.

In other words, the functions of the microprocessors are pre-determined and limited in the old-fashioned microprocessor design by number of transistors for employing register set, instruction set, and something related his architecture on a chip.

The other limitation is regarding the operation speed of a fundamental logic element on a silicon wafer. The machine cycle and the timing design are expected by the operation speed of a transistor of silicon chip. The limitations holds down the performance of microprocessors.

1.3 The V60 Microprocessor

A 32-bit microprocessor V60 (uPD70616) is the newest member of NEC's V-series original microprocessors, and is the first implementation of

CH2345-7/86/0000/1000$01.00 © 1986 IEEE

the 32-bit microprocessor family[6].

Philosophy that the processor functions must be included in a single chip as much as possible reflects the V60 architecture. The bottle-neck problems regarding the data transfers between the CPU and external systems can be solved by reducing the number of times to access slow-speed external resources.

General Purpose Registers	32 (32-bit)
Instructions	273 instructions in 119 types
Virtual Address Space	4GB per a space
Real Address Space	16MB
Virtual Memory Management	Demand Paging (4KB/page)
MMU	On-Chip
Translation Look-Aside Buffer	16-entry Full Associative
TLB Hit-Ratio	over 98%
Floating-Point Operations	On-Chip (based on IEEE-754)
Pipeline Stages	6
Simultaneous Execution	4 instructions
Process	Double-metal layer CMOS
Design Rule	1.5uM
Transistors	375,000
Chip Size	13.92mm X 13.80mm
Clock Rate	16MHz (62.5nS)
Power Supply	+5V
Power Dessipation	1.5W
Package	68-pin Pin Grid Array
External Address Bus	24-bit
External Data bus	16-bit
Performance	3.5MIPS

Table-1 Features of V60

V60 has following 4 design goals and features to realize using the advantages of highly integrated CMOS devices[4].

1).Generality

V60 has instruction and register architecture to support the high-level languages. V60 has 273 instructions in 119 types, 21 addressing modes, and thirty-two 32-bit general purpose registers.

Thirty-two 32-bit general purpose registers decrease data transfers of the operand data from/to the main memory system, and reduce the bus-traffic.

2).Application Supports

V60 employs high-level instructions, and various data types such as Character-String, variable length Bit-Field, and Floating-Point data type based on IEEE-754 Floating-Point standard[3].

Several high-level instructions shorten the total instruction code size and reduce the accesses for the instruction codes.

To decrease the loading of the Operating-System for explodingly increased amount of data and memory protection problems, V60 has on-chip Memory Management Unit (MMU) to supply 4GB virtual addressing space with the demand paging method.

On-chip MMU and Floating-Point operations have the advantage to reduce the communications between the CPU and the other external functional chips.

3).Expandability

It is considered to obtain expandability from the past that V60 has Emulation Mode in which it can directly execute instruction set of NEC's 16-bit CMOS microprocessors at object code level. On the other side, V60 has much transparency to expand with the external functional devices such as Floating-Point Co-Processor for the future.

4).High-Performance

V60 has a peak performance of 3.5MIPS by employing six-stage pipeline structure, operating at 16MHz clock rate, and adopting the architecture such as employing high-level instructions that close almost data-processing in a chip.

1.4 Pipeline Structure

One of V60's design goal is to supply high-performance to the system designers. It can be obtained by high-speed execution using high-speed machine cycle. But there are two general reasons to disturb high-speed machine cycle.

One is the limitation in the number of logic gates that are connected in series and operate in the same clock cycle. It is regarding to the propagation delay time of a transistor. It means that operation clock cycle is determined by operation speed of complex or high-level functional hardware circuits like Arithmetic Logic Unit (ALU).

Second is the limitation in the speed of main memory system connected to the CPU. The machine cycle has been accelerated about 30 times, but the access time of main memory devices (Random Access Memory) has speeded up only a couple of times in this 15 years. It takes more expensive cost to employ the main memory devices matched to the microprocessor operating at high-speed machine cycle.

To solve those problems, it is the best solution to employ pipeline structure to the microprocessor using in the sophisticated general-purpose computer systems[5].

There are some problems to employ a pipeline structure; Increasing the registers to arbitrate the operation of each pipeline stage, hardware to solve the Pipeline Hazard problems related to the preceding execution of various instructions, independent hardware such as ALU in each pipeline stage, and complex control, etc. So much and complex hardware is needed to employ pipeline structure, hardware designers abandoned to a real pipeline structure into the earlier microprocessors.

V60 is freed from the limitations concerned to a great number of hardware by fine CMOS fabrication, and can employ a real pipeline structure and some high-level techniques to enhance the performance.

2.Pipeline Structure of V60

We describe implementation and features of the V60's pipeline structure in this section.

V60 obtains well-balanced high-performance for both the simple instructions but frequently used such as the integer operations, and the complex instructions but infrequently used such as the Floating-Point arithmetic operations. V60 adopts six-stage pipeline structure to obtain high-performance for the simple instructions.

2.1 Pipeline Stages

The pipeline structure of V60 is constructed with six independent pipeline stages; Prefetch Unit (PFU), Instruction Decode Unit (IDU), Effective Address Generator (EAG), Memory Management Unit (MMU), Bus Control Unit (BCU), and Execution Unit

(EXU). An Unit is the hardware that corresponds to each pipeline stage. Each pipeline stage operates asynchronously and up to four instructions are processed in various pipeline stages. In following paragraphs, we describe constructions and functions for each Unit.

Fig.1 shows the configuration of functional Units in V60.

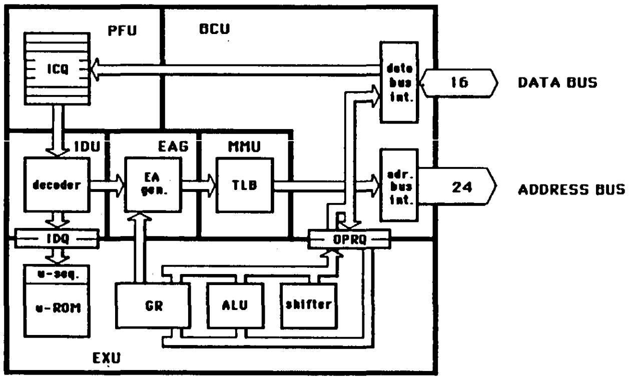

Fig.1 V60 Functional Unit Diagram

2.1.1 PFU (Prefetch Unit)

PFU is the Unit takes charge of instruction code pre-fetch stage preceding to instruction decode and execution stages. PFU has 16B Instruction Code Queue registers (ICQ) and Instruction Code Aligner (ICA). ICQ stores instruction codes transferred from BCU through 16-bit data bus (DBUS).

PFU requires a data transfer request to BCU when PFU detects that more than 4B free area exist in ICQ.

ICA separates instruction code in ICQ to the operation code field, the addressing field, and the displacement field, which are packed into an instruction code.

Fig.2 shows the functional block diagram of PFU.

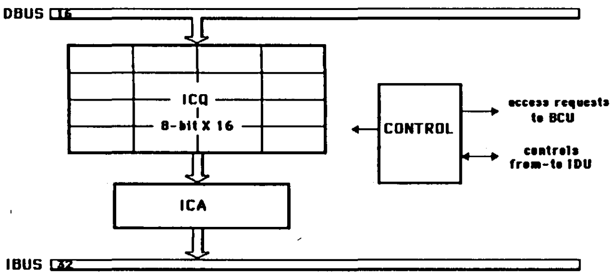

Fig.2 PFU Functional Block Diagram

2.1.2 IDU (Instruction Decode Unit)

IDU is the Unit takes charge of the instruction decode stage. IDU decods the instruction code stored in PFU, and transfers results of the decoding to EAG and EXU. IDU also controls the basic sequence for the pipeline operation.

The instruction decode operations are simultaneously performed for both operation code field and addressing field by the independent decoders.

The results of the decoding transferred to EAG as about fifty output signals that include register, scaling and operand specifying information used for operand Effective Address (EA) calculation. When IDU detects that an instruction needs the EA(s), IDU requests the operand EA calculation to EAG.

In other side, the results of the decoding transferred through Instruction Decode Queue registers (IDQ) to EXU as about fifty output signals that include operand information, arithmetic operation information, and information specifying a microprogram executed for an instruction. When IDU detects that EXU terminates the actual instruction execution, it requests to start of executing of a next microprogram.

Fig.3 shows the functional block diagram of IDU.

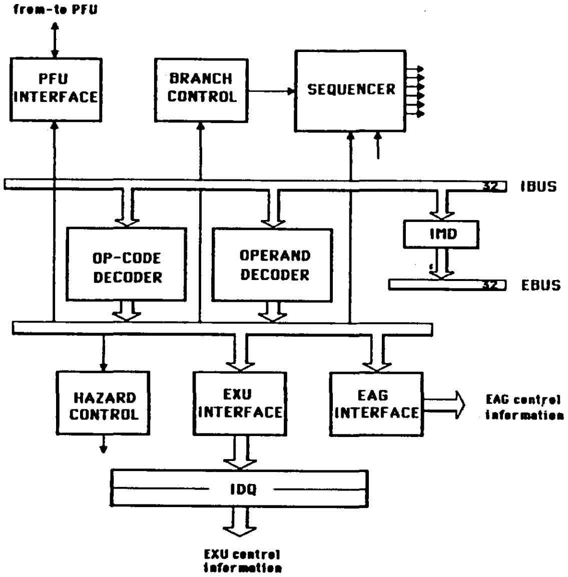

Fig.3 IDU Functional Block Diagram

2.1.3 EAG (Effective Address Generator)

EAG is the Unit takes charge of operand Effective Address (EA) calculation stage. To obtain high-speed EA calculation of 21 addressing modes, EAG adds 4 data stored in EA Temporary registers (EATR0-3) at the same time; base value, index value, displacement, and up-to-date data for pre-decrement or post-increment addressing mode. An adding operation uses high-speed four-inputs 32-bit adder combined with Carry Save Adder (CSA) and Carry Propagation Adder (CPA).

The base and index value of EA stored into the General Purpose registers in EXU are asynchronously transferred through 32-bit data bus (EBUS) for the operation of EXU.

EAG also has Program Counters (PC) to hold the leading address of the instructions corresponding to each pipeline stage. These PCs are up-to-dated at every termination of operation in IDU and EXU, and the contents of PCs are used for EA calculation at PC relative addressing mode.

If a request to calculate EA is transferred by IDU with issuing an external bus cycle, EAG requires the virtual-to-real address translation request to MMU and the access request to BCU. EAG has facility to detect that an access request extends over 2 memory pages (a page is 4KB region), and to calculate new page address and inform it to BCU automatically (Page Boundary processing).

Fig.4 shows the functional block diagram of EAG.

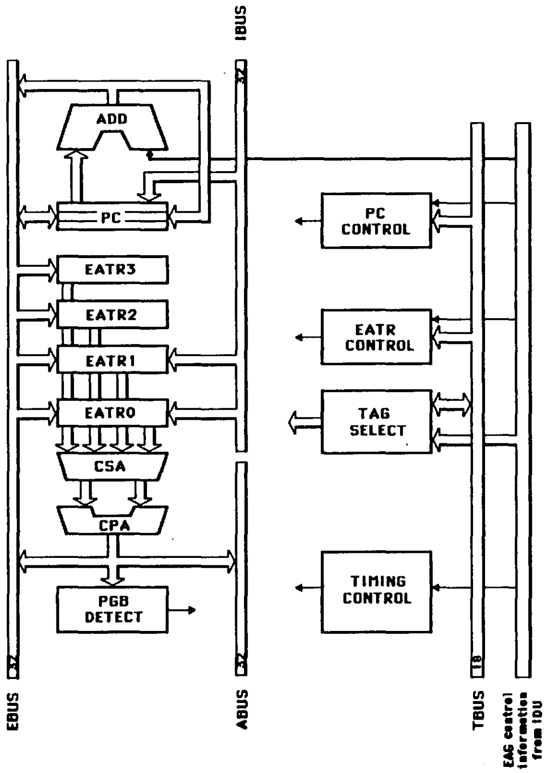

Fig.4 EAG Functional Block Diagram

2.1.4 MMU (Memory Management Unit)

MMU is the Unit takes charge of address translation stage from Virtual Address (VA) to Real Address (RA).

A 4GB VA space is constructed with 3 level hierarchies; Section, Area, and Page. Section is a hierarchy to define basic structure of VA space at construction of multiple-VA spaces, and a VA space has four 1GB-Sections. Area is hierarchy to have common address region privately between VA spaces, and a Section has 1,024 1MB-Areas. Page is hierarchy to realize the Virtual Memory mechanism with Demand Paging method, and an Area has 256 4KB-Pages.

Upper 20-bit of VA (it is called Virtual Page Number) transferred from EAG is translated to 12-bit of upper RA (it is called Real Page number).

This address translation is provided by the Full Associative type Translation Look-aside Buffer (TLB) with 16-entries for high-speed translation. Each TLB entry has 21-bit associative Memory part and 24-bit Data Memory part. 9-bit of the Data Memory part are used as memory protection information (3-bit are used for Page level protection and 6-bit are used for Area level protection), and access rights are checked at the translation.

If no matching entry exists for the translation in TLB, MMU requests to start of a microprogram to replace one of the TLB entries. Pseudo Least Recently Used (LRU) algorithm is used for TLB entry replacement. The TLB achieves about 10^{-2} miss hit ratio (or equivalently 99% hit ratio) in tracing data by computer simulations.

Fig.5 shows the functional block diagram of MMU.

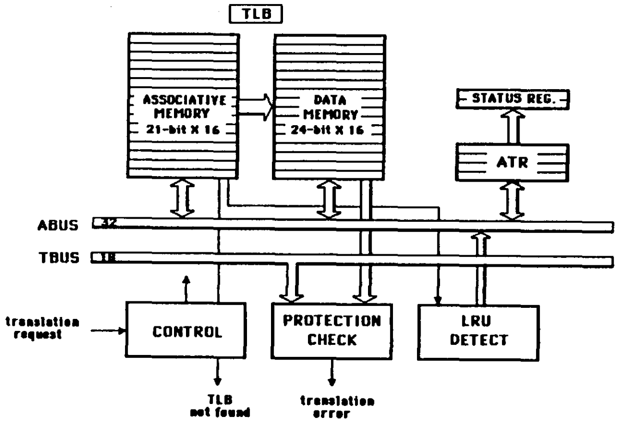

Fig.5 MMU Functional Block Diagram

2.1.5 BCU (Bus Control Unit)

BCU is the Unit takes charge of the external bus access stage for operand read/write and instruction code pre-fetch. BCU takes the interface between V60 and external memory systems or I/O devices regarding the data transfers and pin functions. The requests to issue an external bus cycle from PFU, EAG and EXU are arbitrated by BCU according to specifying of the bus cycle. A request for branch operation has the highest priority, a request for operand read or write operation has next priority, and the lowest priority gives to a request for instruction code pre-fetch operation.

For one operand read/write operation, BCU automatically issue one-to-three external bus cycles according to specified data type and Real Address; 2 bus cycles are issued at a half-word data (16-bit) access for odd address and a word data (32-bit) access for even address, and 3 bus cycles are issued at a word data access for odd address.

Operand Aligners (OWA and ORA) fitly arrange operand data from-and-to EAU. So, EAU can transfer an operand data without any consideration about data type and Real Address.

Two Operand Read registers (OPR) hold data transferred from external data bus until EXU reads out them to reduce idle time in BCU.

EXU transfers the data from OPRs through one of two 32-bit data bus (MBUS and SBUS), operand write to Operand Write register (OPW) through MBUS.

BCU also has the Address Trap facility which is one of the strong software debugging facilities. The Address Trap facility is the mechanism that generates a trap and transfers the control from user's program to a debugging routine when BCU detects that the Virtual Address of an external bus cycle matches pre-determined values. It can select to specify operand read/write and execution (pre-fetch) bus cycle, and two-sets of target address for the Address Trap facility.

Fig.6 shows the functional block diagram of BCU.

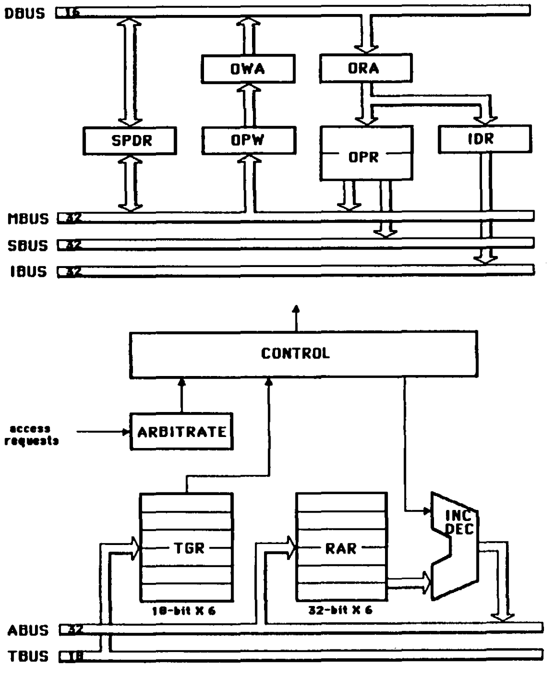

Fig.6 BCU Functional Block Diagram,

2.1.6 EXU (Execution Unit)

EXU is the Unit takes charge of actual execution stage. EXU has thirty-two 32-bit General Purpose registers (GR), sixteen 32-bit Scratch-Pad registers (SPR; parts of them are used for some privilege registers), 32-bit full functional Arithmetic Logic Unit (ALU) with 4 Temporary registers (TEMP), 64-bit Barrel shifter, and some registers for the data processing including Processor Status Word (PSW).

GRs are connected to three sets of 32-bit internal data bus (MBUS, SBUS, and EBUS), and those data buses can be read out the contents of various GRs simultaneously. MBUS and SBUS are used for data paths to transfer two data for ALU operation at the same time. This structure is well known as Dual Bus structure. EBUS is used for Effective Address calculation by EAG. The strong Carry Look Ahead (CLA) circuits are added to ALU to guarantee high-speed operation.

EXU itself is a microprogram controlled machine. A vertical type microinstruction has 32-bit width, and can control 4 control points simultaneously. Microcode is stored in Microcode ROM (MROM) which has 5,184 steps capacity (it equals to 198,108-bit). MROM is addressed by one of Micro-Address registers (MAR). Four 16-bit MARs provide 2^{16} words of addressing space and 4 level nesting structure of Micro-Subroutines.

EXU starts to execute of the microprogram specified by IDU, when IDU terminates the decoding of next instruction. Also a microprogram is activated when EXU detects that an Exception or an Interrupt is requested.

When the execution of a microprogram reaches to the microinstruction for terminating a microprogram, EXU waits its operations until IDU terminates the instruction decoding of next instruction.

Fig.7 shows the functional block diagram of EXU.

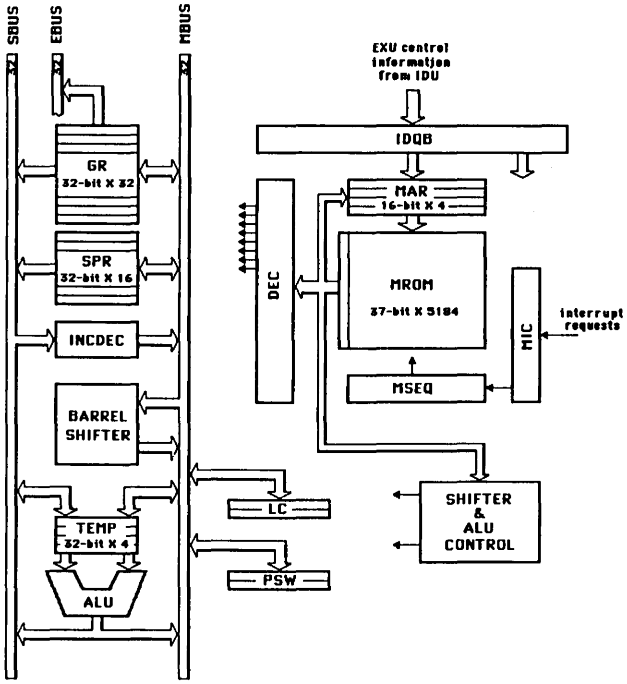

Fig.7 EXU Functional Block Diagram

2.2 Parallel Operation

The basic execution of an instruction in V60 is divided to 7-steps as shown in Fig.8. Fig.8 also shows the Unit corresponding to each step.

In those steps, step-1,5, and 7 are performed by BCU, and each step is sequentially operated. Because V60 reduces the access to slow-speed external resources by employing the General Purpose register architecture and several high-level instructions, the loading of BCU is not so heavy. So, it seldom occurs that BCU is requested to operate for step-1,5, and 7 at the same time.

Also the address translation by MMU in step-4 is always performed following the operand EA calculation by EAG in step-3. In V60 it can assume that the operation time of MMU is not concerned to

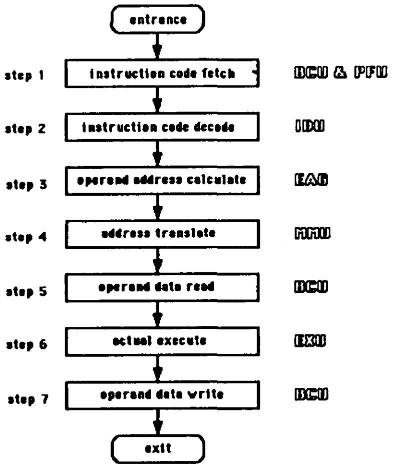

Fig.8 Instruction Execution Flow in Pipeline

the total execution time by employing the high-speed translation mechanism by TLB.

At the some point of the time, step-2,3,6, and one of step-1,5, or 7 are simultaneously performed. So V60 can execute 4 instructions at the same time as shown in Fig.9. Each instruction is executed at every 2 operation clock cycles in the best case. Actually operation time in each pipeline stage changes depend on the instruction to be executed and its addressing mode.

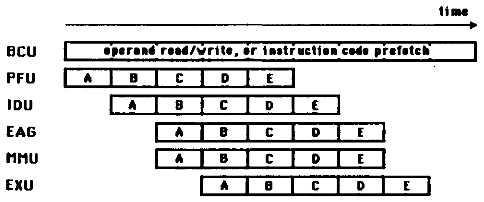

Fig.9 Basic Pipeline Operation

2.3 Queueing Operation

V60 employs the asynchronous pipeline structure considering confliction for the operation time of each pipeline stage. There are some instructions such as the Character-String manipulate instructions which access many operand data in the external memory. In other side, there are some instructions such as multiplication and division instructions which spend much time for their actual execution. In both cases, each pipeline stage might not operate equally; BCU has the heavy loading in the former case, and EXU has the heavy loading in the latter case. V60 avoids the problem that a pipeline stage can not operate depend on the state of other pipeline stages.

To solve above problem, each pipeline stage has the Queueing facility for the next pipeline stage. Under circumstances that each pipeline stage needs different time to operate, V60 avoids the disturbances regarding to other pipeline stages by employing such Queueing facilities.

We describe the Queueing facilities in this paragraph.

1).Instruction Code Queue

PFU has 16B instruction Code Queue registers (ICQ). ICQ stores the instruction code transferred from BCU, when IDU is busy for the instruction decoding. So instruction code pre-fetch operations perform 8 times independent on the state of IDU.

2).Instruction Decode Queue

IDU has the Queueing facility for EXU. Instruction Decode Queue registers (IDQ) stores the results of the instruction decode operation to be transferred for EXU. IDQ is constructed with two sets of the queueing register with about fifty-bit width. So IDU can decode 3 instructions even though EXU is in busy state for actual execution of an instruction.

3).Operand Read Queue

BCU also has the Queueing facility for EXU. Operand Read registers (OPR) are two sets of 32-bit register that store the operand data transferred from the external data bus at an external operand read bus cycle. During actual execution in EXU without an operand read data, BCU can store two 32-bit operand data to OPRs.

2.4 Hazard Detection and Avoidance

The Pipeline Hazard is the obstacle that processing for an instruction depends on the result of execution for preceding instructions in the computer systems with pipeline structure. Detection and avoidance for some types of the Pipeline Hazard regarding that plural instructions are simultaneously executed in various pipeline stages, are general and important problems in the pipeline structure.

The Pipeline Hazard problems that may occur in V60 and the solutions for them are described as follows.

1).Register Hazard

The Register Hazard occurs when preceding instruction uses the contents of General Purpose registers (GR), which are changed by the actual execution of an instruction in EXU, for operand Effective Address (EA) calculations in EAG as base or index value.

Register Hazard detector (RHD) in IDU detects Register Hazard and controls each pipeline stage to avoid it.

2).Flag Hazard

The Flag Hazard occurs when preceding Conditional Branch instruction refers the Conditional flag(s), which is changed by actual execution in EXU, of PSW.

Flag Hazard detector (FHD) in IDU detects Flag Hazard and controls each pipeline stage to avoid it.

3).Memory Hazard

The Memory Hazard occurs when an operand read data or part of it is referred by preceding instruction is changed as the operand write data by actual execution in EXU. Memory Hazard detector (MHD) in BCU checks that the EA for the requested operand read operation has overlapped area with the EA of the expected operand write operation. When MHD detects existing of the overlapped area, BCU cancels the request for the external operand read bus cycle.

Also BCU directly transfer the operand write data in Operand Write register (OPW) to Operand Read register (OPR) as the operand read data using Short-Path, after EXU performs the actual operand write operation. Then an extra operand read bus cycles are not issued.

4).I/O Hazard

The I/O devices are usually connected to V60. They change their internal status through the reading operation by the CPU. In these case, read operations can not retry. If preceding operand read operation (I/O read bus cycle) occurs before the actual execution of an Input instruction (including the instruction which accesses the memory-mapped I/O) starts, an incovenience that it can not perform to retry for the I/O devices may happen. It is that even through an Input instruction is cancelled by requests of some Interrupts or occurring of some Exceptions, the internal status of an I/O device is already changed by the preceding operand read operations.

I/O Hazard detector (IOHD) in EAG always check that the operand read operation for the I/O device is requested. If IOHD detects the request for the I/O devices, EAG instructs to hold the following requests for the operand read bus cycle until EXU starts to execute an Input instruction.

2.5 Exception and Interrupt Handling

The Exception and Interrupt handling are another general problems in the computer systems with pipeline structure and Virtual Memory mechanism.

In the view point of pipeline structure, these are the problems what Unit detect them and when accept them. Basicly an Exception/Interrupt that is detected in earlier pipeline stage than actual execution stage is hold to accept until the actual execution begins. An Exception/Interrupt in the middle of actual execution is accepted only when the internal state of each pipeline stage are guaranteed to hold during execution of Exception/Interrupt processing.

In the view point of Virtual Memory mechanism, these are the problems also what Unit detect them, when accept them, and how restart the instruction. An Exception regarding the Virtual Memory mechanism like Page-Fault is detected in MMU preceding actual execution. Actual execution for the instruction with the Exception is not performed. So, V60 can restart this instruction from top of it after execution of Exception processing.

1).Abort for Pipeline Processing

Basicly an Interrupt request is accepted at the end of actual execution in EXU for an instruction. The Exceptions regarding an instruction, which are detected preceding the actual execution, are accepted just before the actual execution begins. In both cases, an instruction is not aborted in the middle of actual execution except the instructions with continual operand accesses such as String instructions.

EXU checks Exception/Interrupt requests at the end of actual execution for an instruction, and activates a microprogram for them independ on the status of other Units.

2).Suspend for Exceptions

The Exceptions regarding an instruction, which are detected in the preceding pipeline stage, are suspended to accept until the instruction is guaranteed for the actual execution. Page-Fault at the pre-fetch operation and Memory Management Exceptions at operand read operation are good examples for them.

Instruction Decode Queue (IDQ) has some information regarding the Exceptions detected in the preceding pipeline stages. EXU checks the exist of pre-detected Exceptions before the start of actual execution for an instruction.

3).Abort and Restart for TLB not-found

If no match entry exists for the address translation of a memory operand (read/write) in TLB, actual execution sequence is basicly aborted by same manner as Exception/Interrupt. For some instructions such as String instructions, which follow the address translations for memory operands during the actual execution, the execution is aborted in the middle of actual execution.

For both cases, the operations in each pipeline stage are frozen and can be restarted after the processing of the TLB entry replacement from original status.

4).Abort for Executing Instruction

There are two cases that an instruction is aborted in the middle of actual execution. First case is serious Exception like Reset. In this case, the state of each pipeline stage is not kept.

The other case is an Interrupt during the execution for a complex instruction such as String instruction with longer actual execution time than that of basic instructions. In this case the aborted instruction can restart after the interrupt processing. EXU checks an interrupt request at some points of actual execution.

2.6 Other Features

V60 has some other features regarding the pipeline structure to obtain the high-performance.

1).Branch Instruction Processing

The execution speed of a branch instruction is the most effectively for the computer with the pipeline structure, because such instruction avoids the advantages of preceding executions. Because a pipelined machine that executes a branch instruction seems as non-pipelined machine. In general, branch instruction must be detected and executed in earlier pipeline stage than the actual execution stage.

V60 executes branch instructions in IDU. IDU instructs PFU to cancel the validity of pre-fetched instruction codes in ICQ, EAG to calculate the target branch address and transfer the value to a PC in EAG, and BCU to restart the instruction code fetch operation, when IDU detects a branch instruction; EXU operates for the termination of the actual execution of a branch instruction.

2).Burst String Read Operation

To increase the external bus traffic more effectively, BCU has a facility for the preceded operand reading. For such data structures located in memory space continuously and linearly as the Character-String data type, the next addressed data has high probability to be accessed as a data is accessed.

BCU automatically issue the operand read bus cycle in the Burst String mode, as no data is in OPRs independently on the request from EXU. BCU also up-to-dates the address in a RAR for the next operand.

EXU can get the next operand read data during the data processing for the current operand read data.

3).Floating-Point Operation Support

To obtain the excellent performance for Floating-Point arithmetic operations, several hardware supports are provided in EXU.

The 64-bit Barrel shifter does not only shift and rotate a 32-bit data in one operation clock cycle (including logical-shift, arithmetic-shift, and extended rotate operation), but extracts a 32-bit data started from any bit-position in a 64-bit data. The Barrel shifter is used for the scaling operation of a Floating-Point data processing.

The Leading-One detector finds the bit-position, which is the first bit has logical-one value leading from LSB or MSB in a 32-bit data, with high-speed. This Leading-One detector is used for the normalizing operation of a Floating-Point data processing.

The Second-Order Booth's algorithm is implemented for the high-speed multiplication operation. Then the multiplication operation for 32-bit integer is executed in 16 operation clock cycles.

3.Conclusion

In this paper, we described the internal structure of the 32-bit CMOS microprocessor V60, focusing on the pipeline structure and related issues.

Integration of Memory Management Unit and Floating-Point operation on a single chip decreased unnecessary overheads that were typical by multi-chip configuration in earlier generation of 32-bit microprocessors. The pipeline structure is an asynchronous type, i.e., execution time of each pipeline stage may vary, depending on instruction set function. Smooth operation in the pipeline was achieved by designing queueing interfaces among pipeline stages.

The structure was realized by an advantaged VLSI technology, based on 1.5um design rule, double-metal layer CMOS process. It provided not only high-integration density, but higher clock speed due to the shortened propagation delay. Table-2 shows the number of transistors for each pipeline Unit, and Table-3 shows the operation speed of typical circuits.

Unit	Transistors (X1000)	
PFU	4	
IDU	35	
EAG	15	
MMU	17	
BCU	39	
EXU	65	(except u-code ROM)
	200	(u-code ROM)
total	375	

Table-2 Transistors in Each Unit

functional circuit	operation speed (typical)
ALU (32-bit)	15nS
barrel shifter (64→32-bit)	13nS
microcode ROM (37-bit, 5184 steps)	24nS
TLB (16 entries)	36nS

Table-3 Circuit Operation Speed

The V60 chip integrates 375,000 transistors (or equivalent to 45,000 logic gates) on 13.92mmX13.80mm die size. It operates at 16MHz clock rate.

Acknowledgements

The limited space does not allow the authors to list all of the project members to design and implement V60. Instead, they would like to thank M.Suzuki, J.Iwasaki, Y.Sato, T.Iwata, and Y.Yano for their helpful suggestions. They are also indebted to H.Sasaki, K.Kani, J.Takashima, and K.Shimamura for their support throughout the project.

Abstract

A new ASICs (Application Specific ICs) design methodology, called Advanced Super Integration, is presented which allows short-time, one-chip integration of user-built systems created utilizing general-purpose LSI products as cores. Advanced Super Integration uses a hierarchical automatic layout system, a real chip simulator as a system verification method, advanced double-level aluminum CMOS technology, and an enriched CMOS cell library.

[1] Introduction

Continuing progress in device miniaturization is driving LSI packing density to a true "system-on-a-chip" level, where customization for a particular application becomes crucial in order to realize a maximum cost-performance ratio.

To meet the emerging demands for Application Specific ICs (ASICs) in a way that is easily accessible to the system designer, the authors developed a kind of core-based design method which was called Super Integration[1]. Super Integration (SI) has been aimed at reducing design cycle times, costs and risks. Double-level aluminum CMOS technology and a series of CAD software units are the major driving forces for SI implementation. CAD software includes TAPLAS[2],[3] (Toshiba Automatic Pattern Layout and Analysis System) as an automatic layout system, EMAP[4] (Extended Mask Analysis Program) as DRC (Design Rule Checker), and MACLOS[5],[6] (Mask Check Logic Simulator) as a logic simulator.

Furthermore, a new design methodology, called Advanced Super Integration, has been developed which is more progressive than conventional SI. Advanced SI is achieved owing to the introduction of the following new technology factors:

(i) Hierarchical aTAPLAS (aTAPLAS-II: advanced Toshiba Automatic Pattern Layout and Analysis System II), which can be used as an automatic tool to generate the layout of a whole chip.

(ii) Real chip simulator, which enables a designer to simulate a whole chip, including large-scale function blocks, such as an 8-bit microprocessor (MPU).

(iii) More advanced double-level aluminum CMOS process, which realizes high packing density and high speed performance.

Advanced Super Integration, whose scheme is shown in Fig. 1, has the following key features.

(1) Standard products, such as microprocessors, peripheral LSIs, RAMs, and A/D converters can be utilized as super macrocells.

(2) The super macrocells and custom circuit blocks, which provide a customer with design flexibility, are designed hierarchically with aTAPLAS-II, using a super macrocell library and a standard logic library.

(3) They are incorporated on the same chip and interconnected by double-level aluminum technology.

An example of an Advanced SI chip is given in Fig. 2. The chip functions as a hard disk con-

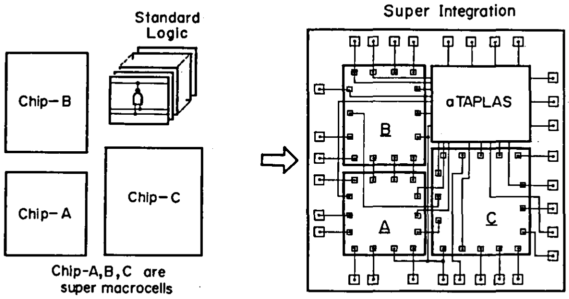

Figure 1 Super Integration Scheme

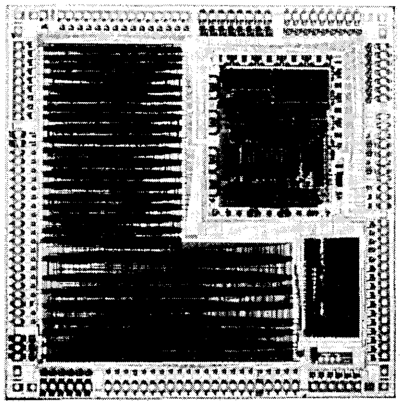

Figure 2 Hard Disk Controller Microphotograph

troller (HDC) and includes the authors' CMOS version of an 8-bit MPU, 128-Byte Timing RAM (TRAM), and 7 k gates for standard logic. It was fabricated with double-level aluminum technology and the 2.0 μm design rule CMOS process. Die size is 95.1 mm^2.

Only 3 man-weeks were spent in designing this chip, from the circuit design to the mask data generation. This fact proves the advantage of using Advanced SI technology.

[2] Design Methodology

The design procedure for an Advanced SI chip is described in this section. Figure 3 shows the general flow in Advanced SI, in comparison with a conventional SI.

2.1 System Design

Advanced SI allows a designer to define a VLSI chip in a hierarchical net-list form of predefined CMOS cells. There are two kinds of cells in Advanced SI. The first category, called macrocells or polycells, implements SSI/MSI-level function. The second category, called super macrocells, is a cell for a large-scale function. Super macrocells implement a high degree of function, such as microprocessors and other peripheral LSI parts.

The designer can design an Advanced SI chip on an engineering workstation (EWS) and create a TDL (TEGAS Design Language) file. This file is uploaded to the mainframe. Figure 4 shows an example of a system-level schematic, designed on an EWS.

Figure 3 Design Method Overview

2.2 System Simulation

When developing a conventional LSI, logic simulation is carried out for the entire system. However, since a Super Integration chip includes super macrocells as large-scale function blocks, a simple simulation method is not applicable to the SI chip.

One possible method is the gate-level software modeling which works so well for super macrocells embedded in the SI chip. The gate-level modeling normally becomes unsatisfactory for the SI chip, mainly because of the computing time needed to simulate the functions of microprocessors and other peripheral LSIs.

The solution for simulating the entire SI chip is to let super macrocells model themselves, which is called a real chip simulator. This real chip simulator is usable on several kinds of EWSs. Advanced SI allows a designer to implement the system verification with the real chip simulator. The real chip simulator does not need detailed gate-level modeling for super macrocells, but requires only their pin descriptions. Since the designer needs to see only the pin information for

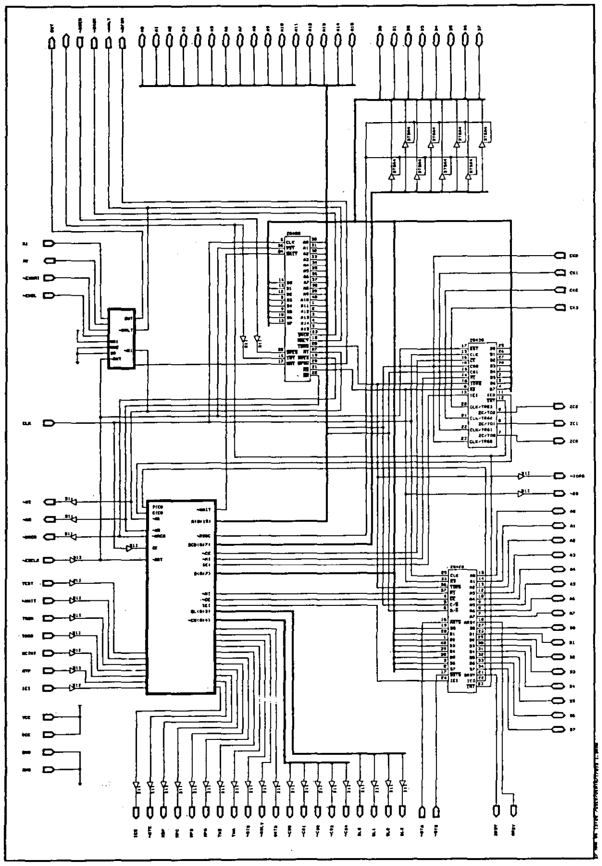

Figure 4 An Example Showing System-level Schematic on an EWS

super macrocells, as shown in Fig. 4, the access level is limited only to the information displayed on the EWS.

Figure 5 shows an example of a simulation output result obtained by the real chip simulator, corresponding to the waveforms from an 8-bit microprocessor.

2.3 Automatic Layout

In a conventional SI, the custom circuit block layout is generated automatically with TAPLAS. The generated custom circuit block can be treated as one of several super macrocells. Interconnection among super macrocells, including the custom circuit block, is performed manually using the graphic editing system.

In the advanced SI, the whole chip layout design is achieved hierarchically using a hierarchical automatic layout system, aTAPLAS-II[7]. This layout system can be divided into three parts: floor planning, automatic layout planning, and polycell block layout.

In floor planning, with the support of the mainframe computer, an engineer can pre-define the following items: 1) the method to partition the system into blocks, defined as clusters of polycells, 2) the global placement of blocks, and 3) the wiring routes for principal signals (e.g. power lines).

In automatic layout planning,[7] the polycell block dimensions can be estimated. Also, the global router attempts to minimize the die size, both by optimally assigning interconnection requirements to channels and by allocating block terminals not only on the block's boundary, but also in its internal area.

Polycell block layout proceeds after the determination of terminal positions, in the same manner as in TAPLAS. Then detailed inter-block routes proceeds. Finally, the detailed over-block routes are also laid out by aTAPLAS-II.

As shown in Fig. 6, layout for a HDC chip is performed automatically, after which part of the layout is modified manually. Some pin locations and related wiring were changed, due to the physical technology and area saving requirements. The result of these modifications was about 5 % reduction in die size.

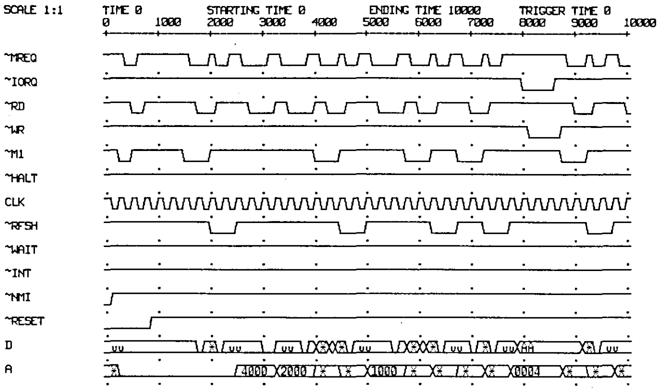

Figure 5 An Example Showing Real Chip Simulation Results

2.4 Design Verification

Design Verification need not be performed in case all the databases of an Advanced Super Integration chip are generated automatically.

However, if parts of the laout are carried out on the mask layout level, as in the case of the HDC chip, or if interconnections are altered manually, design verification tools have to be run. These tools include DRC (Design Rule Checker), ERC (Electrical Rule Checker), and a logic simulator.

For logic simulation, MACLOS (Mask Check Logic Simulator), unit delay switch level simulator, is applied to the transistor network extracted from the final mask database by EMAP (Extended Mask Analysis Program). In the near future, Toshiba is going to introduce an after-layout simulation using estimated routing capacitance and loading.

[3] Cell Library

Since Advanced Super Integration is generally used in a large-scale system, it is essential that a cell library be designed with CMOS technology, both to prevent too much of an increase in power consumption and to promote device miniaturization. The two kinds of cell libraries advocated, macrocell library and super macrocell library, use C^2MOS (Clocked CMOS) circuitry[8]. Thus each cell library has electrical characteristics of low power consumption, high-speed performance, and high packing density.

Each standard product is designed according to the same drawing rule. Its mask data is to be linearly shrunk on the drawn-level data in order to obtain reasonable die size and high performance. Utilizing the drawn-level data for a standard product as drawn-level data for a super macrocell in Advanced SI, the global and most updated shrinkage rate can be selected; even if the actual shrinkage rate for the standard product is different from others.

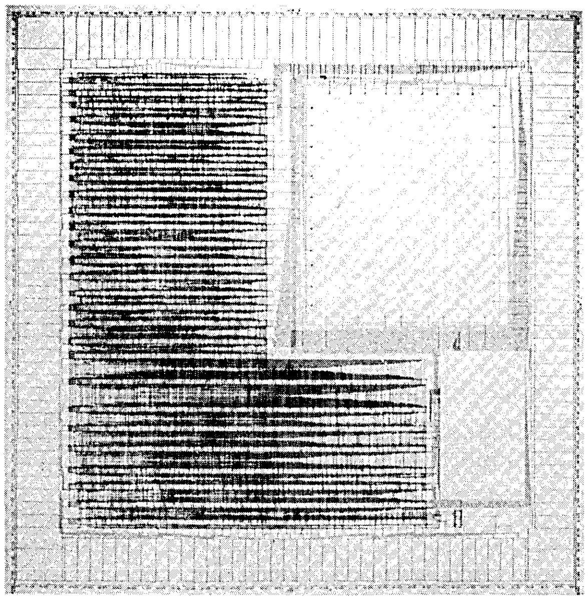

Figure 6 HDC Chip Layout Result

The authors macrocell library includes SC library and SI library. The two are functionally equivalent, but not electrically. In regard to gate propagation delay time, the SI library is inferior by at worst 20 % to SC library according to SPICE simulation results. However, in regard to packing density, the SI library is about 1.5 times as much as the SC library. The reason is that the SI library has smaller dimensions than the SC library and allows over-block routes, as shown in Fig. 7. These libraries allow a designer to select and use either of the two, considering a trade-off between die size and AC performance.

In the above real chip simulation, the performance data for each macrocell, which includes $T_{PHL}$and T_{PLH} equation with variables for fan-out and capacitive load, is needed in order to perform timing verification. Figure 8 shows an overview of the procedure to extract performance data for macrocells automatically from the mask level layout. Transistor network and load information are generated from the layout data and then transformed into SPICE format, based upon the process parameters. SPICE simulation results are compiled in the LDDL (Library Data Description Language) format. The LDDL file is uploaded to the mainframe computer and the EWS. This file is used as performance data for logic simulator and timing verifier.

The super macrocell library includes the complete 8-bit MPU family, DMA controller, UART, I/O controller, VDP, FDC, CRT controller and other peripheral controllers. In addition, 16k/8k/2k/1k-bit RAMs and 8-bit A/D converters are included in the library. 28 super macrocells are available at 1.5 µm / 2.0 µm design rules. These super macrocells are functionally compatible with the corresponding standard LSIs. They have a large AC margin to specification and conform very well with Advanced SI approach. The authors have been designing these super macrocells, without stripping away the bonding pads and large output buffers, considering compatibility with existing standard LSI parts.

[4] Testability Design

In an Advanced SI chip comprising several super macrocells, testability, especially for embedded super macrocells, is one of the major concerns. As shown in reference [1], a conventional SI can gain direct access to each of embedded super macrocells with "cutset circuitry", which includes multiplexers, transceiver logic and other circuits modifying the peripheral circuits around the terminals. In testing a conventional SI chip, entire chip tests follow testing individual super macrocell by a developed test program and testing custom circuit block by a newly-developed test program.

The new test method described in the following has been considered and adopted. This new cutset logic includes additional circuits, which let embedded input signals to the embedded MPU lead to the outside. Connecting the led signals to the corresponding terminals of an existing standard MPU allows a user to emulate the embedded MPU using the standard MPU.

Test efficiency for both user and vendor is achieved with this cutset logic.

[5] Advanced Super Integration Performance

As described in Section 3, the cells and all the standard products for logic LSIs are designed according to the same drawing rule, each of which has a different design rule in the fabrication process. So, it is possible for all standard procucts to be used as super macrocells. The standard products are released after they are evaluated in the same fabrication process as Advanced SI.

Since an Advanced SI chip normally uses databases whose design has been finished and whose performance data has been guaranteed, the Advanced SI chip performance greatly depends on that of the super macrocells. Generally, the LSI performance is determined by both its fabrication process and design level. Since the design level for super macrocells has been fixed, the Advanced SI chip performance mainly depends on its fabrication process.

The relationship between performance and fabrication process will be explained in the following. The progress in the fabrication process has covered the range from 3.5 μm to 1.5 μm design rule. The authors' consistent scaling philosophy allows these processes to be applied to all the super macrocells and Advanced SI chips. Figure 9 illustrates the progress by an example of an 8-bit MPU which is the authors' CMOS version. In 2.5 μm, 2.0 μm and 1.5 μm design rule processes, respectively, the maximum operation frequency is obtained at around 1.3, 2.8, 3.4 times as many as in 3.5 μm process. The power supply current is reduced by around 30 %, 45 %, 50 %, compared with that in the 3.5 μm process.

Individual 2.5 μm, 2.0 μm and 1.5 μm design rule processes allow developing an SI chip embedding 4 MHz, 6 MHz, and 8 MHz version, respectively, of the MPU.

[6] Estimation Results

A design procedure for Advanced Super Integration has satisfied the purpose of reducing the design cycle times, costs and risks, through design automation. As an example of an HDC chip design, the results of an Advanced SI chip design are discussed in the following.

(1) Design cycle time

As shown in Fig. 10, it took only 3 man-weeks to complete the design, from starting the circuit design to making up the EBMT (Electron Beam Magnetic Tape) for mask fabrication. As mentioned before, the layout on the chip corner was accomplished manually at the mask layout level. Also, parts of the interconnections were manually altered, so that an extra 4 man-days were expended on interactive editing.

It is estimated to take nearly one year, for three or four talented engineers, when design is performed by conventional hand-craft method. The approach by SC (Standard Cell) or SOG (Sea of Gate) seems close to the same time as in the Advanced SI approach. However, since it is impossible to describe super macrocells, e.g. and 8-bit MPU, by gate-level modeling, neither the SC nor the SOG approach is generally practical in this case. Advanced SI design method and a conventional SI design method are a practical way to realize a chip which include existing standard LSIs. In the conventional SI, it took 4 man-weeks to complete the design, according to reference [1]. Advanced SI realized 25 % reduction in design cycle time.

(2) Die Size

Automatic layout on the HDC chip took around 1.4 CPU-Hours (on a 7-MIPS computer). The die size obtained by it was 5 % larger than the final die size, which was 95.1 mm^2, as before. Figure 11 shows the die size prediction for the HDC chip with several design methods at both the 2.0 μm and 1.5 μm design rule levels, where SOG is available for the HDC chip only in the 1.5 μm design rule process. It is clear, in Fig. 11, that Advanced Super Integration is superior to SC and SOG, although it is inferior to the hand-craft design in the die-size point of view. This high density comes from usage of super macrocells, which had been manually designed, in order to minimize the number of transistors and to integrate with high packing density.

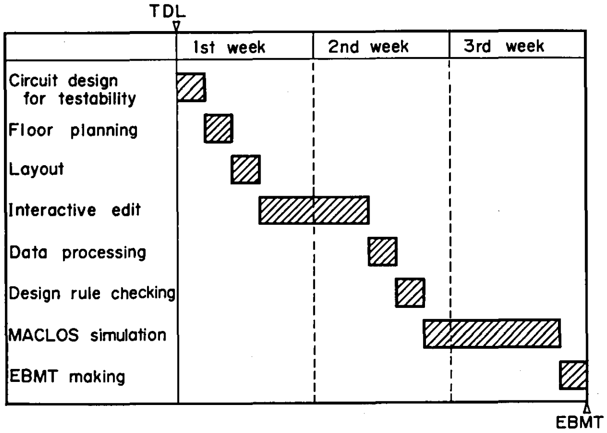

Figure 10 HDC Chip Design Cycle Time

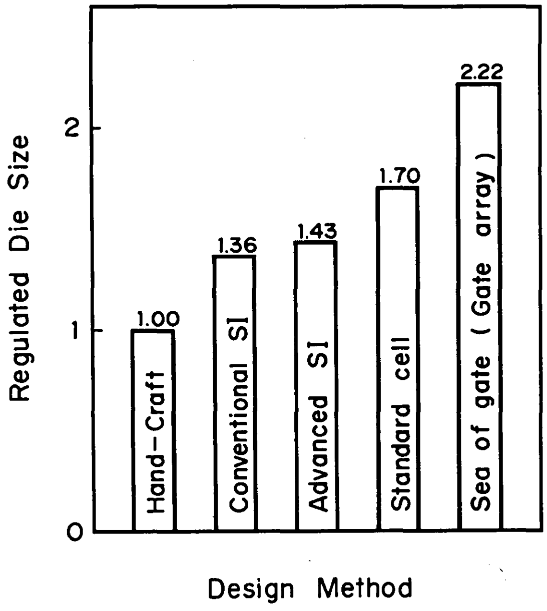

Figure 11 Die Size Comparison

Conclusion

A design method, called Advanced Super Integration, that utilizes high performance microcomputers as cores and that is particularly suitable for ASICs, is proposed and discussed. Advanced SI advantages are discussed in comparison with a Conventional SI. Some of them, especially in regard to the design methodology, are a whole chip simulation on an EWS and an automatic layout by hierarchical aTAPLAS, which realizes both very short design cycle time and high packing density. High speed performance is also achieved, using 1.5 µm double-level aluminum CMOS technology. This design method seems to provide a new field for VLSIs.

ABSTRACT

This paper describes a newly develped microprocessor architecture, which we call a multi-register bank architecture. To accelerate a task switching speed, a microprocessor includes multi-register banks, each of which consists of sixteen general purpose registers.

In the multi-register banks, there are two types of banks. One is a global register bank assigned to an individual task and the other is a ring register bank asigned to a task called by a procedure call like subroutines.

The microprocessor incorporates an orthogonal instruction set with complex and reduced formats to achieve high code efficiency for high-level languages.

INTRODUCTION

Rapid progress in semiconductor technology, in particular, MOS technology, has made it possible to fabricate highly integrated microcomputers that exceed 100 thousand MOS transistors. Microcomputers with many peripheral functions are appearing on the market which reduce system cost and increase system performance. Presently, 8-bit machines are the most popular because of their excellent cost/performance ratio.

However, many applications are beginning to require new generation microprocessors with higher performance which advanced semiconductor technology helps to provide. Several 16-bit microprocessors have been utilized in high-end applications for controllers, and development focus is moving to 16-bit machines.

A real time processing capability is vital for microprocessors serving as controllers. In the real time processing, tasks are switched frequently according to events, e.g., interruptions from I/O devices and software interruption. In microprocessors, not only execution speed of instructions, but the speed of task switching must be improved to achieve high performance at the system level. Additionally, software productivity must be improved. To do this, application programs should be described using popular, high level languages and microprocessor architecture should help in their effective execution.

In this paper, descriptions are given of an architectural concept, and an architecture for real time processing and for a high level language support of a 16-bit microprocessor.

ARCHITECTURAL CONCEPT

HIGH SPEED TASK SWITCHES

One of the main jobs of the conroller is control for I/O devices. Interruptions from I/O devices drive the corresponding tasks. They occur frequently and new tasks are then driven each time. There are many cases in which switching time of the tasks dominates system performance, even though instructions are executed at high speed. Thus, breakthroughs in microprocessor archiecture are required.

SOFTWARE PRODUCTIVITY

Another consideration in microprocessor architecture is software producivity. In the past, mainly assembling languages have been used to describe programs in control applications, as only they made it possible to achieve the maximum performance through their machine dependent functions. As control applications have now gone on to a higher level, software productivity becomes more important. Instead of the assembling languages, high level languages are becoming popular among many software designers.

PROCESSOR ARCHITECTURE

BASIC ARCHITECTURE

Our 16-bit microprocessor is based on a general register machine with a multi-register bank architecture. No distinction between address registers and data registers exists in the general purpose registers. A set of general registers composes a register bank, and plural banks exist in the microprocessor. The addressable memory space of the microprocessor is linear and currently 16M bytes with 4G bytes anticipated in the future. Byte-oriented instructions based on orthogonal and variable length concepts include complex and reduced formats, in order to achieve both high level functions and simple operations. Memory to memory operation is available in most of the instructions.

REGISTERS

The microprocessor registers are shown in Fig.1. It consists of sixteen 32-bit general purpose registers and six 32-bit special purpose registers, a 16-bit status register and three 8-bit special purpose registers. The 32-bit special purpose registers include a program counter (PC), a supervisor stack pointer (SSP), an exception vector base register (EVBR), a RAM relocation base register (RRBR), a bank stack pointer (BSP) and a current bank number register (CBNR). The 8-bit special purpose registers include a bank mode register (BMR), a global bank number register (GBNR) and a valid bank number register (VBNR).

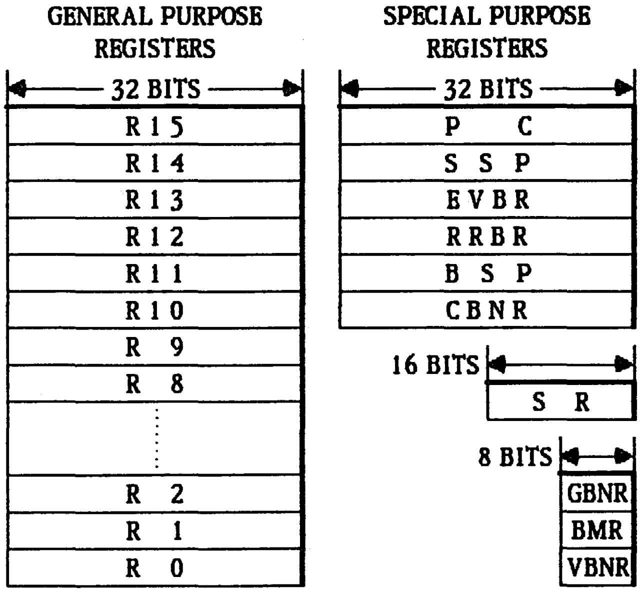

Fig.1: Microprocessor Registers

MICROCHIP ARCHITECTURE

The microprocessor is a microcoded processor and its general purpose registers are implemented in a centralized RAM, which we call a RAM-based architecture. The microprocessor (Fig.2) consists of a memory access processor (MAP), an instruction execution processor (IEP) and a RAM. Each processor consists of an execution unit and a control unit that includes a microprogram memory (ROM). The internal buses are 32 bits wide to ensure high performance.

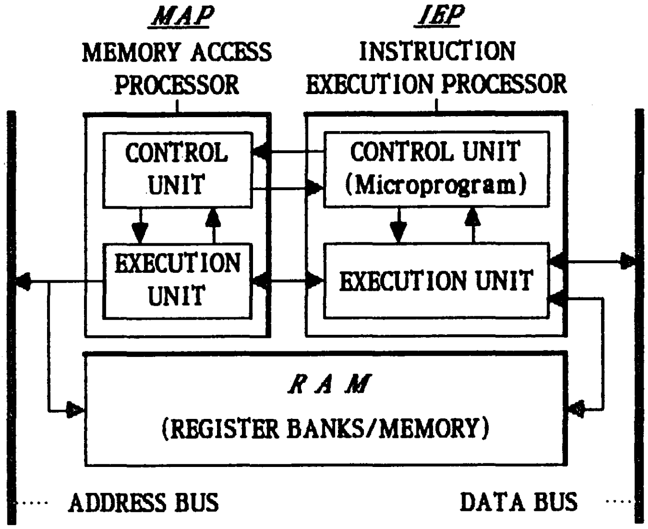

Fig.2: Microprocessor Architecture

MULTI-REGISTER BANK ARCHITECTURE

CONCEPT OF NEW ARCHITECTURE

To achieve high speed task switching, one problem encountered is overhead time for saving contents of the general purpose registers in a main memory and resuming them. In a microprocessor with a single register bank architecture (a conventional architecture), the sequence shown in Fig.3 is performed when one task i switches to another task j. In this case, the microprocessor

--- Saves the contents of the general purpose registers for task i in the main memory.
--- Loads new data from the main memory to the general purpose registers for task j.
--- Executes task j.
--- Resumes the data for task i, which were saved in the memory before task j started to execute, and returns them to the general purpose regis-

ters.
--- Starts task i again.

When the microprocessor executes multi-tasks, task switches occur frequently. These reduce system performance, even if execution speed of instructions is fast. To cut the task switching time, the volume of data transferred between the general purpose registers and the memory should be minimized. To realize this, a multi-register bank architecture has been developed. A register bank, which consists of sixteen 32-bit general purpose registers, is given to each task. Saving and resuming the registers disappear. Thus, the switch between tasks i and j can be performed immediately.

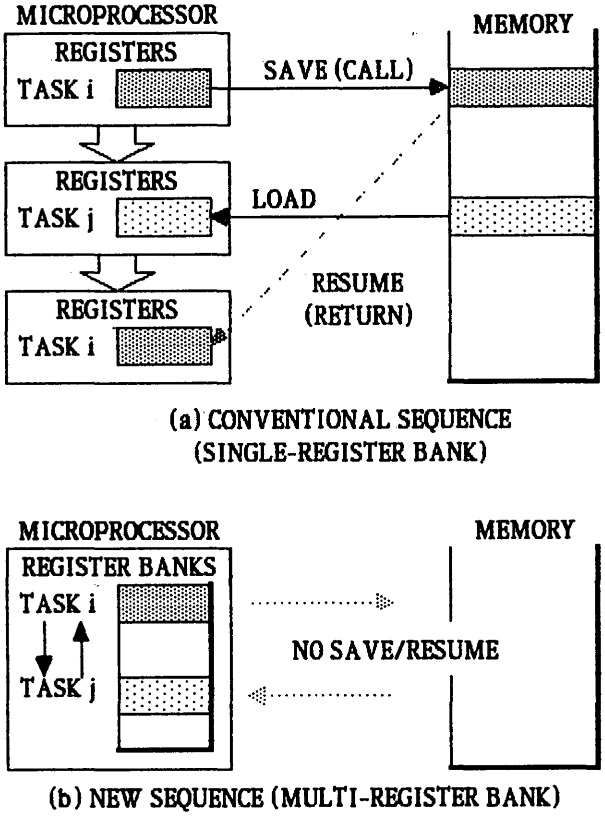

Fig.3: Task Switching Mechanism

PROGRAMMABLE REGISTER BANK

The number of register banks differs with the applications. So, it should be large enough and also programmable by software. The number of register banks can be set to 2, 4, 8, or 16. Therefore, the register banks are implemented in a RAM. When the number is small, for example, in a single task, the rest of the RAM is available to be used as an on-chip high speed memory, as shown in Fig.4.

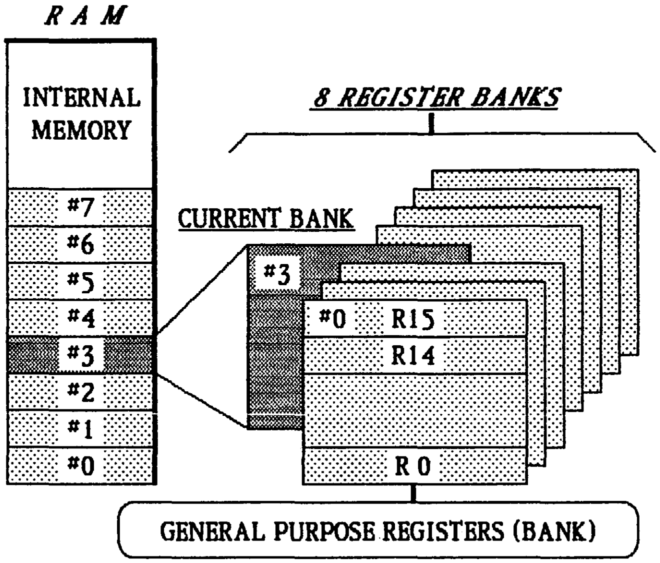

Fig.4: Multi-Register Bank Architecture

GLOBAL REGISTER BANK

One event driven task is independent of others in many cases. One register bank is given to each task. The register bank is designated a Global Register Bank (GRB). In order to switch from one register bank to another, the Global Bank Number Register (GBNR) must be updated by the software (a special instruction).

The register bank switching mechanism is as follows. When a certain event caused by a software interruption (e.g. macro instruction call) or a hardware interruption (e.g. interruption from I/O devices) occurs, an operating system is called and task switching is performed. In Fig.5, GRB #1 is given to the current

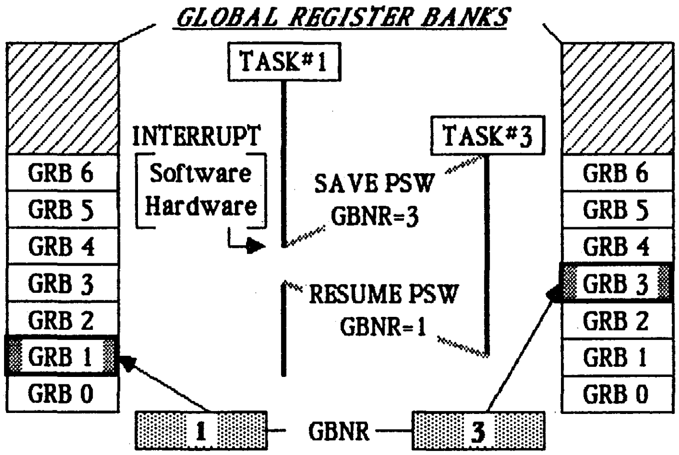

Fig.5: Operation of the Global Register Banks (GRBs)

task #1 and GRB #3 is given to the next task #3. A switch from the current task #1 to the next task #3 is performed by saving the current PSW (Program Status Word; a program counter and a status register) in a predetermined area of the main memory and updating the contents of the GBNR from 1 to 3. It is unnecessary to save the contents of the current GRB, so task switching time is minimized. To return from task #3 to task #1, the contents of the GBNR are updated from 3 to 1 and the old PSW is resumed.

RING REGISTER BANK

In programs described with high level languages, procedure calls and returns often occur. In this case, a stacking mechanism is required. The multi-register bank architecture can be applied to this mechanism, as shown in Fig.6. The top part of the stacks (on the main memory) should be maintained in the multi-register banks, like an on-chip stack memory. These register banks are called Ring Register Banks (RRBs).

When one of the GRBs requires a new register bank via a procedure call, the lowest part of the RRBs is given to the called task. The rest of the RRBs is given to the following tasks. Addressing modes of the microprocessor support three types of register accesses, the GRB, the current RRB and the previous RRB.

The maximum number of RRBs is eight. When an overflow occurs in them, the contents of the least recently used RRB are saved in the main memory and data for the new task are loaded in the open RRB. When an underflow occurs, all of the RRBs are open. In this case, the most recently used data in the memory are loaded in one of the RRBs. In execution of some benchmark programs, the occurrence ratio of overflows or underflows is less than 10%.

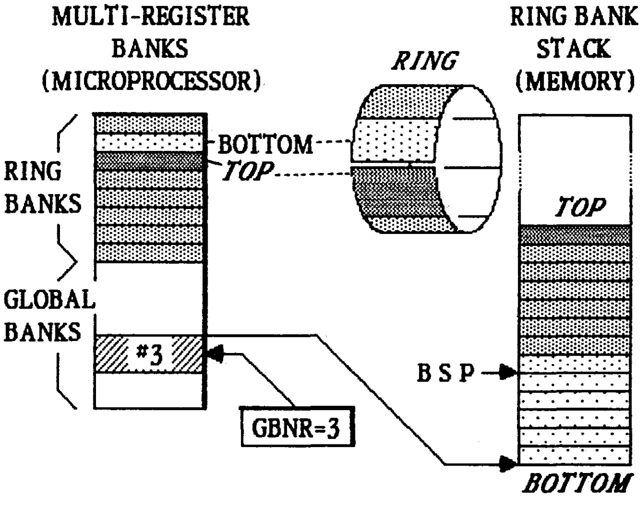

Fig.6: Operation of the Ring Register Banks (RRBs)

ORTHOGONAL INSTRUCTION SET

BYTE ORIENTED INSTRUCTION FORMAT

The instruction format is designed on an orthogonal and variable length concepts. A basic instruction is availble to specify two memory operands. As shown in Fig.7, basic instructions are composed of four fields. The first is an operation code (OP) which specifies the processing function. The second is an operand size (sz) field which specifies the size of the processed operand. The third is an effective address (EA) field which consists of seven bits and specifies the location of the processed operand. An accumulator bit (A) is used to specify an accumulator (R0) as the implied second operand. When this bit is one, the accu- mulator becomes the second operand and the second EA field is omitted.

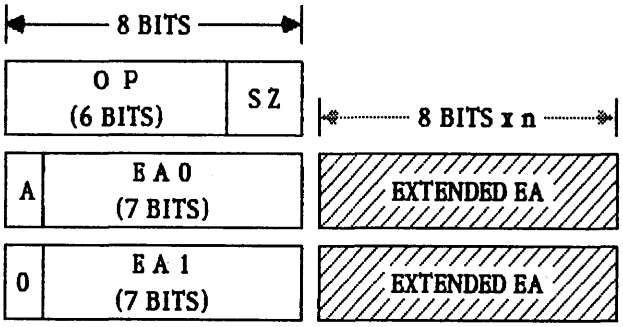

Fig.7: Orthogonal Instruction Format

ADDRESSING MODES

Table 1 shows the thirteen addressing modes of the microprocessor, which include a current bank mode and a previous bank mode for the RRBs. Both of them become prefixes of the following EA fields. The EA field with the prefix makes it possible to specify a register which belongs to the current task or the previous task.

Other addressing modes are for the GRBs. In the addressing modes, sizes of displacement, absolute address and immediate data are defined freely by Sd, Sa and Si fields, respectively. Each field consists of two bits, and one size of 8-bits, 16-bits or 32-bits which is selected by the compilers to optimize object codes.

COMPLEX INSTRUCTIONS

As shown in Fig.8, basic instrucions consist of three formats, 0-operand, 1-

Table 1: Addressing Modes of the Microprocessor

No.	ADDRESSING MODES	EA CODES	EXTENDED EA CODES		
1	REGISTER DIRECT	100 Rn	NOTHING		
2	REGISTER INDIRECT	0Sd Rn	DISPLACEMENT (0,8,16,32)		
3	REGISTER INDIRECT WITH AUTO-INCREMENT	101 Rn	NOTHING		
4	REGISTER INDIRECT WITH AUTO-DECREMENT	110 Rn	NOTHING		
5	IMMEDIATE	11100Si	IMMEDIATE (8,16,32)		
6	ABSOLUTE ADDRESS	11101Sa	ADDRESS (8,16,32)		
7	SCALED REGISTER INDIRECT	11110Sd	Scale Rn	DISP	
8	INDEXED REGISTER INDIRECT	1111100	0LSd Rn	Scale Rn	DISP
9	PROGRAM COUNTER RELATIVE WITH INDEX	1111101	0LSd	Scale Rn	DISP
10	PROGRAM COUNTER RELATIVE	1111101	10Sd Rn	DISP	
11	REGISTER INDIRECT DOUBLE	1111110	SdSd Rn	DISP	DISP
12	CURRENT BANK	1110000	ARBITRARY EA CODES 1-11		
13	PREVIOUS BANK	1110100	ARBITRARY EA CODES 1-11		

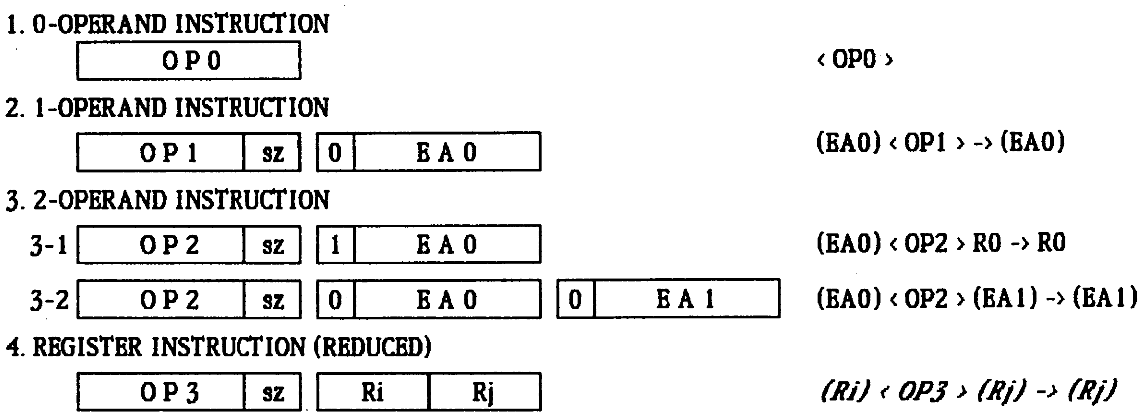

Fig.8: Complex and Reduced Instructions

operand and 2-operand instructions. The 0-operand instruction consists of one byte with no sz field. The 1-operand instruction consists of a minimum of two bytes, one byte for OP-code and sz field and the other byte for an EA field. The 2-operand instruction consists of a minimum of two or three bytes. If the MSB of the first EA field, which is an accumulator bit, is one, the second EA field is not needed, because the acumulator (R0) is implicitly specified. If the MSB of the first EA field is zero, the second EA field is needed.

REDUCED INSTRUCTIONS

Although the basic instructions are orthogonal, the microprocessor has a reduced instruction format as for register-to-register operations. This feature effectively ensures high code efficiency in object codes and also high performance.

CONCLUSION

A newly developed architecture for a 16-bit microprocessor has been described. Its multi-register bank architecture should be effective for executing event driven tasks and procedure calls, by through a combination of global register banks and ring register banks. The microprocessor can be fabricated with advanced CMOS technology to operate at a 16 MHz machine cycle. It should be the nucleus of a 16-bit single-chip or system integrated microcomputer with many peipheral I/O functions included in the same chip.

ACKNOWLEDGEMENTS

The authors would like to extend their sincere thanks to Y. Hatsukano, H. Yasuda, J. Nakajima and I. Masuda for giving them the opportunity to develop this microprocessor and for useful suggestions during the work.

ABSTRACT

The most important point in the design of supercomputers that achieve high-speed execution by parallel processing is to make efficient use of the inherent parallelism in the programs. This means the software-oriented approach is very crucial. Fujitsu's vector processors, the FACOM VP systems, are supercomputers that are designed along this line of approach. Our approach to development and its effectiveness is presented in this paper. Future design trends are also discussed.

1. INTRODUCTION

Recently, in the scientific and engineering fields, the demands for faster and easier to use computer systems is rising because of increased computation needs. This demand for higher performance has no ceiling.

General-purpose computers adopt the concept of serial processing. As we are close to the basic limitations in the device and circuit technology, no drastic improvement in performance is expected in this approach alone. It is therefore necessary to incorporate some kind of parallel processing techniques to obtain increased performance. This is the basis for the development of vector processors.

Powerful parallel processing, however, cannot be achieved by hardware alone. Various techniques in the architectural design are required to exploit the maximum amount of parallelism. This indicates that the previous hardware-oriented approach is not sufficient and that a software-oriented approach is also necessary. We believe this trend becomes more manifest as programs contain higher and higher degree of parallelism.

This paper first presents the problems that must be solved to achieve high speed execution by parallel processing. Next, the actual approaches taken in the development of Fujitsu's vector processors, the FACOM VP systems, in order to cope with these problems is introduced as an example. Finally, the future of high-speed execution by parallel processing is briefly discussed together with the results of our experiments.

2. FASTER EXECUTION BY PARALLEL PROCESSING

The two kinds of parallelism that scientific and engineering programs have are: array operations executable in parallel (SIMD type), and different procedures executable in parallel (MIMD type). In addition, there are various levels of operations and procedures.

Execution performance, P, obtained by parallelization is expressed by the following formula:

$$P = \frac{1}{1-\sum_i r_i + \sum_i [r_i/\alpha_i]} \qquad (1)$$

where i indicates each part of a program which can execute in parallel and r_i indicates the ratio of the relative computation time of each part to the total time when parallelization is not applied. α_i indicates the effect of parallelization for each part.

The ideal value of α_i is the ratio of the peak performance inherent in the hardware for parallel processing to that for non-parallel processing. Unfortunately, α_i usually contains various kinds of degrading factors. For example, if an initialization or termination process is involved in parallel execution, α_i contains a factor caused by that process which degrades the execution performance. If data transfer is involved, α_i will also be affected by the side-effect of that data transfer. If each part of a program can do parallel processing in two ways at the same time, α_i will reflect the effect of such parallel processings.

The values of r_i and α_i largely depend on the types of parallel processing as well

CH2345-7/86/0000/1020$01.00 © 1986 IEEE

as the specific features in architecture and software.

As shown in (1), to get high performance by parallel processing, it is necessary to maximize $R=\sum_i r_i$ and each α_i. In vector processors, R is the vectorization ratio, and each α_i is the performance improvement factor in each vectorizable part. In a multiprocessor system, R is the parallelization ratio, and each α_i is the approximate value of the number of processors which do parallel execution. (The actual value is smaller than this because of overhead in task distribution and synchronization.) Performance degradation by other factors such as overhead caused by data transfer may also have to be considered, depending on the hardware configuration of processor interconnection.

The following are necessary to increase R and each α_i:

(a) high speed circuit and packaging technology
(b) incorporation of parallelism in the architecture
(c) system software to extract the maximum amount of parallelism
(d) an efficient algorithm for parallel execution

As far as the architectural design of a supercomputer is concerned, items (b) and (c) are the most important. In other words, to what degree parallelism can be extracted from actual application programs and how efficiently the extracted parallelism can be executed. To maximize these factors, it is necessary to survey actual application programs, then design architecture and soft ware based on the survey. We define this approach as 'software-oriented approach' throughout this paper.

3. DESIGN OF VECTOR PROCESSORS

This section discusses the approach to the design of processors which efficiently execute the parallelism of the SIMD (vector) type, using as an example the method we adopted in designing the FACOM VP systems.

3.1 Actual method

As is evident from (1), in vector processors, it is important

(a) to increase the vectorization ratio as much as possible, and
(b) to design architecture which can execute array type parallelism as fast as possible.

With regard to point (a), it is important to increase the range of operations executable as vector operations, not to mention simple operations such as Ai=Bi+Ci, i=1,..,N. At the same time, software must be able to detect all corresponding vector operations, and to confirm that vectorization has a positive effect on performance.

With regard to point (b), it is important to identify the bottlenecks in actual application programs and to design an architecture which eliminates them.

3.2 Survey results of application programs

We thoroughly examined actual FORTRAN programs from the point of view of vectorization, according to the ideas mentioned above. Over 1000 programs were examined. See Ref. [1] for details of the results.

We will now discuss the results of these analyses from several points of view:

- vectorizable operations
- ratios of operations
- patterns and ratios of memory accesses
- vector length and number of active vectors

a) Vectorizable operations

Besides simple arithmetic operations in a simple DO loop, vectorizable operations include operations that contain complicated control structures like IF statements, and operations expressed in several statements which can be changed into one vector macro operation. Operations containing IF statements appear in about 30% of DO loops. In some cases, these consume as high as 90% of CPU time. This indicates a need to somehow provide an effective means to speed up the conditional operations.

b) Ratios of operations

In arithmetic operations, the number of addition/subtraction, and multiplication operations is about equal. Other operations like division, comparing(logical) operations, vector macro operations, and intrinsic functions occur at almost the same rate. The linked operations are frequently performed for addition/subtraction and multiplication, or in most other cases they can be executed concurrently.

c) Patterns and ratios of memory accesses

The number of data movement operations required per arithmetic operation is about 0.8. In other words, 8 data movement operations are required to execute 10 arithmetic operations. In vector data, there are contiguous data (73%), constantly strided data (19%), and data located at random positions (8%, which is also significant).

d) Vector length and number of active vectors

The vector length widely varied among programs. The number of active vectors at any one time is usually 3 to 4, and seldom exceeds 30. But in very rare cases, it exceeds 70.

3.3 Requirements and the architecture adopted in the FACOM VP systems

The results described in 3.2 clearly indicate certain requirements for the design of efficient vector processors. This section describes the requirements and an outline of the architecture adopted in the FACOM VP systems. For further details, see Ref. [2,3].

a) Types of operations

The basic requirements are to provide all instructions that correspond to recognizable vector operations and to make sure that these instructions operate efficiently.

To realize this, the FACOM VP system provides not only instructions for simple arithmetic operations and vector macros, such as summation operations, but also instructions for manipulating various types of vector data, such as data editing and data retrieving.

In addition, for greater efficiency, the FACOM VP provides mask bits and mask functions which enable or disable the execution of operations on individual vector elements. The total number of vector instructions is 83.

b) Balance of computational devices and parallel execution

The basic requirements are that there be a good balance between addition-related devices and multiplication-related devices, and that these devices can be executed in parallel. It is also essential to employ an architecture which processes multiple vector elements simultaneously at high speed.

Two alternatives meet these requirements: the pipeline type and the processor array type. We have chosen the pipeline type because it has a good affinity with the architecture of general-purpose computers. Four pipelines are provided as computational devices: add/subtract, multiply, divide, and mask. Any two pipelines of arithmetic operations and the mask pipeline are executable concurrently. Since the mask operation is an auxiliary one, it is executed behind other arithmetic operations to obtain higher performance.

c) Access to memory and parallel operation

The Basic requirements are to ensure sufficient data for full operation of arithmetic and logical pipelines, and to allow a wide variety of functions in load/store instructions for the various patterns of data accesses that occur in application programs.

In the FACOM VP systems, there are two memory access pipelines that continuously feed data to two arithmetic/logical pipelines that can be executed in parallel. These two memory access pipelines are also executable in parallel. When these pipelines are executed in parallel, the order of access to memory data must be consistent with the scalar processing. To realize this, the FACOM VP systems have two serialization functions:

- pipeline identification (pipeline ID)
- POST/WAIT instruction insertion

The pipeline ID function assures the order of vector instruction execution by assigning the same ID to the instructions whose execution order must be maintained. Instructions without an ID are executable in parallel, except for those restricted by hardware register reservation mechanism. This drastically lessens the overhead caused by serialization. The POST/WAIT instruction insertion has the same function as in an operating system. It is mainly used for synchronization between the scalar unit and the vector unit.

The software can achieve the optimal serialization by using these functions.

d) Vector register capacity and configuration

It is desirable to have as large a register capacity as possible and as many registers as possible. Of course, there are limitations in actual hardware implementations.

The vector registers in the FACOM VP systems are dynamically configurable, although total capacity stays the same. The vector register may be reconfigured when vector length is changed, that is, for each DO loop execution. The VP-200, for example, takes the following configurations: 32 (length of a vector register in a 64-bitword) x 256 (number of vector registers), 64 x 128,.., 1024 x 8. This reconfigurable feature of the vector registers enables efficient execution of programs for various vector lengths.

The software automatically selects the optimum vector register configuration for each DO loop.

3.4 Effectiveness of the FACOM VP systems

The previous section discussed several architectural features in the FACOM VP systems. This section discusses the effect of this architecture on actual application programs.

Table 1 shows the results of our measurements. The numbers in each row are the execution times, measured in seconds, for three different levels of parallel processing. These three cases are described in Table 2. The numbers in parentheses are the performance ratios of the execution with full parallel processing to that without parallel processing, and the performance ratios of execution with full parallel processing to that with restricted parallel processing, respectively. All the measurements were made on the VP-200. The vector peak performance of the VP-200 is 570 MFLOPS, and the average scalar performance is 8 to 9 MFLOPS.

From Table 1, it is clear that the techniques used in the architecture have great effect. Case 3 is faster than Case 2 by the factor of 1.2 to 3.7. For details concerning the effect of each function, refer to Ref. [4]. Refs. [5] and [6] evaluate performance of other actual application programs.

Table 1: Effectiveness of various vector processing techniques

No	Program fields	Case 1 T1	Case 2 T2	Case 3 T3 (T1/T3)	Effect (T2/T3)	Primary effective architecture
1	Fluid model	855.56	68.72	35.93 (23.8)	(1.9)	IF
2	Fluid model	607.25	189.53	112.26 (5.4)	(1.7)	Vector register
3	High energy	209.48	33.83	26.83 (7.8)	(1.3)	IF, Vector register
4	High energy	31.22	4.12	2.41 (13.0)	(1.7)	IF
5	Particle in cell	168.04	37.69	32.32 (5.2)	(1.2)	IF, Indirect access
6	Plasma	101.79	70.40	42.93 (2.4)	(1.6)	Indirect access
7	Plasma	96.15	96.60	25.81 (3.7)	(3.7)	IF, Vector register
8	Weather forecast	413.80	192.65	109.52 (3.8)	(1.8)	IF
9	Nuclear	25.71	4.74	3.53 (7.3)	(1.3)	Macro operation
10	Energy transform	76.13	6.31	3.82 (19.9)	(1.7)	IF

Unit=seconds, ( )=ratio

Table 2: Description of three different levels of parallel processing

Case 1	Execution time without parallel processing
Case 2	Execution time when the following functions are restricted - Vectorization of DO loops containing complex control structures such as IF statements - Parallel execution of vector computational pipelines - Parallel execution of memory access-related pipelines - Dynamic register reconfiguration (fixed at 32 registers of 256 elements each)
Case 3	Execution time with full parallel processing

4. FUTURE OF HIGH-SPEED EXECUTION BY PARALLEL PROCESSING

As stated in Section 2, application programs inherently contain MIMD type parallelism as well as SIMD type parallelism.

The MIMD type parallelism is not easily detectable with the techniques for the current system software, because they are mainly based on the data dependence analysis of the programs at the local level. However, detection of the MIMD type parallelism is essential for higher speed execution. It is natural to enlarge the target range from the parallelism of the SIMD type to that of the MIMD type.

4.1 Requirements for MIMD-oriented high-speed execution

It is obvious that multiple processors are required for the execution of the programs with MIMD type parallelism. The problem is how to configure the multiple processors and how to allocate the data among them. The latter is especially related to programming languages. That is, data allocation differs greatly depending on the problems to be solved over all spheres of the scientific and engineering fields. For example, a shared-type memory accessible from multiple processors will be best for a program which involves frequent access to all array data. In contrast, small pieces of local memory will be most effective for a program containing many small procedures. There are also many programs like the structure analysis which combine both frequent access to the array data as well as many small procedures.

The optimal configuration and allocation is determined by the specific program. This means the software-oriented approach, again, is very essential.

From the software point of view, there is a problem of granularity. This depends on the ratio between the overhead time of procedure (task) distribution/synchronization caused by program fragmentation and the net computation time in the procedures to be executed in parallel. For a given application program, granularity and parallelism are strongly coupled: if parallelism increases, granularity decreases, and vice versa. There is an optimal point where the parallelism and granularity are balanced. This point varies according to the problem characteristics.

4.2 Multitasking with a multiprocessor system

We have experimented the multitasking in October, 1979, using the FACOM M-200 tightly-coupled 4-multiprocessor system, the highest performance general-purpose computer at that time. This was reported in newspapers, nation-wide. An outline of the experiment follows.

a) Problem

The problem is to solve the 2-dimensional Laplace equation as given in (2) and (3) by SOR (Successive Over Relaxation), after approximating (2) by the finite difference scheme (size: 320x320) as given in (4).

$$\frac{\partial^2 U}{\partial x^2} + \frac{\partial^2 U}{\partial y^2} = 0 \qquad (2)$$

Boundary condition:

$$U(x,y) = \sin(x) * \sinh(y) \qquad (3)$$

Finite difference scheme:

$$U_{i,j}=U_{i,j}+\omega\{(U_{i+1,j}+U_{i-1,j}+U_{i,j+1}+U_{i,j-1})*0.25-U_{i,j}\} \qquad (4)$$

To perform multi-tasking, an array U is divided into four rectangular domains as shown in Figure 1, and each domain is assigned to one of four CPUs for parallel execution. To assure the same execution order as would be executed by one CPU and one task, the tasks are synchronized whenever tnere is an operation on data at a boundary of the four domains.

b) Program for multitasking

Multitask programs are written in FORTRAN. For controlling tasks, the following basic subroutines are provided. Figure 2 outlines the program for multitasking.

CALL FORK	subtask generation
CALL JOIN	subtask termination
CALL QGET CALL QPUT	synchronization of operation on data at boundary (synchronization between subtasks)
CALL POST CALL WAIT	synchronization between task and subtask

To obtain larger granularity, the convergence check was made as follows:

Step one:

Check the convergence every 200 iterations until the value becomes 1.5 times as large as the convergence criterion.

Step two:

Check the convergence every 10 iterations after the first step is completed.

c) Results

In executing our multitask program, we found that convergence took place at the 2150th iteration. We obtained the following timing results:

System	Wall clock	ratio
M200-1CPU	7 min 44 sec	1
M200-4CPU	2 min 6 sec	3.68

4.3 Survey on multiprocessing

We believe that MIMD type parallel processing should be the next target; since it is a more generalized concept. We are conducting a survey of actual application programs from this point of view.

Various kinds of levels being considered as the target for MIMD type parallelization are:

- multiple DO's (DO loop slicing)
- procedure blocks in a subroutine
- subroutines

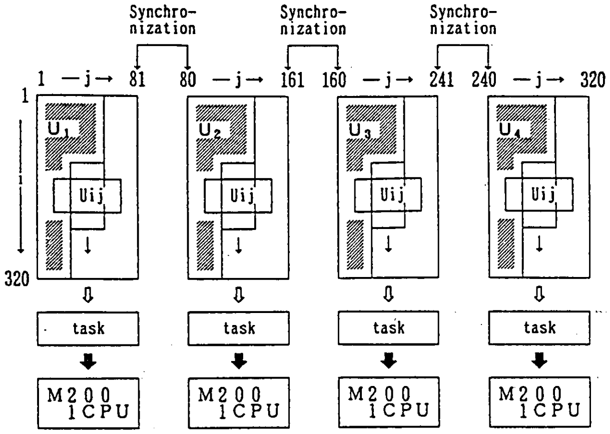

Figure 1: Dividing array U into 4 domains

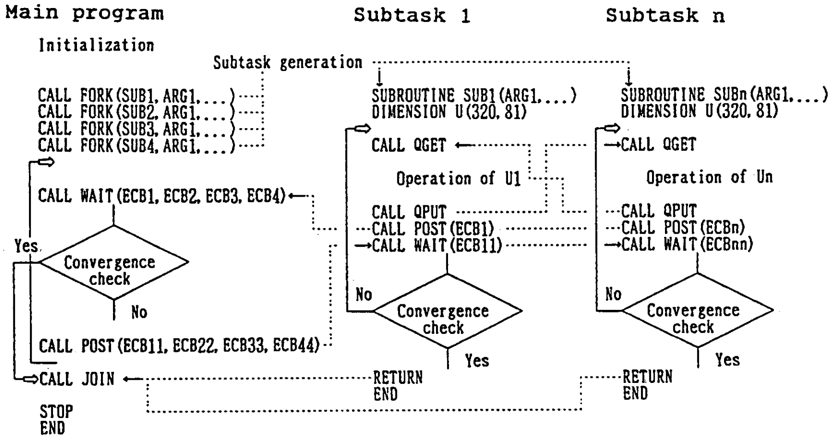

Figure 2: Outline of multitask program

The granularity increases in this order.

Table 3 shows part of the survey of two processor systems. The comments in the column "parallelization level" in Table 3 refer to the combined levels described above. Execution times are the simulated values by hand-parallelization.

4.4 Future of using parallel processing to get high performance

At present, the pipeline architecture for the SIMD type parallelism and the multiprocessor architecture for the MIMD type parallelism are the common combinations. Full utilization of these two types of parallelism is necessary to achieve the maximum performance for wide range of application programs. Any system that targets only one of the two types will soon reach its limit; the best system is a well-balanced one that utilizes both types of parallelism.

As for the ease of use, however, there already exists a vast amount of software in actual use that employs the automatic vectorization technique. Systems for the SIMD type have become very easy to use. Yet, there is little software that exploits the MIMD type parallelism. As indicated in the previous section, implementation of the MIMD type parallelism requires a great deal of program modification. In the previous example, a program with ten steps for a general-purpose computer was recoded into a program with several hundred steps for parallel processing and took three weeks just to run this program. This indicates the challenging nature of developing the parallelizing software. But, because use of the MIMD type parallelism is inevitable to obtain higher execution performance, more software will be developed that aims at applications in MIMD type parallelism.

5. CONCLUSION

The effectiveness of a software-oriented approach to achieve high performance in parallel processing has been discussed in this paper, using the Fujitsu's FACOM VP systems as an example. In addition, the importance of MIMD-type parallel processing as a future trend has been pointed out. For very high-speed execution, however, circuit and packaging technology, programming languages, and parallel processing algorithms are also important and will continue to be so.

"Ease of use" is also a very important factor in a high-performance system.

We will continue our systems development based on the primary goals of higher performance and ease of use.

Table 3: Effectiveness of parallel processing by two processors

Program field	Parallelization ratio	Execution time ratio	Parallelization level
Energy transform	99.9 %	2.0	routine + procedure
Weather forecast	99.9 %	1.9	multiple DO's
Plasma	92.3 %	1.8	multiple DO's + procedure
Plasma	88.9 %	1.7	multiple DO's + procedure
Plasma	46.4 %	1.3	multiple DO's + routine + procedure
Fluid model	33.9 %	1.2	routine + procedure
Nuclear	60.9 %	1.2	routine + procedure
Nuclear	1.0 %	1.0	multiple DO's + procedure

"ADVANCED IMPLICIT SOLUTION FUNCTION OF DEQSOL AND ITS EVALUATION"

Chisato Kon'no, Miyuki Saji, Nobutoshi Sagawa, Yukio Umetani

Central Research Laboratory, Hitachi Ltd. Kokubunji, Tokyo 185, Japan

ABSTRACT

DEQSOL is a programming language specially designed to describe PDE problems in a quite natural way for numerical analyses. This language has two design targets. One is to enhance programming productivity by establishing a new architecture-independent language interface between numerical analysts and vector/parallel processors. The other is to automatically generate highly vectorizable FORTRAN codes from DEQSOL descriptions, thus realizing efficient execution. An advanced function has been introduced, so that the descriptive capability of DEQSOL for practical and complex problems has been highly elevated.

1. Introduction

Recently, demand for numerical routines which simulate physical phenomena has been rapidly increasing. The hardware used for such numerical simulation has made remarkable advances through innovations in LSI technology and computer architecture, such as vector and parallel processors. However, the programming itself still remains at a relatively elementary level.

The development of simulation programs by such conventional languages as FORTRAN faces the following problems. A long period of time is necessary to develop even a simple simulator, and special knowledge of numerical analysis methods like discretization is needed. In addition a specialized programming technique is required to exploit the performance of vector/parallel processors. Moreover, such programs are so lengthy and complicated that they are unfeasible to extend.

One approach for coping with these problems is the use of mathematical libraries or software packages designed for the special application fields. However, there are distinct limitations in applicable fields and the adopted numerical algorithms. Additionally, users can not control the numerical scheme in detail, and they frequently can not understand or utilize the complicated functions and interfaces.

To address these limitations, several simulation language systems has been developed, such as SALEM[1], PDEL[2], and ELLPACK[3,4]. ELLPACK especially seems to be a powerful system. ELLPACK has ample problem solving capabilities due to its extensive library, which is still expanding in response to the demands of the interactive and distributed system environment[4]. However, the new solver architecture which has been proposed for ELLPACK is not for enhancing its application to practical complex simulation problems.

On the other hand, the present study proposes a high level programming language system DEQSOL(Differential EQuation SOLver)[5,6] by which the numerical models can be described flexibly and which can automatically generate efficient simulation programs from the high level descriptions. This system has two main targets:

(1)To enhance programming productivity by establishing a new architecture-independent language interface between numerical analyst and computer.

(2)To generate highly vectorizable FORTRAN codes from DEQSOL

CH2345-7/86/0000/1026$01.00 © 1986 IEEE

descriptions using its intrinsic parallelism.

The structure of the previously developed DEQSOL system and its processing flow are shown in Fig.1. The DEQSOL description is automatically translated into the FORTRAN simulation program by the DEQSOL translator. The results of several benchmark tests, which indicate that the programming productivity has been improved by almost an order of magnitude over FORTRAN, are shown in Table 1. The table also shows that most of the generated codes have extremely high vectorization ratios(91%-98%) on the Hitachi S-810 vector processor.

Both the Finite Difference Method(FDM) and the Finite Element Method(FEM) are available as discretization method. The key feature of DEQSOL is that users can describe various numerical schemes for a wide range of problems quite naturally by using fundamental DEQSOL statements.

One of the principal functions in DEQSOL is the implicit solution function. Here, this function acts to discretize the objective linear PDE into a system of linear equations. It then obtains a discrete PDE solution by solving this linear equation system. The restriction on the former DEQSOL implicit solution function has been that only one PDE in a rectangular region is permitted for a single implicit solution function. As a result, tightly coupled simultaneous PDEs, or PDEs defined in non-rectangular regions, have not been accepted. Because practical problems are sometimes formulated as described above, this restriction must be eliminated in order to make DEQSOL a practical solver.

In this paper, an advanced implicit solution function is presented for removing these restrictions. Consequently, the tightly coupled simultaneous PDEs defined in regions described by unions or by differences in rectangular subregions can be solved by DEQSOL. In addition, a block-iteration scheme aimed at reducing the region size needed to execute large-scale problems can be developed.

In the following sections, the implicit solution function is first outlined. Then, the method for processing the advanced function is presented. Finally, the results of the benchmark test are shown.

2. DEQSOL scheme description and the implicit solution function

A sample of the DEQSOL scheme description is shown briefly[6] for a simple diffusion problem in Fig.2. Statement (2) indicates the discretization method chosen by the user. Statements (3) to (10) indicate the structure of the numerical model respectively: domain(DOM), time domain(TDOM), FDM meshes(MESH), unknown physical variables(VAR), known physical constants(CONST), subregions(REGION), initial condition(INIT), and boundary conditions(BOUND).

Between 'SCHEME' statement(11) and 'END SCHEME' statement(17), a numerical algorithm is described. To develop a numerical algorithm for this problem, the time differentiation is replaced by the forward difference and the left term is estimated according to either an explicit or implicit method. For the explicit method, statement(14) is used, which assigns the evaluated value of the right terms to the left variable. Statements (12) to (17) represent a numerical algorithm by Euler's explicit method, where the statements between 'ITER'ation and 'END ITER'ation are executed until the specified condition is satisfied. For the implicit method, the 'SOLVE' statement is used, which solves the PDE for the indicated variable. If the implicit method is selected, such as the backward Euler's method, statement(14) should be replaced by 'SOLVE' statement(19). 'SOLVE' statement can be applied not only for the implicit method in transient problems, but also for any PDEs.

The method of translation for the 'SOLVE' statement is described in Fig.3. First, the region is broken down into several subregions according to the given PDE, boundary conditions, and discretization rule, such that each subregion is dominated by a unique equation and discretization rule. For example, the domain in the figure is broken into 6 subregions: 5 boundary and 1 inner point subregions. Each subregion is a unit where the same pattern of linear equations is formed by discretization onto every mesh point. As a result, the generated FORTRAN codes which calculate portions of the total matrix and constant vector can be combined into a single DO-loop.

Fig. 2 A Simple Example of Description by DEQSOL

For each subregion, the DEQSOL translator discretizes the equation according to the discretization rule. It then generates a part of the linear equations, and creates the FORTRAN codes which calculate the corresponding part of the total matrix and constant vector elements of the linear equation system. After the total matrix is completed, it is linked to the efficient matrix solution library which has been prepared beforehand. A portion of the generated FORTRAN codes consisting of the matrix generation and the linkage to the matrix solution library is shown in Fig.4.

The intrinsic parallelism in processing the 'SOLVE' statement is classified into two categories. The first category is the mesh point parallelism which appears when generating a matrix and constant vector from the discretized equations. The other is the algorithm which is dependent on parallelism to solve the linear equations. The first type parallelism is ensured by creating the codes so that the elements of the matrix and constant vector can be uniformly calculated within each subregion by using a single DO-loop, as stated above. The latter parallelism is accomplished by using the efficient matrix solvers in the DEQSOL library.

3. Advanced implicit solution function

3.1 Implicit solution function for simultaneous PDEs

The numerical scheme for simultaneous PDEs, F(A,B,C) = 0,G(A,B,C) = 0,H(A,B,C) = 0, using the former implicit function, is shown in Fig.5(a). Each equation is solved successively and iteratively until a convergent condition is met. If the coupling relationship among the variables is not tight, this scheme can successfully attain to an appropriate solution within a reasonable period of time. However, when the coupling relationship is tight and the dominating variable in each PDE is not clear, this iteration loop takes a lot of time for convergence, or does not converge at all. To solve such a problem, the implicit solution function can be extended such that any coupled variables and

PDEs are specifiable in a simple 'SOLVE' statement with appropriate boundary conditions specified using the 'UNDER' clause. This is shown in Fig.5(b). By using this clause, the coupled boundary conditions can definitely be assigned to each 'SOLVE' statement.

The extended, advanced implicit solution function discretizes the coupled PDEs, regards them as one system of linear equations for coupled variables, and generates a large matrix for them. In this case, the form of the generated matrix depends on the order in which the linear equations and discrete variables are arranged. For example, suppose F,G,H are PDEs and A,B,C are variables of these PDEs. In addition, Fi,Gi,Hi and Ai,Bi,Ci are discretized equations and variables at point i. The forms of the matrices generated for typical arrangements of Fi,Gi,Hi,Ai,Bi, and Ci are shown in Tab.2. In this table, the solid lines in the matrix indicate the position where non-zero elements may appear. From the viewpoint of solving the linear equations, a band matrix is desirable for the direct method, such as GAUSS elimination. In addition, the dominance of diagonal elements is necessary for iterative methods, such as Conjugate Gradient(CG) or Bi-Conjugate Gradient(BCG), to converge. Therefore, the DEQSOL translator generates the matrix in the form shown by case.1 of Table 2. Furthermore, the generated matrix is manipulated into the compressed form which retains only non-zero elements.

The BCG algorithm for the advanced DEQSOL implicit solution function is described as follows. If the small block matrix consisting of elements for each discrete point is regarded as an element of the matrix in Fig.6, the matrix form coincides with that of the conventional FDM matrix. As a result, the BCG algorithm for this block matrix can be constructed in similar way to conventional ones if the operation between the elements is carefully defined. Here, the product corresponds to the matrix product, and the quotient corresponds to the product of the inverse matrix, where these operations are non-commutative.

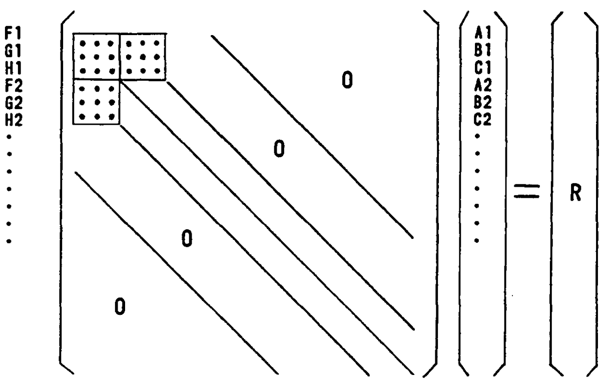

Fig. 6 Matrix Form Representing Discretized Simultaneous PDEs

The DEQSOL translator calculates the necessary matrix size. This size depends on the number of coupled systems involved for each 'SOLVE' statement in the given numerical algorithm. Only the maximum region is secured and it is shared alternatively among all 'SOLVE' statements.

3.2 Implicit solution function for partial regions

It is desirable that the implicit solution function can be applied to not only rectangular region, but also to the unions or differences of rectangular regions. Furthermore, this function should be applied to partial regions for processing problems which have inner boundaries. It is also beneficial for block iteration schemes to be developed for large-scale problems in order to reduce the region size needed for computations. To accommodate these requirements, the implicit solution function is expanded so that it can be applied to any region or regions which can be expressed by unions or differences of sub-rectangular regions.

An extended form of the statements 'SOLVE' and 'BOUND' is shown in Fig.7. The 'AT' specification is introduced into the 'SOLVE' statement to express such partial regions. For the boundary conditions, four types are allowed: 'equation', 'discrete equation', 'GIVEN' and 'NOC'. Here 'equation' specifies the ordinary conditions(first,second,and third types of boundary condition). Next, 'discrete equation' specifies the discretized form, and 'GIVEN' specifies that the point on the boundary of the partial region takes the value which was already calculated as the first type of boundary condition. Finally 'NOC' specifies that the PDE given on the inner point is also adopted and discretized on the boundary point. On this boundary point, the referred points outside of the designated partial region take previously calculated values.

The specification of 'GIVEN' and 'NOC' mainly aim at constituting the block iteration scheme for large-scaled or multi-block problems. On the other hand, 'equation' and 'discretized equation' aim at setting ordinary conditions and also at developing schemes for inner boundary problems.

The translation method for this function is basically similar to that explained in Section 2.

4. Evaluation

As the physical models increase in complexity, an advanced implicit solution function becomes necessary for simultaneous PDEs. Such a model can be found in the fields of fluid analysis, LSI device simulation, etc.. The results of a benchmark test for the analysis of Stokes flow in a non-rectangular region are now given. Stokes flow in the 2-dimensional domain is expressed using three equations for pressure P, velocity of flow U and V, and external forces Fx and Fy for each coordinate direction. This benchmark test utilizes both facilities as stated in the above section.

The physical model is shown in Fig.8(a). An iteration scheme for this model in which each equation is solved for one specific variable can not obtain a convergent solution. Two numerical schemes which utilize the advanced implicit solution function for simultaneous equations are shown in Fig.9. Fig.9(a) represents a scheme in which block iteration is applied. The simultaneous PDEs are iteratively solved by the implicit solution function in each partial region REG1 and REG2, until the norm of the difference of the new and old values becomes less than the specified value "eps". In Fig.9(b), the simultaneous PDEs are solved in the total region REG1 + REG2. The generated FORTRAN program from scheme (a) uses far less memory during execution than that from (b), but setting of the initial value for the iteration in (a) is quite critical. From either of these schemes, however, a good approximate solution can be obtained.

(b) Scheme Applying Advanced Implicit Solution Function

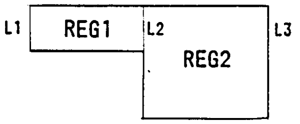

Fig. 9 Numerical Scheme for Stokes Flow

The flow velocity for the calculated results of the program generated from scheme (a) in Fig.9 is shown in Fig.8(b). Furthermore, the results of the DEQSOL translation and the execution of the generated FORTRAN program are shown in Table.3. The descriptive efficiency of DEQSOL still attains more than 10 times that of FORTRAN, and the vectorization ratio of the generated FORTRAN has marked over 90 %.

5. Conclusion

The advanced implicit solution functions in FDM schemes concerning simultaneous PDEs and partial regions have been developed. Due to these functions, the fields of application have been extended and the descriptive capability of the numerical algorithms have been greatly improved. The problems formulated by tightly coupled PDEs - those involving inner boundaries and those defined in non-rectangular regions - have become solvable by DEQSOL. Aside from these extensions in capability, DEQSOL has maintained a high descriptive efficiency versus FORTRAN, and the created FORTRAN program has demonstrated an extremely high vectorization ratio.

ABSTRACT

The supercomputer SX system is an ultra high-speed, large-scale computer system with a large capacity of main memory and extended memory. One of its main design objectives was to offer an easy-to-use environment to users as well as high-speed vector and scalar computation capabilities. This paper outlines an optimizing FORTRAN compiler with automatic vectorization functions and some tuning utilities to enhance vectorization ratio, which we developed to attain these goals.

INTRODUCTION

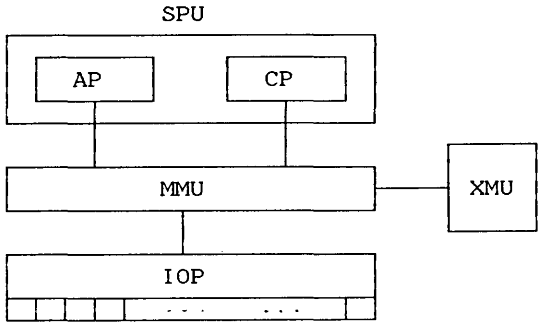
Early supercomputers were mainly used by professional people in big laboratories or companies. Though the main programming language was FORTRAN, it was necessary to use special vector extension added to FORTRAN or an assembly language to make full use of their capabilities.

Today, with the advance in computer technology, supercomputers have come to be able to provide far more computational power at lower cost. They are being brought into common use,for example, in universities and in industry. Non-professional people have begun to use them. Under these circumstances, ease of use has become very important, as well as computational speed. To meet this requirement, recent supercomputers provide a standard FORTRAN77 compiler with a sophisticated automatic vectorization function. FORTRAN77/VP of Fujitsu VP series, FORT77/HAP of Hitachi S810 series and FORTRAN77/SX of our SX system are examples. Cray Research enhanced an automatic vectorization function of their CFT compiler. Furthermore, they also provide some compiler functions or utilities for program tuning to get more performance easily. CFT's flow-trace function, VP's Interactive Vectorizer, S810's VECTIZER, SX's ANALYZER/SX and VECTORIZER/SX are examples.

In designing our supercomputer SX system, the first design objective was, of course, to realize high-speed vector and scalar computation capabilities. We attained this goal by the following hardware features:

- fast machine cycle (6 nanoseconds)
- multiple parallel vector pipelines consisting of four identical sets of four arithmetic pipelines
- a fast main memory of up to 256 million bytes and a semiconductor extended memory unit of up to 2 billion bytes
- the control processor (CP) integrated into the system to perform supervisory functions and cooperating with the arithmetic processor (AP) which takes charge of high-speed scientific computations.

With these features, the SX system has a peak performance of 1.3 gigaflops in vector operations. In scalar operations, it is about 1.5 times as fast as our current fastest mainframe computer ACOS S1500. The configuration of the SX system is shown in Fig.1.



SPU : SCIENTIFIC PROCESSING UNIT
AP : ARITHMETIC PROCESSOR
CP : CONTROL PROCESSOR
MMU : MAIN MEMORY UNIT
IOP : INPUT OUTPUT PROCESSOR
XMU : EXTENDED MEMORY UNIT

Fig.1 SX System Configuration

Considering the above requirements, our next design objective was to offer an easy-to-use environment both in programming and in operation. To meet this goal, we developed the following software products.

- SX system control program (SXCP) which was developed on the basis of the ACOS mainframe operating system and has abundant functions including a TSS function
- FORTRAN77/SX with automatic vectorization functions and optimization functions
- various utilities including ANALYZER/SX and VECTORIZER/SX to assist program preparation, debugging, tuning and maintenance.

All these programs run on the CP using its own memory. Thus programs running on the AP are not affected by them.

CH2345-7/86/0000/1034$01.00 © 1986 IEEE

In this paper, we describe the outlines of FORTRAN77/SX: mainly its vectorization and optimization functions, and also the outlines of tuning utilities to improve vectorization ratio.

FORTRAN77/SX

In the SX system, there are two FORTRAN systems: FORTRAN77 and FORTRAN77/SX. FORTRAN77 generates object codes for the CP and is used for debugging with the interactive debugging support program IDSP. FORTRAN77/SX generates vectorized object codes for the AP and is used for actual computations. Their language specifications conform to the standard FORTRAN, that is, the ANSI FORTRAN 77. As a result, users can make full use of the SX system through standard FORTRAN programs.

Automatic Vectorization Functions

FORTRAN77/SX compiler has sophisticated automatic vectorization functions. The outlines are shown in Table 1. Extended automatic vectorization functions here are the features to vectorize loops wholly or partially which are very hard or almost impossible to vectorize as they are. To increase vectorization effect by loop transformation is also one of its features. Some examples of vectorizable loops are shown in Fig.2.

```
    DO 10 I=1,N                         Vectorize using masked

```

Fig.2 Examples of Vectorizable Loops

The compiler analyzes global data flows of all variables and arrays in a program unit and uses this information in automatic vectorization. For example, in the case that a variable is defined in a loop, it does not generate codes to ensure the final value for the variable, if it is not alive on the exit of the loop.

Table 1 Summary of FORTRAN77/SX Automatic Vectorization

(1) Basic Conditions for Automatic Vectorization

Vectorizable Loop	DO loop
Types of Vectorizable Data	Integer, Logical Real (Single, Double) Complex (Single, Double)

Vectorizable Statements	Assignment, CONTINUE
	IF(Arithmetic, Logical, Block)
	ELSE IF, ELSE, END IF
	Unconditional GO TO

Vectorizable Operations	Add, Subtract, Multiply, Divide Power, Type Conversion Intrinsic Functions Inner Product, Summation Continued Product, Iteration Maximum, Minimum Search
Vectorizable Vector	Contiguous Vector Equal Distance Vector Indirectly Addressed Vector Index Variable

(2) Extended Automatic Vectorization Functions
(a) Extension of Vectorizable Loops

A loop including unvectorizable parts	Vectorize by splitting it into vectorizable parts and unvectorizable parts
Nested loops	Vectorize the outer loop by dividing it before and after the innermost loop
A loop including user function calls	Vectorize by putting a system subroutine between an object code and the functions to invoke them as many times as the number of loop iterations
A loop including array references that have dependencies unsuitable for vectorization	Vectorize by exchanging statements or substituting the references by a work vector
A loop that the compiler cannot decide whether it may be vectorized or not	Vectorize under specifications of a vectorization directive

(b) Increase of Vectorization Effect

Tightly nested loops	Exchange an outer loop and the innermost one or make some of them into a single loop to expand the vector length or to avoid access to the same memory bank
A loop including a special processing for boundary conditions	Eliminate IF's by moving them out of the loop

With the vectorization functions, together with the multiple parallel vector pipelines, the compiler generates efficient object codes for the DO loops ranging from simple loops to complicated loops. We show the results of the Livermore 14 kernels in Table 2 as an example.

Optimization Functions

In addition to the automatic vectorization functions, FORTRAN77/SX compiler uses all sorts of optimization techniques to obtain full performance from the SX system. Some of the conventional ones such as common subexpression elimination, code motion and strength reduction were extended to apply to vectorized codes. A register assignment optimization was also extended to make full use of 128 scalar registers and 80 K byte vector registers. Besides them, an instruction scheduling optimization was newly introduced to minimize pipeline interlocks and functional unit interlocks.

In an instruction scheduling, the compiler makes reordering at three levels: a source expression level, an intermediate code level and an object code level. This is because more than one instruction is generated from an intermediate code, though the first two hold more information about a source program.

In determining which instruction is to be scheduled next, the compiler uses the following information:

- the number of instructions waiting for their completion
- the duration of each instruction
- the busy time of each vector functional unit.

A large number of scalar registers ease this optimization and increase its effect. This optimization has more effect on scalar codes than on vectorized codes and can reduce the execution time by about 20%-40% for an average program. Table 3 shows the effect of an instruction scheduling for the Livermore 14 kernels.

Let us show a small example of reordering. The SX system has four sets of independent vector pipelines: add, multiply, logical and shift, which can work concurrently. Suppose a vectorized part contains an expression, A(I)*B(I)+C(I)*D(I)+E(I). The compiler evaluates it in the following order to fully utilize vector pipelines:

(A(I)*B(I)+E(I))+C(I)*D(I)

Let us show another small example of optimization. Suppose a loop includes a vector addition in the form of A(I)+A(I). The compiler generates a vector addition, vector multiplication or vector double instruction for it depending on which pipeline is free. Note that a vector double instruction is executed by a shift pipeline.

Table 3 The Effect of the Instruction Scheduling Measured by the Scalar Codes for the Livermore 14 Kernels

Loop No.	Not Scheduled (MFLOPS)	Partially Scheduled (MFLOPS)	Fully Scheduled (MFLOPS)
1	17.3	18.4(6.4%)	18.1(4.6%)
2	17.9	26.8(49.7%)	31.4(75.4%)
3	13.3	13.9(4.5%)	15.9(19.5%)
4	11.5	11.5(0.0%)	11.5(0.0%)
5	12.0	16.4(36.7%)	15.9(32.5%)
6	12.0	14.9(24.2%)	16.7(39.2%)
7	20.0	33.8(69.0%)	32.2(61.0%)
8	24.7	43.9(77.7%)	46.2(87.0%)
9	20.5	29.3(42.9%)	32.0(56.1%)
10	13.7	13.6(-0.7%)	18.5(35.0%)
11	8.3	8.2(-1.2%)	8.3(0.0%)
12	8.3	8.3(0.0%)	8.3(0.0%)
13	6.3	7.2(14.3%)	9.3(47.6%)
14	11.6	12.0(3.4%)	14.3(23.3%)
Average	14.1	18.4(30.5%)	19.9(41.1%)

Note:(1) Parenthesized figures show the effects of the instruction scheduling.
(2) "Partially scheduled" means reordering at an object code level is not performed.
(3) "Fully scheduled" means full reordering is performed.

High-speed Input/output Functions

As the speed of a computer becomes faster, the size of an application program for it becomes larger. Though the main memory of the SX system has a capacity of up to 256 million bytes, it sometimes cannot accommodate its data. In this case, the disk I/O time may become a system bottleneck. To avoid this, FORTRAN77/SX provides high-speed input/output functions such as:

- Asynchronous input/output function which allows unformatted input/output operation to proceed on the CP in parallel with program execution on the AP
- Parallel input/output function which allows parallel data transfer between a file and a main memory where the file is subdivided and distributed among multiple disk units
- Asynchronous output editing function which allows editing and output processing to proceed on the CP in parallel with program execution on the AP.

The asynchronous input/output function makes full use of a distributed configuration of the SX system and is useful to reduce the turnaround time. However, the program must be modified to use it. The parallel input/output function, on the contrary, can be used simply by changing the JCL specification. No program modification is necessary. The asynchronous output editing function is very similar to the asynchronous input/output function, but it is to speed up a formatted output statement, whereas the latter is to speed up an unformatted input/output statement that transfers a large amount of data. Fig.3 shows these functions.

Besides them, the extended memory unit (XMU) can be used as a high-speed secondary storage. Users can use it through FORTRAN READ or WRITE statements simply by assigning a file to the XMU in a JCL. It achieves a drastic reduction of data transfer time.

(c) The Asynchronous Output Editing Function

Fig.3 High-Speed Input/Output Functions

High-speed Libraries

FORTRAN77/SX provides high-speed intrinsic functions both in scalar and vector. Some performance data is shown in Table 4. Besides them, the Advanced Scientific Library SX (ASL/SX) is provided including an FFT subroutine using a vector bit reversal instruction, a simultaneous linear equation solving subroutine and an eigen value calculating subroutine. For example, a one-dimensional complex FFT of data length 1024 can be solved in 133 microseconds (462 MFLOPS). Two-dimensional complex FFT of data length 256 x 256 can be solved in 9.41 milliseconds (557 MFLOPS). Simultaneous linear equations of order 1000 can be solved in 429 milliseconds (792 MFLOPS).

Table 4 The Performance of Some Intrinsic Functions

Function	Scalar(S) (microsec.)	Vector(V) (microsec.)	Ratio(S/V)
SQRT DSQRT	0.79 1.09	0.05 0.05	16 22
EXP DEXP	0.76 1.44	0.03 0.04	25 36
ALOG DLOG	1.10 1.30	0.04 0.06	28 22
SIN DSIN	0.89 1.37	0.03 0.03	30 46

Linkage With Other Languages

In the SX system, FORTRAN is the only language available for the AP. Because the CP has the same architecture with the ACOS mainframe computers, all the language processors for them are available on the CP. In addition, subroutines on the CP and FORTRAN subroutines on the AP can intermix freely. For example, a PASCAL subroutine can call a FORTRAN subroutine with the normal CALL statement whether it is for the CP or the AP. The linker, which makes up a load module, judges whether each object module is for the CP or the AP, and set the last bit of the pointer to the callee's entry point to 1 if a CP subroutine calls the AP subroutine or vice versa. When a CP subroutine calls an AP subroutine, the CP firmware knows it by the last bit of the pointer and gives control to the AP subroutine. When an AP subroutine calls a CP subroutine, a CP-call exception is caused by the bit and the exception handler gives control to the CP subroutine.

TUNING UTILITIES

The key factor to obtain a high performance from the SX system is to increase the vectorizable part of a program as much as possible. Another important factor is to make generated codes more efficient: for example, to lengthen the vector length, avoid the memory bank conflict, and so on. In order to make these tuning activities easier, the SX system provides two utilities named ANALYZER/SX and VECTORIZER/SX.

ANALYZER/SX analyzes and reports the dynamic characteristics of source programs. The information reported is as follows.

- For a whole program:
  - its vectorization ratio indicating whether it is already vectorized enough or not
- For each program unit:
  - the number of times it is called
  - its vectorization ratio
  - its "cost" which is an approximated index of the time spent by it
  - the total number of the DO loops processed, the number of the vectorized DO loops and the ratio of their costs
- For each DO loop:
  - its cost
  - the average loop length
  - vectorization diagnostic messages which indicate why it is not vectorized
- For each statement:
  - its execution frequency
  - its cost
  - a mark indicating whether it is vectorized or not

ANALYZER/SX can get these data by inserting some statements for measuring them in the source program, executing the program on the CP or optionally on the AP and collecting them after execution. Fig.4 shows an output listing by ANALYZER/SX. The cost and vectorization ratio is calculated by accumulating execution frequencies of each statement weighted by the number of instructions generated for it.

(b) A Format Listing

Fig.4 ANALYZER/SX Output Listing

ANALYZER/SX has a special feature to measure and report only the execution time for each program unit. Users can see real effect of vectorization by comparing execution time in scalar mode and vector mode for each program unit by using this function. When executed on the AP, the vectorized operation ratio is measured by using hardware counters and also output in the listing.

ANALYZER/SX has another features to analyze static characteristics of a source program, such as a tree diagram depicting a module structure of a program, a COMMON data cross reference listing, a module cross reference listing and a listing showing the correspondence between actual arguments and dummy arguments. This information is useful when considerable modification is necessary.

VECTORIZER/SX is the utility program to help users tune their programs to get higher vectorization ratio. It works in a screen mode of the TSS environment. The dynamic characteristic information of the program to be tuned is passed from ANALYZER/SX through a file so that users can see it through a terminal screen. Vectorization diagnostic messages are also passed from FORTRAN77/SX compiler so that they can know why DO loops are not vectorized. In addition, VECTORIZER/SX has screen editor functions in it, and the above information is merged with source program lines in an edit buffer. Consequently, users can modify their source programs directly while referring to necessary information. An operational flow of VECTORIZER/SX is shown in Fig.5. Its program editing panel is also shown in Fig.6.

CONCLUSION

The outlines of FORTRAN77/SX and some tuning utilities of the SX system have been described. Now the use of supercomputers has become very common, and the programmers who have no special knowledge on them have begun to use them. As we have mentioned, we think that the ease of use is essential to today's supercomputers. Furthermore, high performance must be attainable at the same time. We believe we could achieve these goals with above software products.

Abstract. This paper describes an IXM machine for the parallel processing of large knowledge based systems written in a semantic network language, IXL. The potential performance of IXM is thousands faster than conventional machines, as IXM can find all the solutions of the query simultaneously. IXM consists of a pyramid-shaped network(PYN) and one thousand proccesing elements(PEs). IXM utilizes two thousand associative memories in order to exploit the concurrencies in the fundamental operations of semantic network: association, set operation, and marker propagation. A network processor at each node of the PYN has an associative memory for parallel marker propagation. A PE also has two types of associative memories; one for the parallel processing of association and set operation, the other for exploiting the parallelism in IXL language interpreter described in non-procedural instructions.

1. INTRODUCTION

The semantic network is one of the most important representation schemes to develop knowledge based systems[1,2]

The authors are developing the IX[iks] system which includes a semantic network language for knowledge representation (IXL)[3,4] and a massively parallel hardware (IXM)[5]. The objective of the IX system is to support all the processes of semantic network processing in an integrated fashion: from using IXL in the modeling and description of knowledge based systems to their parallel execution on an IXM machine.

This paper focuses on the architecture of IXM. IXM is a high performance multiprocessor thousands of times faster than current machines used for semantic network processing. IXM consists of a pyramid-shaped network and one thousand processing elements.

It is very important for the design of the semantic network machines[6,7] to utilize the parallelism in three fundamental operations in the semantic network: marker propagation, association, and set operation.

Therefore, the network processor located at every node of the pyramid-shaped network employs an associative memory in order to exploit the concurrency in marker propagation.

Furthermore, the processing element also includes two kinds of associative memory; one to perform association and set operations in the SIMD manner, and the other to exploit the concurrency in an IXL language interpreter.

Section 2 describes the background of the semantic network and the programming language IXL since the IXM architecture design is IXL oriented. Section 3 is an overview of IXM. The design features are discussed in Section 4. Section 5 describes the processing element and Section 6 describes the pyramid-shaped network.

2. BACKGROUND

2.1 Semantic network

The advantage of the semantic network is the representation of declarative knowledge. Taxonomical knowledge and inheritance can be represented more naturally than predicate logic. Inheritance of properties from the super class is very useful to describe especially large knowledge bases because it can save memory spaces. Compared with frame systems, the meaning of the relation between concepts can be defined more flexibly. Procedural knowledge, however, can not be expressed well using only the semantic network. Therefore, semantic network languages have to include methods for procedure addition.

The semantic network can be processed efficiently by assigning marker bits to each node of the network2. A marker bit is a one-bit flag on which the result of processing is stored. Fundamental operations in the semantic network are performed using maker bits. For example, the question, "Which member belongs to both A-group and B-group ?" is asked in the semantic network of Figure 1.

In order to find the solution, the association operation is executed firstly to set the marker bit No.1 of the A-group node. Then the marker propagation is executed to set the marker bits No.1 of the nodes which belong to the lower hierarchy of the A-group along the 'isa' links, starting from the A-group node going downward. These nodes represent members of the A-group. As well as the A-group members, the marker bits No.2 of the B-group members are set using association

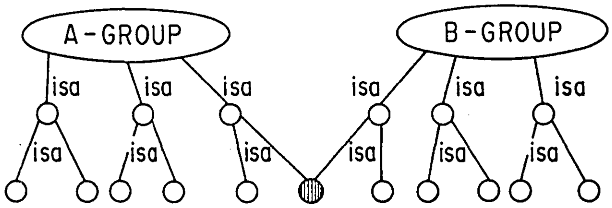

Figure 1. A Semantic Network

CH2345-7/86/0000/1041$01.00 © 1986 IEEE

and marker propagation. Finally, the set operation is executed to find the intersection of the A-group and the B-group; marker bits No. 1 and No.2 of each node is ANDed.

Parallelism in marker propagation can be utilized to greatly reduce the execution time in large knowledge bases. This is because marker propagation can find all the members of a set in the length of time proportional to the depth of the tree. Therefore, if the set is represented as a binary tree of a million nodes, only 20 steps are required to mark all the members. Association includes as many concurrencies as there are nodes in the semantic network. This also applies to set operations. As will be mentioned later, the IXM machine can exploit these parallelisms fully by using associative memories.

2.2 IXL

IXL is a semantic network language for knowledge representation. The design philosophy of IXL is to solve the problems of existing semantic network languages: the description capability of relations themselves, the method of procedure addition, and the treatment of negative knowledge.

As shown in Figure 2, IXL is a command language which looks like a logic predicate. IXL can perform (1) modifications, (2) inquiries, (3) descriptions of knowledge bases. For example, an IXL command for knowledge description, 'link(is_a, penguin, bird)', is used to state that a penguin is a bird. Once this knowledge is stored and an IXL command for inquiry,'isa(penguin,X)', is issued, the answer becomes bird.

The main features of IXL are:

1) User-defined relation represented not by a link but by a network of nodes in order to define the meaning of the relation precisely and flexibly.

2) Procedural knowledge described in logic-based expressions.

3) Negative knowledge explicitly described.

A problem with the semantic network is the expression of procedural knowledge which is used to describe complicated inference rules for knowledge bases. IXL defines procedural knowledge in the form of a clause in Prolog. For example, the following procedural knowledge represents an inference rule to determine whether a restaurant is classified as high-class or not:

```
isa( X, high_class_restaurant):-
                    asst( entree, X, Y),
                    asst( main_dish, X, Z),
                    Z + Y > 100.
```

This rule classifies a restaurant, X, as a high-class restaurant if the sum total of the entree and the main dish exceeds 100 dollars. The predicates in the above clause are all IXL commands. Arithmetic and logical expressions are also allowed to appear in the body of the clause. Notice that IXL commands can be used to describe both declarative and procedural knowledge. Therefore, once the IXM machine is designed to execute IXL commands efficiently, the IXM can process both types of knowledge uniformly.

3. IXM SYSTEM ARCHITECTURE

3.1 Overall structure

IXM operates under the control of the host computer. IXM consists of the pyramid-shaped network and processing elements (PEs) as shown in Figure 3.

The pyramid-shaped network has a network processor at each node of the network. One network processor at the bottom layer of the pyramid-shaped network connects four PEs. Each upper network processor is connected to four lower network processors. In addition, a network processor is connected to four adjacent network processors of the same layer. A network processor includes message routing logic and an associative memory to exploit the concurrency in marker propagation.

The PE includes two kinds of associative memories. The first one is for the storage and the processing of the partitioned semantic networks, for a large semantic network for knowledge bases is partitioned into sub-semantic networks and distributed among the PEs. Association and set operations are executed using the function of the associative memory in parallel and equal to the number of the memory words.

The second one is to store the IXL language

```
To connect nodes by a link:
 link(is_a, X, Y).
 link(not_isa, X, Y).
 link(instance_of, X, Y).
 link(a_kind_of, [X,Y,..], Z).
 link(source, R, X).
 link(destination, R, Y).
 link(rule, X, ((
   asst(R, X, Y):- ....
   prop(R, X, Y):- ....
   isa(X, Y):- ....
   instance(X, Y):- ....)).

To construct a relation:
 assertion(R, X, Y).
 property(R, X, Y).
```

```
To inquire about a link:
 isa(X, Y).
 instance(X, Y).
 ako(X, Y).
 source(R, X).
 destination(R, Y).

To inquire about a relation
 asst(R, X, Y).
 prop(R, X, Y).

System-supported primitive links;
 is_a,  not_isa,  instance_of
 not_instanceof,  a_kind_of,
 source,  destination

X,Y: concept node
R: relational node
```

Figure 2. The list of IXL commands

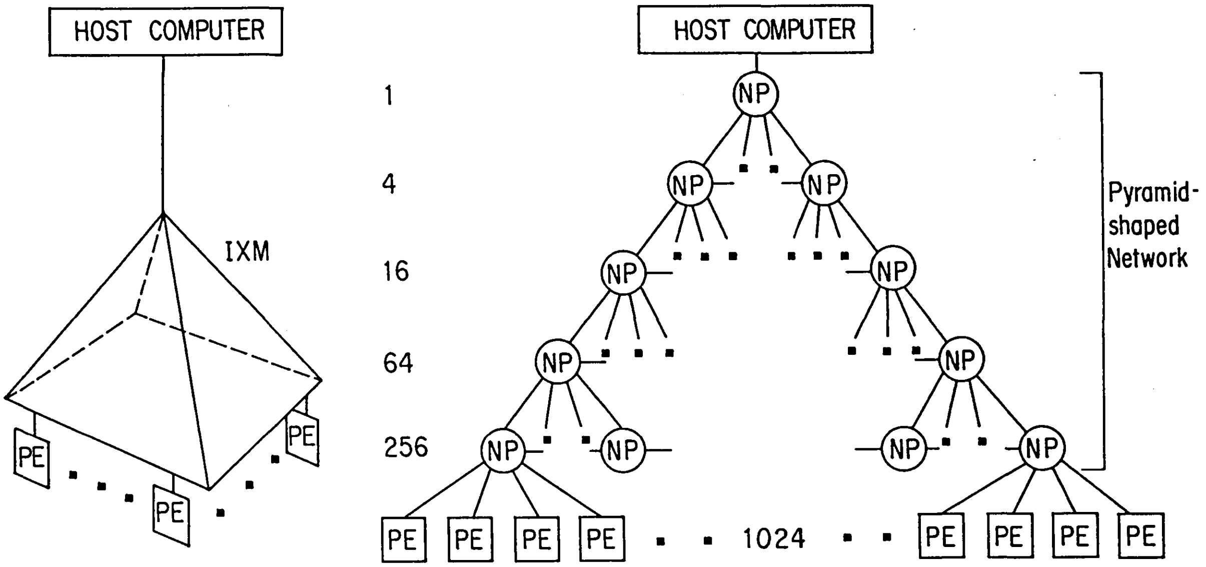

Figure 3. System organization

interpreter. The interpreter is described in the IXM machine instruction set of which the execution is asynchronous; the associative memory is used to fetch asynchronous IXM machine instructions.

A microprogrammed control unit is also included in the PE to execute IXL commands and arithmetic operations specified in procedural knowledge.

3.2 Instruction levels

There are three instruction levels in the IXM; (1) IXL commands, (2)IXM machine instructions, and (3) IXM micro instructions.

The interface between the IXM and its user is an IXL command. For example, user inputs an IXL command, 'is_a(penguin, X)' into the host computer in order to find out what a penguin is. The host computer accepts the IXL command and broadcasts it to each PE via the pyramid-shaped network, as shown in Figure 4. The IXL command is input into the IXM one at a time from the host computer; synchronization is needed each time a new IXL command is input into IXM. All the PEs execute the same IXL command in parallel because each PE stores the IXL language interpreter and the sub-semantic network in two associative memories.

The IXL language interpreter consists of subroutines; a subroutine is a non-procedual program and executes an IXL command asynchronously. Because subroutines are written in IXM machine instructions, an IXL command is executed in IXM by the IXM machine instructions.

Execution of IXM machine instructions are asynchronous to exploit the parallelism existing in IXL commands. During the execution of an IXL command, PEs require no synchronization with each other; a processing element can return the answer to the host computer as soon as the solution of the IXL instruction is found in the PE. This concurrency speeds up the IXL interpreter. Notice here the difference in execution modes; the IXM machine instructions are executed asynchronously (MIMD mode) , while the IXL commands are executed synchronously (SIMD mode).

IXM micro instructions are used mainly for the emulation of the IXM machine instructions.

4. DESIGN FEATURES

4.1 Nodes of equivalence for parallel marker propagation

Marker propagation can mark all the members of a set with O(log N) if the set is represented in a tree-shaped semantic network of N nodes. It seems to be very effective in speeding up large semantic network processing. However, it is not necessarily true when many links concentrate on one node, since such a node would have to repeat propagations as many times as the number of the links connected to it and would become a bottleneck in marker propagation. Nodes with hundreds of links appear frequently in semantic

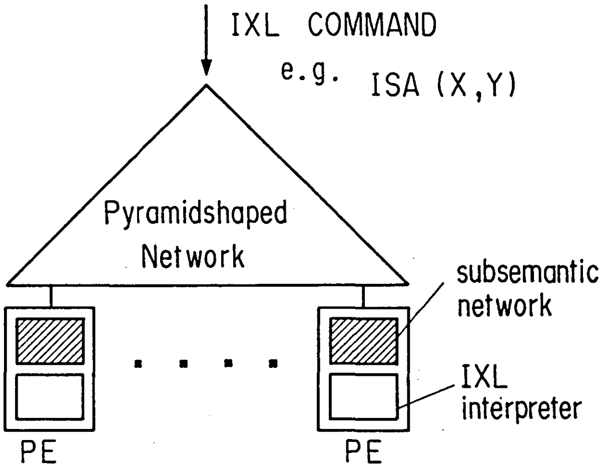

Figure 4. Execution of an IXL command

network applications because semantic networks are useful to represent taxonomical knowledge.

The authors introduced the idea of 'nodes of equivalence' in order to solve this problem and exploit concurrency in marker propagation. The idea is to partition the bottleneck node into nodes with a smaller number of connecting links and to distribute them among the PEs. A partitioned node is called a node of equivalence. For example, the student node in Figure 5(a) is the bottleneck of marker propagation, because it must repeat propagations 26 times. Therefore, the student node is divided,for example,in this case, into three nodes of equivalence as shown in Figure 5 (b). If the bottleneck node is partitioned into N nodes of equivalence, the parallelism increases N times.

If a message is sent to one of the nodes of equivalence, the message hasto be duplicated and sent to the other nodes of equivalence. For example, the hatched PEs in Figure 6 (i.e. B,C,D) contain the nodes of equivalence. If a message comes from the PE A and the destination is B, the message is duplicated and sent to C and D by the network processors of the pyramid-shaped network. The details are described in Section 6.

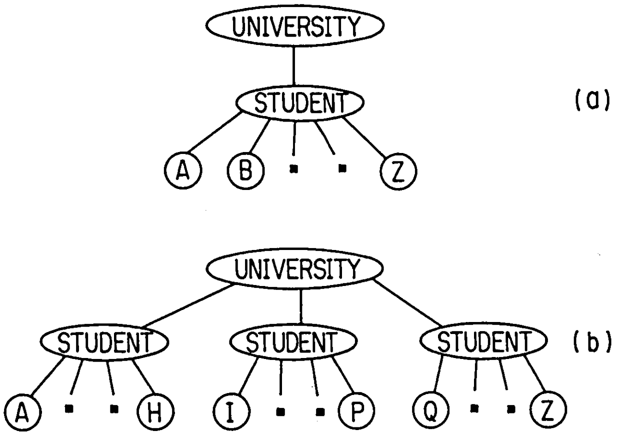

Figure 5. The nodes of equivalence

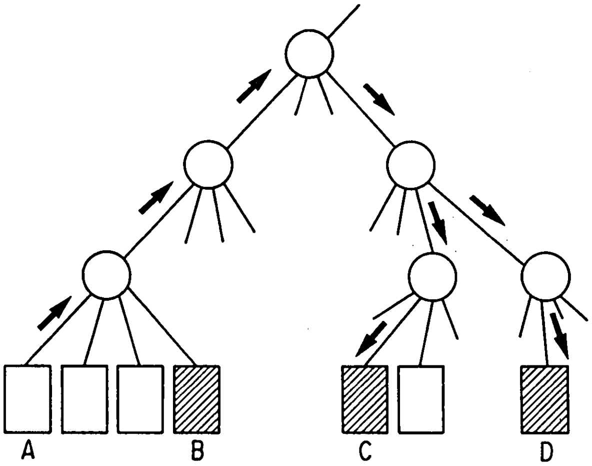

Figure 6. Message transfer using nodes of equivalence

4.2 Asynchronous IXM machine instructions

The authors have proposed an asynchronous execution mechanism of IXM machine instructions in order to utilize the parallelism in the IXL interpreter. As mentioned earlier, the IXL interpreter consists of subroutines written in IXM machine instructions; a subroutine corresponds to an IXM command. The parallelism in the IXL interpreter can reduce considerably the total execution time of the IXM.

For example, suppose the IXL command, 'is_a(X,animal)', is entered in order to find the solutions which come under the heading of animal. In Figure 7, the solutions are bird, penguin, and robin. Marker propagation marks these solutions, starting from the animal node. Therefore, the bird node is marked earlier than any other node.

So, if the bird node is returned immediately to the host computer as a solution (without waiting for the completion of marker propagation), the turn around time can be reduced to a large extent. In order to realize this, IXM machine instructions must be asynchronous.

Now we shall explain the asynchronous execution mechanism. Here it is assumed that each node has a subroutine for an IXL command to be executed; the hatched rectangular in Figure 7 represents a subroutine. The subroutine is written in asynchronous IXM machine instructions. An IXM machine instruction in the subroutine specifies a marker bit in the input marker field of the instruction format; as soon as the marker bit of a node is set, the IXM machine instruction can be started to the node, independent of the other nodes.

In Figure 7, if the marker bit No.1 of the bird node is set by marker propagation from the animal node, the bird node searches its subroutine for the IXM machine instruction which specifies the marker bit No.1 as the input marker. If there are two such IXM machine instructions in the subroutine and if they are the return and the marker propagation instructions, the bird node can immediately return its identifier to the host controller and then mark the marker bit No.1 of the penguin node. Thus,the asynchronous execution of the IXM machine instructions utilizes the parallelisms existing in the IXL interpreter.

The PE employs an associative memory to find

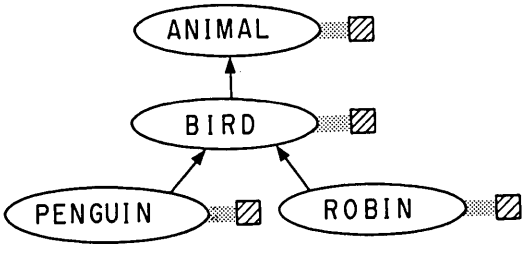

Figure 7. Taxonomical knowledge

executable IXM machine instructions quickly. The details are described in Section 5.

4.3 Associative memory to store and process semantic networks

The association operation and the set operation are very important in the IXM design because they appear in semantic network processing very frequently as well as marker propagation. The IXM employs an associative memory for each PE to utilize the parallelism in these operations.

The large semantic network of the knowledge base is partitioned into sub-semantic networks. Each sub-semantic network is stored in the associative memory of a PE. Therefore, multiple nodes are stored in a PE. For these nodes, the association operation and the set operation are executed in the SIMD manner, using the function of the associative memory.

Because the IXM consists of one thousand PEs, it is an advantage that the IXM design highly utilizes the associative memories suitable for VLSI implementation.

5. PROCESSING ELEMENT

As shown in Figure 8, the PE of the IXM consists of three components: an associative memory for semantic networks (SNAM), an associative memory for the IXL interpreter (IRAM), and a microprogrammed control unit (CU).

SNAM stores a sub-semantic network which is a partition of the large semantic network. Each word of SNAM contains not only a node but also the marker bit field where the processing results to the node are stored. Using its association function, the set operation and the association operation are executed simultaneously for all the data in the memory.

IRAM stores the IXL interpreter described in the IXM machine instructions. If a marker bit of a node in an SNAM word is set by the semantic network operation, then it causes the execution of another IXM machine instruction. Therefore, IXM machine instructions are asynchronous just like dataflow instructions[8]. IRAM finds executable IXM machine instructions by its associative function.

CU is a microprogrammed processor and it controls SNAM and IRAM to perform three functions: the execution of IXL commands, arithmetic and logical operations, and the processing of communication packets sent from either the host controller or other PE's. CU executes the IXM micro instructions.

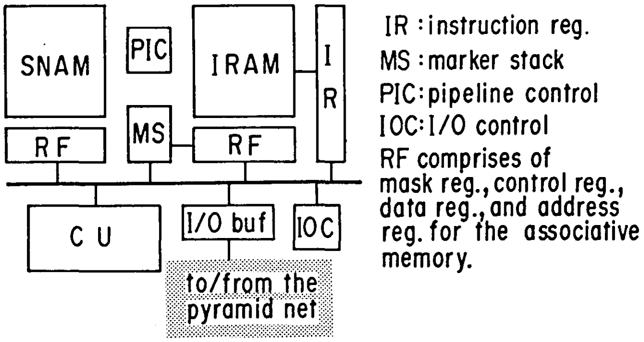

Figure 8. PE block diagram

5.1 Execution cycles of an IXM machine instruction

The microprogrammed control unit (CU) controls the fetch and the execution of an IXM machine instruction, as shown in Figure 9. Firstly, an IXM machine instruction is fetched from IRAM. Secondly, the IXM machine instruction is executed by CU, using SNAM. The marker bit of SNAM is updated as the result of the execution.

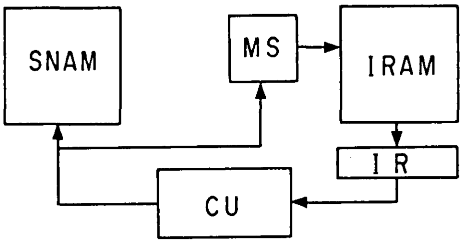

Figure 9. The execution mechanism of an IXM machine instruction

When the marker is updated, the marker bit number is also stored into the marker stack (MS). Thirdly, CU searches IRAM for the next executable IXM machine instruction, using the marker bit number in the marker stack, since the update of a marker bit enables the execution of another IXM machine instruction. These cycles are repeated to find the solutions of an IXL command.

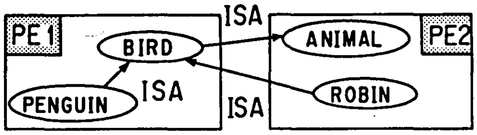
5.2 SNAM

Figure 10 shows the organization of SNAM and how the partitioned semantic networks are stored in SNAMs. The semantic network in the figure is partitioned into two sub-networks and stored separately in two SNAMs.

SNAM is 2K-word associative memory with a width of 64 bits. One word consists of four fields: the identifier field (21 bits), the destination field (21 bits), the link name field (4 bits), and the marker bit field (18 bits).

An SNAM word represents a link and the node which is connected to the link. A link occupies two SNAM words , since a link has two nodes on both edges. For example, as shown in Figure 10, the 'isa' link between the animal node and the bird node occupies the two words: the first word of SNAM1 and the first word of SNAM2. The identifier field distinguishes between the two million links stored in the IXM. The link name field indicates a system-support link such as 'isa' and 'instance_of' ; four bits are required to distinguish between the system-support links (a user-defined link is translated into system-support links). The destination field consists of the PE number and the displacement within SNAM where the node is stored; for example, the destination of the robin node at the first word of SNAM2 is represented as 'PE1(1)', because the animal node, which is the destination of the robin node, is located at the first word of SNAM1 in PE1.

The marker bit field contains 18 marker bits (numbered from 0 to 17). Each marker bit holds the result of the semantic network processing such as association and set operations. For example,



IDF(21bit)	DSF(21bit)	LN(4b)	MBF(18b)
BIRD	PE2(1) ANIMAL	ISA	·
BIRD	PE1(4) PENGUIN	RISA	·
BIRD	PE2(2) ROBIN	RISA	·
PENGUIN	PE1(1) BIRD	ISA	·
SNAM1 (PE1)			

ANIMAL	PE1(1) BIRD	RISA	·
ROBIN	PE1(1) BIRD	ISA	·
SNAM2(PE2)			

LEGEND IDF: identifier field LN: link name
DSF: destination field -> PE No.(displacement)
MBF: marker bit field RISA: reverse isa

Figure 10. SNAM organization and the partition of a semantic network

suppose an IXM machine instruction, 'ASSOC(bird, 2)', is executed in the IXL interpreter program, this instruction is for the association operation. It searches for the SNAM words which contain the bird node. If it exists, each marker bit No.2 of the corresponding words is set; in this example, the No.2 marker bits of the three words in SNAM1 are set.

When the marker bit is set in SNAM, the marker bit number is also stored in the marker stack. The marker stack is accessed by IRAM to find IXM machine instructions which have become executable.

Using SNAM has two advantages. The first one is the parallel processing of the association and the set operations. The IXM can process both of them in O(c) steps, while the algorithms for them on a sequential machine take O(n) and O(n*log n) steps respectively. The second advantage is that the establishment of new links is relatively easy. The two new words of SNAM are added in order to establish a new link between the two concepts.

5.3 IRAM

Figure 11 shows the organization of IRAM. Each word consists of the operation code field (3 bits), the input marker field (5 bits), the argument field (21 bits) and the resulting marker field (5 bits). The input marker field specifies a marker bit of SNAM. If an IXM machine instruction specifies a marker bit in the input marker field, the IXM machine instruction becomes executable as soon as the marker bit is set. The resulting marker field specifies the marker bit which is to be set as the result of the execution.

The IXL interpreter consists of subroutines for IXL commands and each subroutine is written with these IXM machine instructions. Figure 12 shows an IXL command, 'isa(penguin,X)', and its subroutine written with IXM machine instructions. This IXL command searches for the higher-class concepts of the penguin. In order to find the solution, two steps are required. First, the penguin node is determined. Then, 'isa' links are traversed starting from the penguin node. The nodes on the traversed 'isa' links become the solutions of 'isa(penguin,X)'; they are the bird node and the animal node.

op-code field (3bit)	input marker field (5bit)	argument field (21 bit)	resulting marker field (5bit)
ASSOC	*	PENGUIN	0
MARK	0	ISA	0

Figure 11. IRAM organization

```
IXL command:    ISA(penguin, X)

IXM machine instruction:
                ASSOC(penguin,0)
                MARK(0, isa, 0)
```

Figure 12. An IXL command and the subroutine for it

The subroutine to implement this IXL command is stored in IRAM as shown in Figure 11. At first, 'ASSOC(penguin, 0)' is selected from IRAM. After the execution, the marker bit No.0 of the fourth word of SNAM1 in Figure 10 is set because it is the penguin node. After the marker bit No.0 is set, IRAM is searched to find the IXM machine instruction which has the marker bit No.0 in the input marker field. Then, 'MARK(0,is_a,0)' is selected.

Figure 13 explains the MARK instruction. Suppose 'MARK(n1,is_a,n2)' is to be executed. If node A has the marker bit No.n1 which is set and if an 'isa' link emerges from node A, the MARK instruction becomes executable. As the result of the MARK instruction, the marker bit No.n2 of node B which is connected to node A with the 'isa' link is set.

Therefore, if MARK(0,is_a,0) is executed to the example of Figure 6, the marker bit No.0 of the bird node is set. Then, MARK(0,is_a,0) is selected once again from IRAM and is executed. So, the marker bit No.0 of the animal node is set. Thus, the execution of the IXM machine instruction proceeds asynchronously.

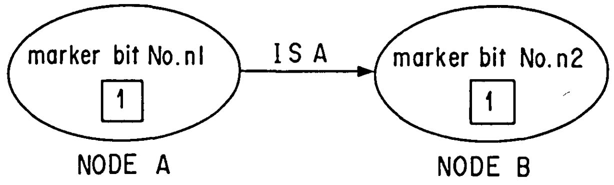


Figure 13. MARK instruction

5.4 Control unit (CU)

Processing by CU is roughly classified into the following two types. The first type is the emulation of IXL machine instructions. The IXM machine instruction such as MARK is executed in terms of IXM micro instructions. As mentioned in Section 5.1, read and write operations to SNAM and IRAM are frequently done in order to fetch and execute IXM machine instructions. These associative memories are controlled with IXM micro instructions.

The second type of CU processing is the arithmetic and logical operations which appear in the description of procedural knowledge; the inference rule mentioned in Section 2.2 is shown again as an example.

```
isa( X, high_class_restaurant):-
                     asst( entree, X, Y),
                     asst( main_dish, X, Z),
                     Z + Y > 100.
```

The first IXL command in the body, 'asst(entree,X,Y)', looks up the price of the entree,'Y'. The second looks up the price of the main dish, 'Z'. The third calculates the sum and decides whether the sum exceeds 100 dollars or not.

Although the rule looks like a clause in Prolog, notice that all the solutions of an IXL command can be determined simultaneously. Solutions of a predicate in Prolog are determined sequentially. Therefore, the IXM can be regarded as a parallel logic machine taking this viewpoint.

6. PYRAMID SHAPED NETWORK

The structure of the pyramid-shaped network (PYN) is shown in Figure 3. Network processors are connected in the shape of a pyramid. However, the connection path between the PEs of the same layer of the network is not used in the first version of the IXM for the convenience of implementation.

PYN is used for the following three types of packet communication.

(1) Host computer-to-PE: Broadcast of an IXM command.

(2) PE-to-PE : Marker, value, and (or), node identifier are transferred from PE to PE.

(3) PE-to-Host computer : Collection of computation results.

The destination of the packet in the PE-to-PE communication is the node identifier to which the packet is sent. The node identifier consists of the PE number and the displacement in the SNAM where the node is stored. The network processor routes the packet according to the node identifier. The network processor always watches the node identifier to distinguish whether the node is the member of the particular nodes of equivalence or not. If the packet is sent to a member of the nodes of equivalence, the network processor copies the packet and send the copies to all the members of the nodes of equivalence. For this operation, a table for nodes of equivalence is stored in an associative memory of each network processor.

6.1 The node of equivalence

Figure 14 shows the marker propagation to the node of equivalence. It shows the case of the university node in PE No.1 sending a packet to the

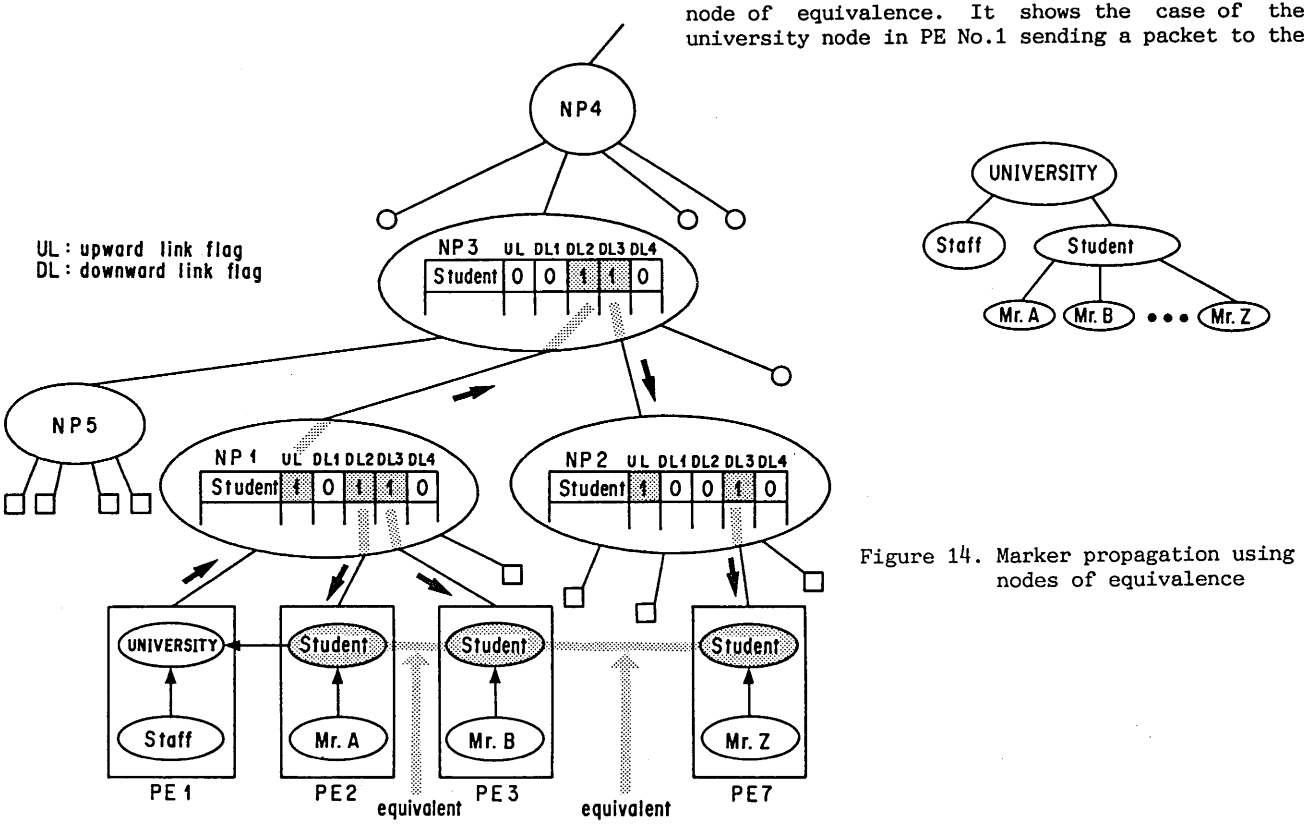

Figure 14. Marker propagation using nodes of equivalence

nodes of equivalence,'student'. The 'student' nodes are distributed in processing elements No.2, No.3, and No.7. Therefore, the packet has to be copied and the copied packets have to be sent to these PE's by the network processor No.1, No.2, and No.3.

The network processor has a table for nodes of equivalence (EQNT). Each item of EQNT consists of the node identifier of the node of equivalence and the routing information to deliver the copied packets.

The routing information is in five flags indicating the distribution of the nodes of equivalence among PEs. Four bits correspond to four downward links to four lower network processors or PE's, and the remaining one bit corresponds to one upward link to an upper network processor in the network hierarchy.

It is required to determine which network processors have the EQNT items for a particular node of euivalence. For example, network processors No.1, No.2, and No.3 have the EQNT items for 'student' node as shown in Figure 14.

The algorithm to select the network processors where the EQNTs are to be located is as follows:

(A1) Select the PEs which contain the nodes of equivalence.

(A2) Find a root network processor of the minimum sub-tree which has all the PEs selected in (A1) as its leaf.

(A3) Traverse the connection path starting from each PE of (A1) to the root network processor selected in (A2).

(A4) Select the network processors traversed in (A3).

The routing information of each EQNT item is determined as follows:

(B1) If a network processor has downward links which are connected to either the network processors of (A4) or the PEs of (A1), then the downward link flags corresponding to the downward links are set.

(B2) If a network processor has an upward link which is connected to the network processor of either (A2) or (A4), then the upward link flag is set.

For example, the downward link flags No.2 and No.3 of the 'student' item in the network processor No.1 are set as shown in Figure 14.

6.2 Structure of network processor

The network processor consists of the following components:

(1) Input/output buffer queues for asynchronous communications between network processror and a PE, or between two network processors

(2) decision logic for packet routing

(3) the associative memory to store the table for nodes of equivalence (EQNT)

(4) the control processor

Figure 15 shows the block diagram of the network processor. A packet arriving at a network processor is queued into input buffer registers. Then, the destination of the packet is examined using the associative memory in order to identify whether the destination is a node of equivalence or not. If it is identified, the packet is copied and sent to the other member of the node of euivalence according to the routing information in EQNT. If the destination is not a node of equivalence, the packet is delivered using simple routing logic.

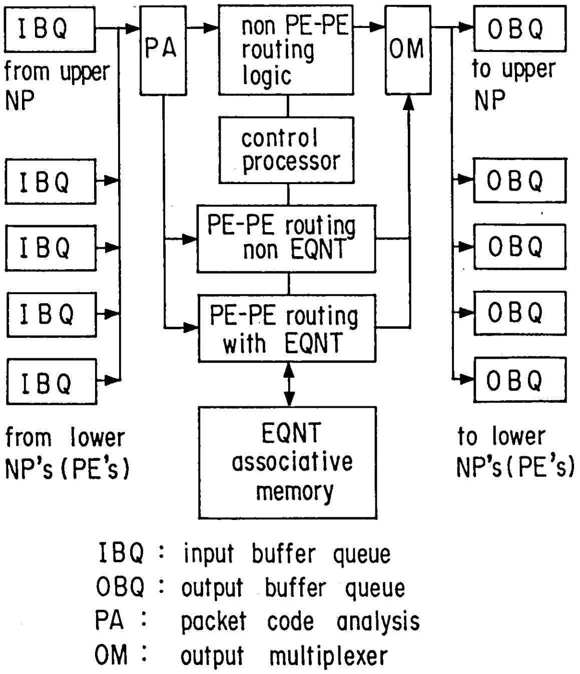

Figure 15. Network processor
- block diagram

7. PERFORMANCE

We show here the simulation results of the IXM machine and discuss its performance. At first, the execution time of semantic network processing on a conventional computer (Micro VAX II) is shown for the comparison with IXM.

We developed the IXL interpreter in K-Prolog on Micro VAX II. A French wine knowledge base has been written in IXL. A user can issue an IXL command to get various knowledge about wine. Table 1 shows the execution time of two types of queries to three knowledge bases of different size.

The query (1) asks the knowledge base whether a particular fact holds or not. For example, an IXL command, "prop(rate, 'chablis_wine', '**')",is issued to ask whether the chablis wine is rated as two-starred or not. As shown in Table 1, a user can get an answer (yes or no) in about two second, although the execution time depends on where the fact is located in the knowledge base.

The query (2) asks the knowledge base all the solutions of the query. For example, "bagof(X, prop(rate, X, '**'),L)" command replies all the wines rated as two-starred in the variable L. The execution time of this type of query increases abruptly as the knowlede base grows larger. A user have to wait fifteen minutes for the query to the knowledge base of 4500 links which is far from practical knowledge base. This is because of the exponential explosion of the search space. Even

Table 1. Execution time of the knowledge base(KB) search by IXL language processor on Micro VAX II

KB size	1600 links	3300 links	4500 links
query (1)	66 - 600 msec	66 - 1183 msec	66 - 1633 msec
query (2)	2.1 min.	8.7 min.	14.6 min.

Table 2. IXM machine cycles for the knowledge base search

KB size	1600 links	3300 links	4500 links
query (1)	1560	2112	2404
query (2)	2452	2756	3556

if the IXL interpreter is implemented not in Prolog but in Lisp, the result will show the same tendency as in Table 1.

On the other hand, as shown in Table 2, the result of IXM machine simulation shows that the total of IXM machine cycles required for query (2) does not increase abruptly even if the knowledge base grows. The potential performance of IXM is thousands faster than conventional computers. This is because IXM machine can find all the solutions in parallel using the procedures written in asynchronous IXM machine instructions.

We are currently designing the details of the IXM machine of which machine cycle is 100 nano second, assuming the associative memory of which access time is 300 nano second and 6 mega byte/sec transfer rate between network processors.

8. CONCLUSION

Knowledge bases of a few million nodes described in the semantic network will be used in practical applications within a decade. The authors have proposed a massively parallel architecture which highly utilizes associative memories to exploit the parallelism in semantic network processing.

The associative memories in IXM are used for three purposes. The first is the utilization of parallel structure in association and set operation. The second is the parallel marker propagation. The third is the exploitation of the parallelism in IXL interpreter.

The IXM machine is also a language (IXL) oriented machine. IXL gives a method to treat declarative and procedural knowledge uniformly. IXM machine can process both declarative and procedural knowledge efficiently by adopting the IXL oriented approach.

The simulation result shows that the potential performance of IXM machine is thousands faster than conventional machines. In order to utilize IXM fully for large knowledge based systems, it is also very important to develop an optimizing allocator which partitions a large semantic network and allocates each sub-semantic network onto a PE. This is because the throughput of IXM is greatly influenced according to the allocation algorithms; the communication pattern in IXM, the parallelism in marker propagation, and the conflicts on the pyramid-shaped network change considerably.

Associative memories can be implemented with a high integration density because of its regular cell structure. The authors have started the VLSI implementation of IXM[9]. Though associative memories of large capacity are not in practical use at present, the associative memory approach will lead to one of the most promising architectures for large knowledge based systems.

ACKNOWLEDGEMENT

The authors thank Dr. Hiroshi Kashiwagi for providing the opportunity to pursue this research.

NTT Electrical Communications Laboratories
P.O. Box.8, YOKOSUKA POST OFFICE, KANAGAWA, JAPAN

Abstract

This paper describes high-performance optical loops for main-frame coupling and its application to complex, large-scale computer systems. Emphasis is placed on problems concerning alteration of the system configuration, system operation and rapid system recommencement in the event of break-down. A communications method using the optical loop and the "Global Manager" (GM) concept in the "System Control Processor" (SCP) are proposed. The rapid system recovery method using total integration via optical loops along with the GM concept are discussed and evaluated in terms of enhanced reliability.

1. Introduction

NTT has developed and furnished nation-wide data communications and processing systems for banking, national and municipal government and many other public services. [1] Enhancing the expandability of these large-scale systems became a crucial theme, because the rapid expansion of services and system scale, such as nation-wide information-base access, was needed with this movement toward on information society.

To achieve such large-scale systems, a method for loosely-coupled multi-processor construction is appropriate from the view points of performance and reliability. This, in turn, requires development of a high speed inter-processor communications method which allows for easy alteration of a multi-processor construction. Such development will simplify system operations and improve reliability.

In light of the above, high-performance optical loops, consisting of Processor-Processor Communications Interface equipment (PCI) and optical fiber cables, has been developed. A System Control Processor (SCP) has also been developed, which centralized and simplified the command and control functions in a loosely-coupled multi-processor construction. PCI and SCP development led to creation of the Denden Information Processing System (DIPS) Computer Complex with Optical Loops (CCOL) offered for nationwide commercial services. Even though the DIPS-CCOL system consists of a number of subsystems, operation is smooth. In the event of trouble in a given subsystem, the immediate switch-over of processing to another (standby) subsystem serves to enhance the reliability of the whole system.

This paper describes the characteristics of the optical loops used in the DIPS. Additionlly, it outlines the DIPS-CCOL and technology employed, and provides an evaluation of this highly reliable system.

2. High-performance Optical Loops for Coupling Processors

NTT's optical fiber loops have a token-passing ring consisting of PCIs and dual optical cables. The objectives involved in achieving a complete subsystem integration using optical fiber loops are as follows.

1) Reduction of the required CPU load for inter-subsystem communications processing
2) Simplification of subsystem addition and alteration
3) Enhancing optical loop reliability

Inter-subsystem Communication Processing

Multiple data-links for inter-subsystem communications are used in the optical loop communications method to achieve complete subsystem integration. The method to dynamically establish data-links for every message[2] is not suitable because of the excessive overhead in real-time processing systems and the complexity of a subchannel assignment mechanism. Consequently, a method for statically holding data-links was adopted. The data-link maintenance capability was developed using the PCI subchannels to enable the followings:

1) Maintaining the predetermined data-link control information between processors for each subchannel.
2) Control of data-link information by any processor in the PCI loop.

Figure 1 outlines an inter-subsystem communications processing method. To achieve a full duplex path, a logical path with two one-way data-links was constructed to avoid retranmission due to conflict and associated transmissions rights control. Another feature of this system is that, by permanently setting the data-receiving end of a data-link on Read Command, Attention Interruption requiring the reading of transmitted data can also be reduced.

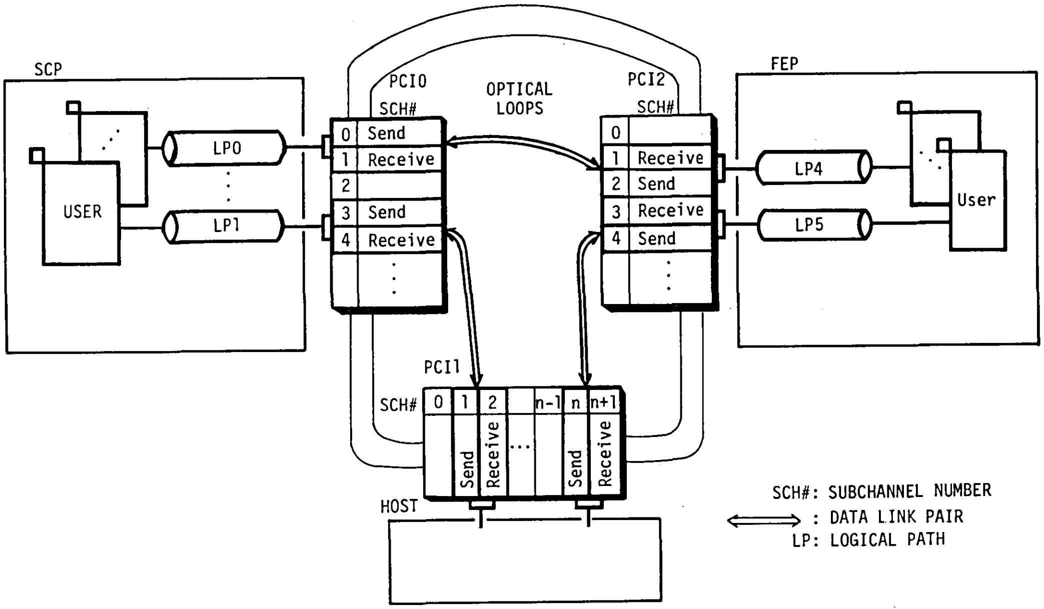

Figure 1. Inter-Sub-System Communications Processing

System Expansion

Information concerning configuration status, including the data-link control information of all PCIs, must be simultaneously altered with the addition of a new subsystem. A related difficulty concerns the method of load balancing to multiple PCIs.

The DIPS-CCOL Global Manager (GM) function maintains unified control of all data, including the configuration status information. It determines data-link control information for each PCI, and distributes this to each subsystem. The GM uses a specified subchannel pair as a "control data-link" in order to distribute information before establishing a data-link.

Two methods were considered to distribute data to multiple PCIs: dynamic and static routing. A logical path allocation method based on the latter was developed because of the necessity for a high-performance facility. In a real-time processing system required to satisfy specific response-time, the maximum subsystem loads must be smaller than the total PCI performance potential which is found in the linked subsystem. As a result, the following mehtod was proposed to determine the route automatically and simplify the equipment plan.

1) Logical path classification
2) Allocation of PCI data-links for each classification at initial use
3) Making uniform the number of opened paths belonging to the same class in all the PCIs of a given subsystem.
4) Making possible path allocate to any PCI by control of the initial use.

Implementation of the methods described above, as well as utilization of the developed components resulted in the achievement of high-performance, computer-to-computer communications to which extra subsystems could be easily added.

Enhancing the High Reliability of Optical Loops

Both optical cable and PCI breakdown may occur in optical loops, and this reflects badly on system reliability. Figure 2 illustrates an automatic loop back, using a dual path, which can be carried out by PCIs when such breakdown occur.[3] With PCI breakdowns, message processing can also be continued by the reallocation of other PCI data-links to the damaged logical paths. It should be noted that this is possible only when the subsystem has more than one PCI. Reserve PCIs, shared by the whole system, can also be set up and with automatic integration executed by the SCP. As a result, continued operation is possible despite optical loop breakdown, thereby enhancing the overall reliability of the system.

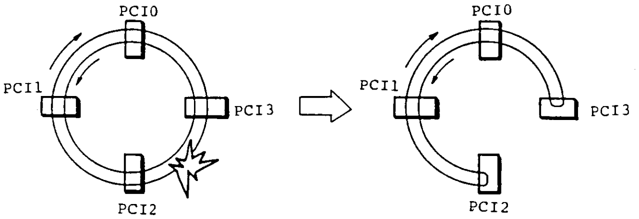

Figure 2. Safety mechanism in the event of Optical loop breakdown

3. An Outline of the DIPS-CCOL

The configuration of a highly reliable, DIPS-Computer Complex with Optical Loops is given in Fig.3. The special features of this system are that optical loops have been used to join the subsystems and that a System Control Processor (SCP) has been installed. It should be noted that use of the term subsystem, within the contex of the system outline, refers to the Host and Front End Processors (FEP).

SCP is the actualization of the Global Manager (GM) for governing operation of the whole system. It also supervises other subsystems and controls overall system structure. In addition to a database containing the knowledge required for system operation, the GM concept, at the core of the SCP, contains the functions enabling management and control of inter-subsystem links as well as the handling of console messages transmitted via the optical loop to other processors. Each subsystem has the ability both to send messages concerning the whole system to the SCP and to process messages from the SCP as console commands. The SCP exchages messages with each subsystem and carries out hardware reconfiguration based on the knowledgebase. Two SCPs can also be utilized, one on a standby basis, to create a redundant system structure offering high reliability.

As part of the attempt to ensure high reliability in the system, one "reserve" subsystem is installed for n subsystem units. As all subsystems share the magnetic storage units, the reserve unit can either remain on standby or execute other jobs.

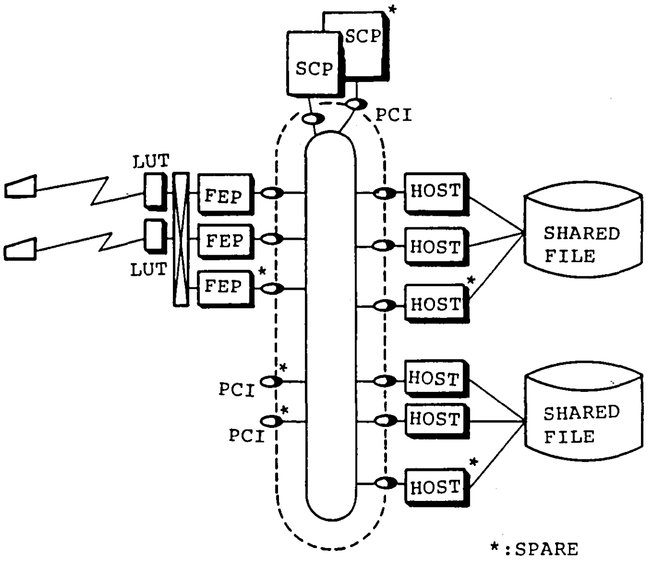

Figure 3. DIPS Computer Complex with Optical Loops

4. DIPS-CCOL Developmental Topics

The installation of extra hardware and modified software and the enhancement of system reliability have become major goals in order to provide increased system capability and more comprehensive user services. This is especially true in regard to the current trend toward a wider range of services in computer systems. One current proposal for achieving these goals concerns utilization of the distributed processing method, in which the system is constructed by a number of sybsystems.[4] [5], [6]

However, system alteration and operation is not so easily achievedwhen dealing with large-scale distributed processing systems which employ main frame computers. There are two main difficulties. The first lies in the greatly complicated interface between subsystems made necessary by the increase in overall system size. The second concerns the more complex operations which arise in conjunction with the increase in component numbers.

In light of these problems, technological development was chosen in two areas as means to achieve the goals mentioned above. The first area concentrated on Global Manager development for smooth operation of the overall system. The second sought continuous transaction processing capability at times of Host breakdown.

Global Management of the system

An increase in the number of subsystems not only causes an increase in the operations required to manage the system but also complicates the operations of the whole system because of associated complex operations for the joint use of peripheral devices between subsystems. The concept of a Global Manager for the SCP has been proposed as a mean of solving these problems. The main features of this Global Manager are:

1) Unified management and control of all subsystems. Status responsibility includes all device connections as well as execution of operations in response to messages.
2) Substitution for human operators as regards operating instructions.
3) Harmonious global system management in conjunction with operators.

Enhancement of System Reliability

The larger the system scale, the greater the effect of service suspension on society becomes. Consequently, the recommencement of service after a subsystem breakdown, before the user is even aware of any interruption, is most effective from the dual viewpoints of MTBF (Mean Time Between Failure) extension and MTTR (Mean Time To Repair) reduction. Through use of an optical-loop-based, complete integration, quick service recommencement can be achieved. In times of Host breakdown, this function puts messages on hold in the FEPs, switches over to a stand-by Host and then carries out high-speed file recovery.

5. Global Management

In a CCOL system, the following conditions must be satisfied in order to facilitate system operations:

1) Each subsystem can be individually controlled.
2) Inter-subsystem control can be either automatic or by a single operation.
3) Various system operating conditions can be achieved。

Thus, noting that system operation centers on console interation, the basic fuctions of the GM were identified as automatic console response and response procedure creation, as well as a console message transmission function.
Figure 4 diagrams the Global Manager of an entire system.

Automatic Console Response Function

A function which invokes procedures describing the automatic response process is the most primitive function in terms of achieving an automatic response. Two cases, either the arrival of a console message or a specified time, were selected as triggers for procedure invocation. The following functions were developed in order to simplify this definition.

1) Registration of both the procedure and the console message invoking it.
2) Registration of both the procedure and the time at which it is invoked.
3) Invoking the procedure when the required conditions are satisfied.

This function is designed to be present in both the SCP and each subsystem, and renders automatic response processing hierarchical and distributed.

Automatic Response Procedure Creation Function

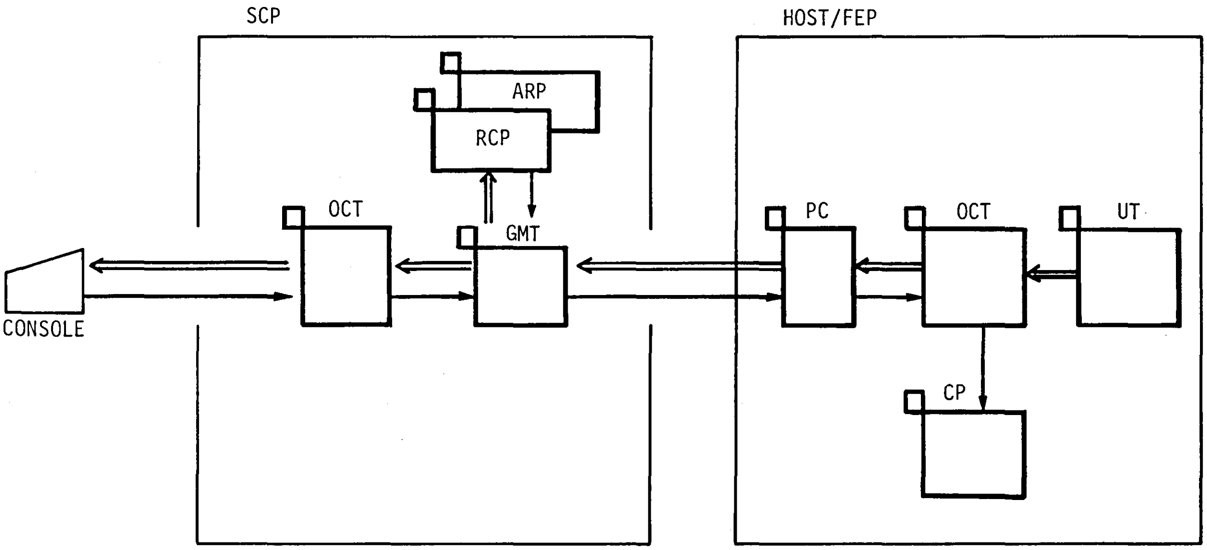
Because automatic response procedures vary from one system to another, a simple language function has been provided to describe the response process. This allows a new command definition due to the function's ability to input console commands from the procedure.

Console Message Transmission Function

Transmission of console messages to the GM has been achieved in order to permit exclusive resource control and processing synchronization spanning multiple subsystems. An example of these functions would be the necessity for simultaneous alteration of line control information in multiple subsystems which are sharing line switchs, when these line switchs are modified. In a case like this, the console message controlling the hardware switch can be transmitted to the SCP, from where a command affecting the reconfiguration of the whole system can be issued.

It is additionally necessary that reprocessing of console messages, given the possibility of various abnormalities, be done accurately and rapidly, for function reliability in commercial systems. In this regard the function is accompanied by the following.

1) Console message loss prevention
2) A check-point which makes the global parameters maintain these values at system restart.



⇐ : MESSAGE
← : COMMAND
ARP: AUTOMATIC RESPONSE PROCESSING
RCP: RECONFIGURATION PROCESSING
OCT: OPERATOR CONSOLE TASK
GMT: GLOBAL MANAGER TASK
PC: PROGRAMMED CONSOLE
CP: COMMAND PROCESSOR
UT: USER TASK

Figure 4. The Mechanism of Global Manager Processing

The system presented in this paper is superior to conventional system,[7] which employ a pseudo-console device, for the following reasons.

3) The alteration response in system operating conditions is simplified.
4) Because operations knowledge is distributed to the subsystems, autonomous operation by each subsystem is simplified. This feature also enables prevention of excessive loads being placed on the SCP.
5) Because console messages are transmitted by optical loops, transfer is rapid and does not require separate hardware for connections.

6. Rapid Operation Recommencement

System reliability can be greatly enhanced by making possible the rapid recommencement of processing, that is, before most users are even aware of trouble in their subsystems. This calls for early detection of any abnormality in subsystem operating conditions automatic reconfiguration, and increased speed in message recommencement processing on standby.

Early Detection of Abnormal Conditions in the Subsystem

This is of vital importance in the reduction of both user trouble and the need for recovery, but the problem lies in the incidence of no-response events in loops due to software bugs. In order to speed detection and increase its accuracy, a "health checks" was programed, to mutually supervise in both Host and FEP, addition to a "self check" hardware of whether a timer extension operation had been carried out within a specified time.

Automatic Reconfiguration

When the GM contained the SCP is notified of a malfunction, it invokes appropriate reconfiguration action according to the information received. When a malfunction occurs in the Host, the GM selects a substitute Host, checks that this substitite is on Final Standby and then commands it to take over operations. So that system designers can re-edit the reconfiguration procedures to match each individual system, they were given a hierarchical structure using an automatic response procedure creation function.

Continuous Reception of Messages

When it takes too much time to get the standby Host ready, the time supervisor at the users terminal cuts the circuits. If, however, the switch-over and Host recommencement are completed in a shorter time, and messages can be stored in the FEP, the user can remain completely unaware of the fact that the Host went down. The method chosen for this was to use an optical loop to preset the logical path between processors as an integrated configuration, and to execute a switch-over of message transmission merely by having the FEP's communication processing program alter the logical path.

Intial Setting of the Reserve System

To achieve faster processing of messages retransmitted from the FEP, the proposed design calls for the reserve Host to be on standby, having both joint use of the present file and also the ability to operate as a load sharing system. This particular Final Standby method eliminates the need for intial system setting during service recommencement processing.

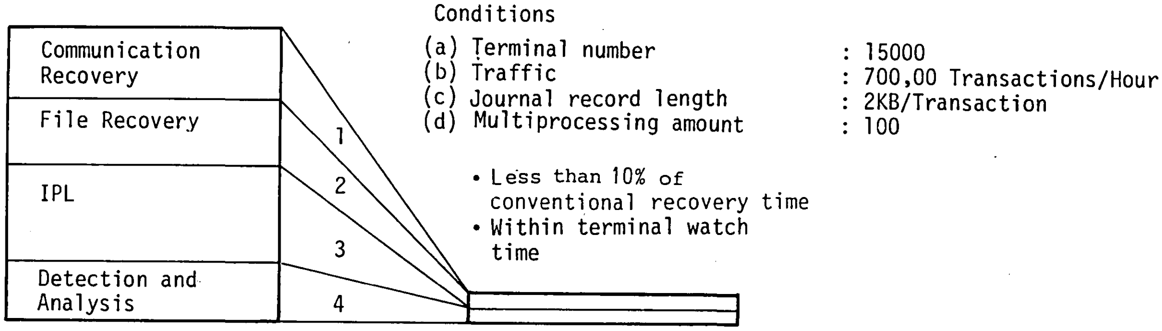
Quick System Recovery

During an on-line, system recommencement following system shutdown, both file restoration and transaction recovery are essential because file storing is accomplished by message processing. Thus, executing data restoration simultaneous with on-line services makes recovery time far shorter than that found in conventional methods. In the latter, services are recommenced only after the damaged transactions have been re-processed or abandoned following data recovery.

Services are able to be quickly recommenced in a file-sharing system because the files which need restoring are excluded by a suspended subsystem in use as a Serial Reusable Resource (SRR). However, extreme requests to the SRRs indicates that the services are barely recommenced. The effect of this conflict must be lessened, and this is done by retrieving the data under commencement from the journal file, prohibiting access to the damaged data in the file, and then releasing the SRR. In this way access is given to almost all files, making quick service recommencement possible. The data to which access was prohibited can be restored to present status with journal information. It then can be used in service.

Continuous job Execution when on Standby

If jobs that were being processed continue to be processed even when the system is on standby, there is a very real danger of a Host switch-over. This could lead to an excessive on-line system load. To avoid this hazard, a CPU has been utilized, along with a memory and I/O resource schedule. These allocate remaining resources according to high or low-priority jobs. This method suits the Final Standby method due to the fact that jobs to be executed that are currently on standby are usually processed in the background of real time operations.



Communication Recovery
File Recovery

Strategies for Rapid Recommencement

1. Lack of necessity for IPL processing due to FEP's independent operation.
2. No need for operator assistance in recovery processing and high-performance equipment.
3. Introduction of a Final Standby method, making IPL unnecessary for reserve switch-over
4. Avoidance of delayed detection and analysis through program supervision

Figure 5. Rapid Service Recommencement

7. Conclusion

In this paper, two major features of high-performance optical loops for inter-computer communications and the computer complex have been described. The first, global management, is constructed by centralizing the data-link control, moving the physical console interface from each subsystem and programing system operations. The second, rapid operation recommencement, enhances system reliability by switching FEP message transfer and actualizing the Final Standby method.

These technologies have made large-scale on-line systems far more reliabile than previously possible. In the system example shown in Fig.5, more than 95% of messages which would have been damaged in the past can now be continuously processed even under the maximum load condition. Its message abnormality results from excessive loads associated with recovery.

Abstract

An autonomous decentralized software structure has been developed to achieve software on-line expansion and on-line maintenance and fault-tolerance. In this structure, a software subsystem installed in each of the distributed computers has an autonomous operating function for selfmanagement and coordination with the subsystems without external direction and/or execution. The data field(DF) concept is introduced in order to realize autonomy in each software subsystem. Every data is broadcasted, with the attached content code corresponding to its meaning, into the DF without specifying the receiver. Each module in the software subsystem is connected only to the DF and judges whether to receive the data, or not, from the DF on the basis of its attached content code. The module runs independently from all the other modules after receiving all the necessary data from the DF. This autonomous data-driven mechanism and DF structure ensure that an application software module can be independently produced, loaded through the DF, tested by the data in the DF and begin execution while the other modules are operating. Every subsystem checks the consistency of the received data. Hence, fault tolerance of the software system in event of the software subsystem's failure is attained. Evidence of the effectiveness of this software system is provided by its application to real-time control systems for steel production process control.

1. Introduction

Distributed computer systems have developed rapidly based on the cost reduction of microelectronics and the advancement of communication techniques. On the other hand, the relative cost of software has increased in comparison with the hardware cost. Hence in the distributed system, production, expansion, maintainance and fault tolerance of the application software itself rather than economical sharing of the hardware resources have become important.

Recently distributed operating systems have been discussed but most of them are experimental systems (1). Some of them are network operating systems and others are only extensions, which manage to communicate and share resources and are added to the existing operating system. HYDRA (2) and Medusa (3), the distributed operating systems of the Carnegie-Mellon University C.mmp and Cm* multimicroprocessor systems, are aimed at not only efficient resource sharing but also system reliability. COCANET UNIX (4) developed at the University of California, Berkeley, a network operating system, modifies UNIX so that the existing programs can share remote resources using the standard UNIX interprocess communication mechanism. A language concept, communication port, is proposed to support communication between modules in distributed processors(5), but this concept is limited to one-to-one communication. This communication relation cannot be changed during system operation. CONIC, a language and support system, has been developed for dynamic configuration of distributed systems. However, in this system a specific configuration manager exsists to translate requests to change the system, expressed in CONIC language(6).

In these conventional operating systems and languages, every software subsystem or specific manager is assumed to know the partial and/or total system structure represented by the communication relation between software subsystems. But in a large and complex system in which the structure frequently changes and partially fails and/or recovers, this assumption can not be easily satisfied and it becomes difficult to manage the system in a centralized manner.

Therefore Autonomous Decentralized Software Structure is proposed here to meet the requirements of on-line expansion, on-line maintenance and fault tolerance of the software system. This software structure has the feature that every software subsystem has autonomy to manage itself and coordinate with the other software subsystems. Coordination is attained by communicating with the other subsystems through a proposed data field(DF), in which the data circulates and the software subsystem selects whether to receive the data on the basis of its content. In this system, there exists no specific manager and no master/slave relation among the software subsystems. This software system structure is proposed on the basis of the Autonomous Decentralized System Concept (7)-(9). This concept has already been realized in the hardware systems of a local area network : ADL and a multi-microprocessor system : FMPA and these hardware systems have operated successfully (7)-(9).

2. Design Concept - Autonomous Decentralized System Concept

2.1 Software Features and System Requirements

Previously, computing system hardware has been expensive in comparison with software. The software structure has been mainly designed under the constraints

CH2345-7/86/0000/1056$01.00 © 1986 IEEE

of the predetermined hardware structure. But the recent advancement of LSI technology and the reduced cost of LSI have gradually made the software structure design flexible and substantially reducing the dependency on the hardware structure. Moreover there have been increasing demands for the software system to satisfy the following objectives.

(1) On-Line Expansion

As system size increases, step by step construction is required. Open-ended system construction during partial operation should be made possible. Even after completion of the construction, the system may be improved. Hence on-line expandability of not only hardware but also software is required.

(2) On-Line Maintenance

In the large system, the frequency of fault occurence somewhere in the system increases. It should be ensured that the maintenance and the test procedures can be carried out without suspending system operation, especially in the case of on-line and real-time systems.

(3) Fault-Tolerance

The reliability of the hardware has been sufficiently improved in comparison with the software. But even if the software includes some bugs, the system is not required to stop its entire operation to prevent the fault.

(4) Performance

Of course, high system performance is needed. For attaining high performance, reducing the peak of the computer load and making the load smooth by improving the software processing mechanisms are required.

All these criteria should be met in the construction and operation of large-scale systems. However the conventional centralized and distributed systems are developed from standpoint that the total system must be previously determined. Thus the hardware and software structures are fixed and have little flexibility. It is therefore difficult to satisfy these requirements.

2.2 Autonomous Decentralized System Concept

The Autonomous Decentralized System Concept has been proposed to attain on-line expandability, on-line maintainability and fault tolerance of not only the hardware but also the software system.

This concept, based on biological analogy, has the perspective that a system almost always has faulty parts and undergoes modifications. That is, a total system cannot be previously defined. A system is defined as the result of the integration of subsystems. A system is called an autonomous decentralized system, if the following two properties are satisfied.

(1) Autonomous Controllability

If any subsystem fails, the other subsystems can continue to manage themselves.

(2) Autonomous Coordinability

If any subsystem fails, the other subsystems can coordinate their individual objectives among themselves.

In these properties, only subsystem failure is considered. But they can be applied to subsystem addition and repair. Hence, these properties assure fault tolerance, on-line expandability and on-line maintainability of the system. They suggest that every subsystem requires an intelligence to manage itself and to coordinate with the other subsystems. The software subsystem in the subsystem is called the Atom. The Atom consists of not only the application software but also its own management system software. This system software in each Atom is called the ACP (Autonomous Control Processor).

To realize an autonomous decentralized software system with autonomous controllability and autonomous coordinability, each ACP is required to satisfy the following three conditions.

(1) Uniformity

Each ACP must be uniform. That is, every ACP functions are self-contained. The ACP can manage its own application software modules without being dependent on the other ACPs functions. This condition means that even if the ACPs in some Atoms stop their operation, the other Atoms can contiune their operation.

(2) Equality

Each ACP must be equal. Hence, every ACP can manage its own application software modules without being directed by or giving directions to the other ACPs. That is, there is never a master-slave relation among the ACPs. This condition assures that each ACP can continue its operation even if the other ACPs fail.

(3) Locality

Each ACP must be able to manage its own Atom and to coordinate with the other Atoms based only on local information. This condition means that every ACP can continue its operation even if the ACP cannot collect the global information because of the other subsystems' failures. The locality condition excludes a common global information file.

It is difficult to satisfy these three conditions under the conventional software structure and its management techniques. Hence the Autonomous Decentralized Software System has been proposed.

3. Software Structure

3.1 Data Field

The basic feature introduced in the Autonomous Decentralized Software Structure is the Data Field (DF) where the data circulates among the modules in the Atom and moreover among the Atoms. The DF in the Atom is called the Atom Data Field (ADF). In the DF, each data has a content code which indicates its meaning.

This feature means that the software module broadcasts all data with its content code into the DF and it judges whether or not to receive the data from the DF on the basis of its content code. Here not every software module uses the destination address of the data. The message format is shown in Fig. 3.1.

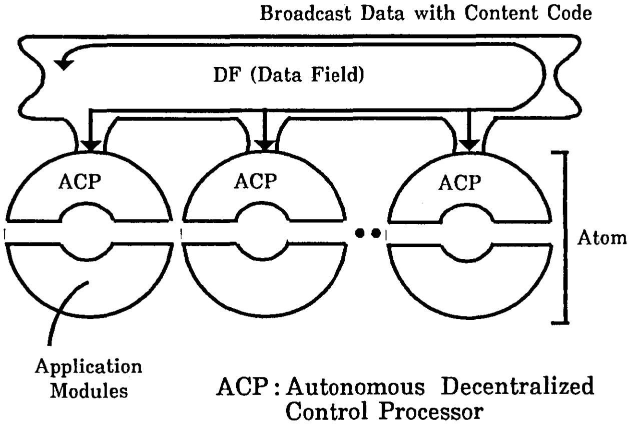
In the DF concept, there is no distinction regarding broadcast among the data, the parameter, the file and the program. All of them, attaching their corresponding content codes, are broadcasted in the DF in the same message format. Moreover no message in the DF has priority. Each Atom independently judges what data, parameters, programs in the DF to accept and how to process them on the basis of their attached cotent codes. Moreover each Atom broadcasts every processed result data, parameter, file or produced program into the DF without knowing how to process them or which modules to receive.

F	CC	SA	C	Data	CRC	F

F : Flag
CC : Content Code
SA : Sender Address
C : Control Code
CRC : Cyclic Redundancy Check

Fig. 3.1 Message Format Including Content Code

In this software structure, every Atom is connected to the DF (Fig. 3.2). This feature indicates the autonomous data-driven mechanism of the module in the sense that no module ever drives the others nor directs them to receive and process the data. This mechanism makes the modules loosely coupled. No module controls the others but each independently controls itself. Moreover any module can communicate with any other module connected to the DF. The module can collect all information necessary to coordinate with the others according to its situation since all information is broadcasted without specifying the destination modules.



ACP : Autonomous Decentralized Control Processor

Fig. 3.2 Autonomous Decentralized Software Structure

This communication protocol using the content code makes it possible for every Atom to control itself and coordinate with the others without having global information on the entire system but having local information on the content codes necessary for the modules in the Atom itself. The content code protocol is not designed for the sender and receiver modules, but for the data itself.

For example, physically, the DF among the Atoms corresponds to a computer network. Each Atom is installed in one computer unit. For example, the ADF corresponds to FIFO memory which is divided into every software module and can be locally accessed only by its module (Fig. 3.3).

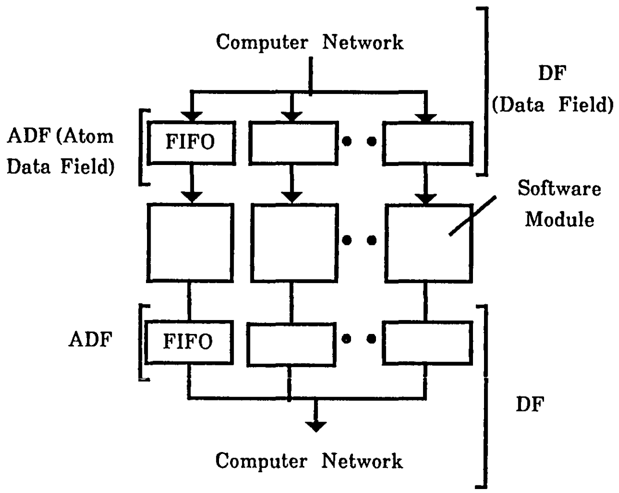


Fig. 3.3 Data Flow in Software Subsystem (Atom)

3.2 Modular Software Structure in System Software and Application Software

Not only the autonomous data-driven mechanism but also the modular structure of the system software : ACP and application software are derived from the DF concept. That is, every software module in the ACP and the application software is a unit of function which receives data from the DF and sends out data into the DF (Fig. 3.4).

Fig. 3.4 Modular Software Structure in System and Application Software

Each ACP has the functions of managing the data flow route, checking the data, supporting the test and diagnosis and so on. The function of the application software module is characterized by the relation between the content codes of the input data and those of the output data.

Each application software module can be installed in any distributed computer without knowing where the other application software modules are installed. This is because all modules anywhere are connected only to the DF and driven by the data in the DF. Moreover the application software module can be moved from computer to computer without informing the others of its movement. Hence, portability of the application software modules is attained.

The ACP is installed in every computer.

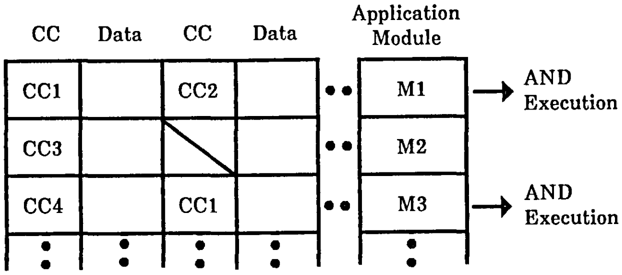
4. ACP Functions

4.1 Data-Driven Mechanism

The autonomous data-driven mechanism of the application software modules is realized by the following two management modules of the ACP.

(1) DF management

The DF management module acts as the interface between the DF and the ADF. The ADF includes the table of the relationship between the application software module in the Atom and the content codes necessary to execute this application software module (Fig. 4.1). According to these registered content codes, the DF management module receives the data from the DF and stores it in the corresponding area in the ADF. The data originating within the Atom is broadcasted into the DF by this management module.



CC	Data	CC	Data		Application Module	
CC1		CC2		••	M1	→ AND Execution
CC3		╲		••	M2	
CC4		CC1		••	M3	→ AND Execution
⋮	⋮	⋮	⋮		⋮	

CC : Content Code

Fig. 4.1 ADF Format

The same data may be used by the different application software modules in one Atom and then it is stored in all the corresponding areas in the ADF.

The DF management module may be installed in a separate communication I/O processer to improve computer performance.

(2) Execution Management

The execution management module monitors the ADF. As soon as all the data necessary to the application software module is received in the ADF by the DF management module, the execution management module drives the application software module. The number of data necessary to execute the application software module is one or more (Fig. 4.1). With this execution management module, the application software modules run asynchronously and freely. This autonomous execution property ensures that the application software module cannot be directed to execute by any other application software module. In addition it ensures that the application software module can continue its operation even in the event of fault occurence, expansion and maintenance of the other application software modules.

4.2 Data Consistency

The asynchronous and free run mechanism of the application software modules makes it possible to replicate the same application software module to be stored in the Atoms and to independently execute these software modules. The number of replications of the module can be arbitrarily settled according to the fault tolerance level required. The replicated application software module runs independently and sends the processed result data into the DF. But some of them may be faulty because of the failures of their corresponding ADF memory and the computers themselves.

Thus, the first problem is for each ACP to check the replicated data received from the DF and select the correct one.

The second problem arises in the case of "AND execution condition", which means that an application software module needs more than two data to execute (Fig. 4.1). The application software modules independently process and they send their result data into the DF. Hence these multiple data are asynchronously received from the DF by the Atom. The second problem is for each ACP to logically synchronize these multiple data which are asynchronously received from the DF for the AND execution condition.

The data consistency management function for the first problem is to select the correct data from among "the same data", which are sent out from the replicated application software modules. A threshold-voting technique is proposed. The data consistency management module identifies "the same data" not only by the content code but also the event number attached to the data. The event number is originally set at the module that received the information from an external source via input devices such as sensors and terminals. Although the data is successively processed by the modules, the original event number is preserved. "The same data" with the same content code and the event number is collected from the DF within a predetermined interval or up to a predetermined number. The correct data is selected from among "the same data" through the majority voting logic which can be flexibly adapted corresponding to the total number of received data or the minimum time interval. By this logic, the fault occurence is detected and each application software module can avoid being affected by fault propagation. This data consistency management module in the Atom can detect a fault that occured in the Atom itself by making a comparison with data that originated from the Atom itself and the other Atoms. The thresholds of the predetermined interval and number for the majority voting logic are applied to the systems aiming at high responsibility and reliability.

The second problem resulting from the "AND execution condition" is resolved by using the event number. The data consistency management module selects all of the multiple data with the content codes satisfying the "AND execution condition" of the application software module and it arranges the data in the order of the event number set by the original module. With this arrangement mechanism, the data consistency management module can detect whether all of the necessary multiple data have been completely received and whether some data is missing.

Through data consistency management, every Atom can independently check the correctness of the data and logically synchronize multiple data that originated from the other Atoms. Hence, in data consistency the autonomous controllability and coordinability properties are satisfied.

This data consistency mechanism to assure fault tolerance is easily adopted to system reconfiguration while the system is operating.

4.3 Test and Maintenance

The autonomous execution mechanism of the Atom and the DF concept make it easy for the application software modules to be debugged and tested while the system is operating. This on-line maintenance is supported by the BIT(Bilt-In Tester module) in each ACP and by the EXT(External Tester module) as the application software.

The BIT in each ACP has the functions of setting the application software module into the test mode, generating test data, and checking test results independently of the other modules.

After the installation of the application software module into the Atom and the recovery from the fault of the application software module in the Atom, the BIT in the Atom determines to begin the start-up test for this application software module and sets the application software module into the test mode. The application software module being in the test mode receives only test data with the attached test flag from the DF and processes them. It broadcasts the test result data attaching the test flag into the DF. However, it is prohibited to output the signal to output devices such as controllers. The EXT monitors the test data and the test result data in the DF. By collating the test data with the test result data, the EXT can check for fault occurence in the application software module in the test mode and broadcasts the fault detection. The BIT independently decides whether to start the operation of the application software module on the basis of the test result by the BIT itself and/or its check by the EXT.

The test data can be generated by the EXT or the BIT itself. The test data for the start-up test is previously stored in the BIT. The EXT can successively generate the test data according to the fault occurence situation in the system.

It is possible to drive the application software module while it is in the normal mode by the test data. This module broadcasts the test result data into the DF, but it prohibits sending the signal to the output devices. The test result data is successively used to test the other application software modules. With this mechanism, the application software modules can be successively tested while they are operating. The EXT monitors the test data and the test result data successively output from the application software modules and it detects any failed application software module in this test process.

The BIT independently tests the application software modules. The EXT does not direct the other modules to test and diagnose them. Hence the autonomous controllability and coordinability properties in test and fault diagnosis are obtained.

4.4 Program Loading and Expansion

In the DF, the program as well as the data circulates with its corresponding content code. The application software module including the relation between the content codes of the input and the output data is produced on the conventional OS in the software development subsystem and by using the conventional language. This produced application software module is broadcasted with its content code. The construction management module in the ACP, in which the content codes of the necessary application software modules have been previously registered, judges whether or not to receive the application software module from the DF on the basis of the registered content codes. This management module stores the application software module into the program area, makes the table of the relation between the content codes of the input and the output data for the application software in the ADF and sets the application software module into the test mode for the start-up test.

The ADF corresponding to the application software module is generated whenever this module is loaded in the computer. The construction management module does not need to know about the expansion and the replacement of the application software modules in the other Atoms . That is, the construction management module can independently install the application software module into the Atom without interrupting the other Atoms. Hence, the autonomous controllability and coordinability properties in software construction are attained.

5. System Design Criteria

In the autonomous decentralized system, the data originating within the computer is broadcasted at the time of its generation. The data is not stored in the memory of its originating computer or in the global common memory. Therefore, the module need not access the data in the memory of the other subsystems and the global common memory. The application software module can use the data received from the DF as needed without any time lag or concern for the condition of other subsystems.

The computer in this system executes the modules whenever the necessary data for the modules originates within itself or from the other computers. The computer is not directed to execute at any specific time by the others. Thus, the performance of the system is substantially improved by the reduction of the peak load of the computer. In this system, the computer load is normally high and almost always smooth. That is, in the autonomous decentralized system design, lower performance computers is sufficient compared with those required by the conventional system.

6. Application

One of the applications of the autonomous decentralized software system is a steel production process control system. As an example, the cold mill process control system is explained below (Fig. 6.1).

The computerization of steel production process control has already reached an advanced level. Recently the requirement for integrating the steel production subprocesses, which have been separately computerized, in order to reduce the stocks between the production subprocesses and improve the steel quality has gradually

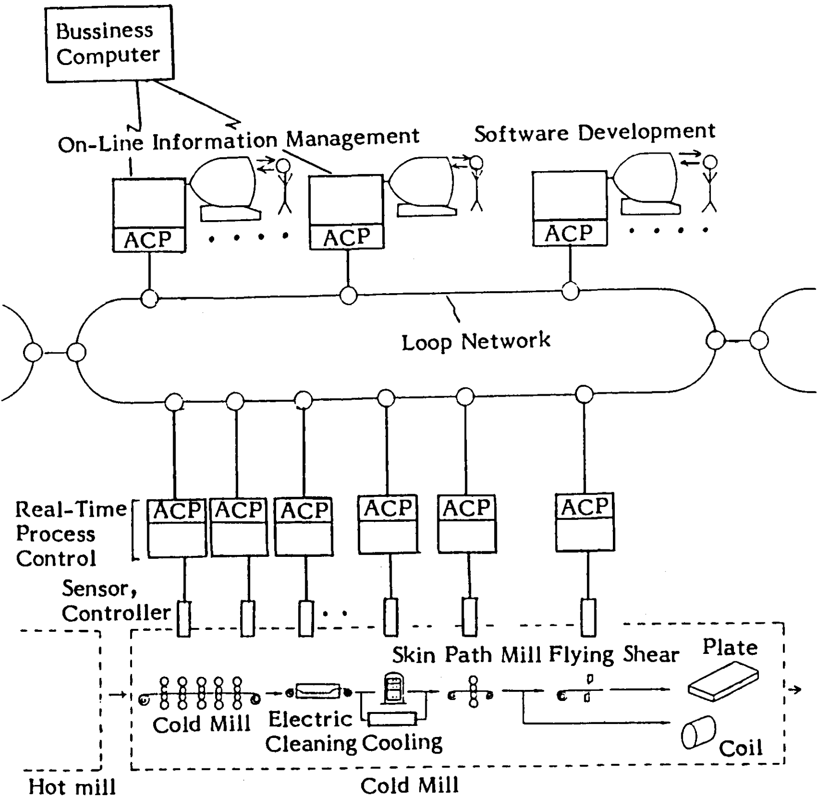


Fig. 6.1 Steel Production Process Control System

increased. Hence, the on-line expandability, on-line maintainability and fault tolerance of not only the hardware system but also the software system have become indispensable.

In this system, there are three major subsystems for real-time process control, on-line information management and software development. The functions in each major subsystem are distributed into several mini-computers HIDIC V90/5 series. These computers are connected by the loop local area network ADL(Autonomous Decentralized Loop Network) using optical fiber cable(8).

In the software development subsystem computers, the application software modules are produced, partially revised, and remotely loaded into the computers for real-time process control and on-line information management.

The main application software modules in the on-line information management subsystem are the steel production scheduling, the process data logging, the linkage to the large-scale business computer system, the EXT and the man-machine communication modules. The steel production scheduling module makes the detailed schedule for the production process on the basis of the rough production schedule transmitted via the linkage module from the business computer. This scheduling module dynamically revises it according to the current condition of the process. The condition is recognized from the current process data broadcasted from the real-time process control subsystems into the DF.

The production schedule data broadcasted from the steel production scheduling module is recevied by the real-time process control subsystem. The real-time process control subsystem consists of the cold mill process, the electric cleaning process, the cooling process, the skin path mill process, the flying shear process and so on. One or more computers are distributed to every process and each computer has its own responsible control region. The real-time process control software subsystem installed in each computer includes the application software modules for tracking and controling the iron slabs in its own control region. The tracking module receives the signal upon the detection of the iron slab from the detector in its own control region. This module identifies the iron slab by consulting the production schedule for this region and then generates the tracking information.

This tracking information is broadcasted from this module and is received at the controlling module in the same real-time process control subsystem. It is also received by the tracking module in its adjacent subsystems on the downstream process, the process data logging module and the man-machine communication module. The control module driven by the tracking information controls the apparatus for processing the iron slab in its own control region. The tracking information received by the adjacent subsystem is used to check the production schedule and, if necessary, to revise its own production schedule. The process data logging module driven by the tracking information edits

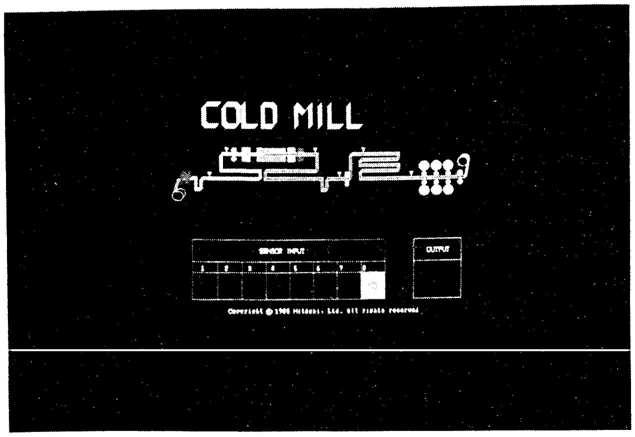

Fig. 6.2 Display of Tracking Information on Cold Mill process

and stores this information. The man-machine communication module is driven by the tracking information to display that information (Fig. 6.2).

The EXT is driven by the test data and the test result data, and it can detect faults in the software modules.

In this system, these application software modules are replicated according to their level of importance. This system has been gradually expanded function by function in the same process. Expansion has continued process by process in the cold mill process control system and from the cold mill process control system to the upperstream and downstream process control systems.

As the byproduct of development of this autonomous decentralized steel production process control system, software productivity has been much improved. In this system development, only the protocol of the content codes is previously determined. Then each application software module can be designed in a closed form being independent from the others. Each module is independently produced, loaded, tested, begins operation and is modified. Even when the system expands module by module, the existing system need not be modified. Therefore, in particular, the load for each software module debug and for total software module linkage tests decreases.

7. Conclusions

Autonomous Decentralized Software Structure aimed at software on-line expansion and on-line maintenance together with fault tolerance has been developed. Each software subsystem consisting of the system software ACP and the application software has autonomy through the ACP functions and the data field(DF) concept. Every data with the attached content code corresponding to its meaning is broadcasted. The ACP has the functions of receiving the data from the DF on the basis of its content code and checking the correctness of the received data. The application software module is driven only by the correct and necessary data received by the ACP. The process result data is also broadcasted with its content code. This autonomous data-driven mechanism makes it possible to test and repair the application software module during the operation of the other modules since the module can be independently set in the test mode. The program as well as the data is broadcasted into the DF together with its content code. Each application software module is produced by the software production subsystem and can be remotely loaded into one or more computers while the other application software modules are operating.

The autonomous decentralized software structure has been applied to the steel production process control system and so on, and its validity has been verified.

ABSTRACT

There has been a rapid improvement in the technology of local networks and office equipment. Unfortunately, our current understanding of office equipment is only for a single machine, operated in a separate 'stand alone' environment.

Nowdays, it is required to have a methodology for extending these environments over many machines without being hampered by any new problems of integrating remote processes. This paper describes our approaches to integrate the office environment, in which several pieces of equipment such as database servers, file servers, personal computers, workstations, and minicomputers, jointly work through a local area network. The transaction concept is exploited and defined as the network-wide transaction to integrate various environments. The resources integrated in this paper are the file server, the database server, and several application programs. New efficient implementation techniques for network-wide transaction processing are proposed.

1. INTRODUCTION

The development of network technology allows us to use several distributed resources. Distributed database systems make it possible to access remotely located databases[11,14]. The same benefits arise in distributed file systems[2,4,5,7,8]. The development of office automation equipment on local networks has also increased the demand for using Remote Procedure Calls for distributed applications[3]. It is the tendency of a distributed system to treat everything attached to the network as a network resource[13].

In a highly integrated environment, the key point is the effective use of network resources. One defines the integration as "glue"[1]. The resources may be servers, application programs, personal computers, workstations, mini-computers and so on. Taking into account the integration of these resources, we are developing the "integrated information network system", as is shown in Fig. 1.

In this paper, only the "integrated LAN system" is focused on and discussed, in which a file server, a database server and dispersed application programs, those connected by local networks, are treated as network resources[12]. The rationales and some techniques applied for integration are described.

This paper describes the integration constraints imposed in an integrated office environment, and some techniques to solve these constraints. Some novel integration techniques of several servers and the dispersed application programs through a local network are presented. In section 2, the transaction in an integrated environment is modeled and defined. In section 3, implementation techniques for the transaction are described. Section 4 describes the experimental development of multi-bit-map oriented file server system, in which the proposed extended transaction model is implemented.

2. THE ENVIRONMENT

2.1 TRANSACTION

A transaction is a unit of atomic actions, and the transaction itself constitutes an atomic action. An atomic action has the property of either being completely done or nothing being done. Also, the atomic action must inherit the above property, called atomicity, even in cases of failure or concurrent execution[9,14]. This means the transaction is closely related to recovery and concurrency control. We explicitly define the network-wide transaction's behavior as follows.

CH2345-7/86/0000/1064$01.00 © 1986 IEEE

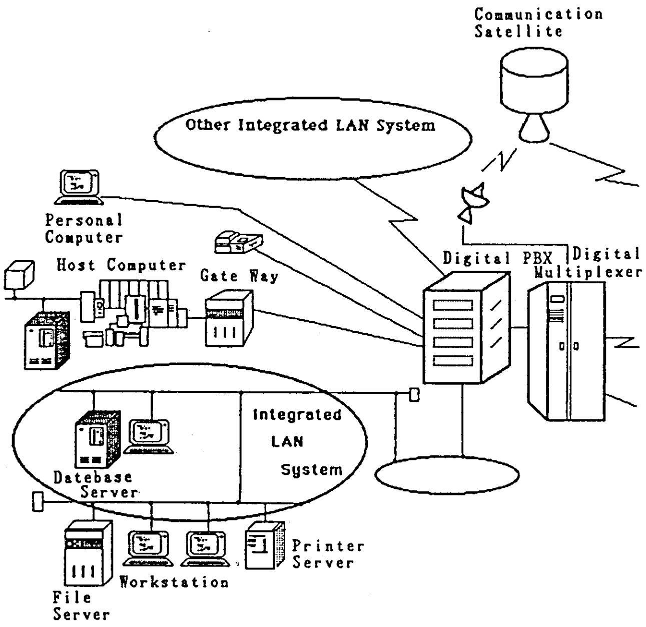

Figure1. Integrated Information Network System

(i) **ATOMICITY** --- In all cases, including node failure, the atomicity of a transaction must be guaranteed.

(ii) **CONSISTENCY**--The transaction must be processed consistently. Namely, atomic actions defined in the transaction must have serial execution on it's order without affecting it's environmental factors such as communication delay or existing concurrency control . Communication delay or concurrency control must not cause atomic actions within a transaction to be executed other than sequentially.

To maintain the above constraints in an integrated environment, we introduce the traditional transaction concept to the application itself. Introducing the transaction concept to the application program is equivalent to defining n-party transaction control. Any resources accessed by the application are integrated into one transaction. This transaction is called the "network-wide transaction". One application might consist of several transactions, in which all of these are affiliated with the network-wide transaction.

2.2 APPLICATION ENVIRONMENT

The construction of an integrated system must be based on either of two types of external environments . One environment bases the integrated environment on previous existing systems, and is called the bottom up approach. In this environment, the restrictions on existing systems, such as imposed on transaction processing and concurrency control, must be inherited. The other environment does not have any restrictions on it's construction, and this is called the top down approach. Efficiency is the whole purpose of the top down approach.

Our approach assumes the bottom up approach in an office environment. For components in our integrated environment, a file server, a database server, and several dispersed application programs, which are distributed throughout the network, are assumed[12]. Each server is basically a traditional transaction oriented system, and can only perform transaction processing over it's own resources[9].

Our step-wise approaches toward the integrated system are as follows. The first step focuses the integration of one server and several dispersed applications(see Fig.2-1). N co-related application programs and one transaction based server, all connected by a local network, are integrated as a network-wide transaction. The second step expands the first step to several servers(see Fig. 2-2).

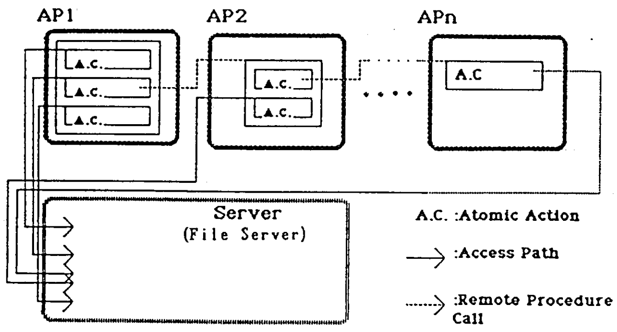

Figure2-1 Step1 : Single Server - Multiple Applications

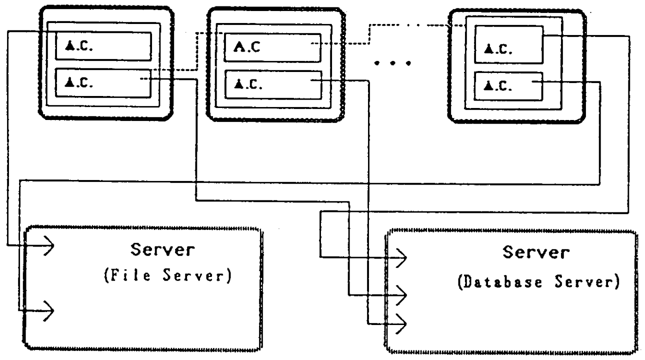

Figure2-2. Step2:Multiple Servers -Multiple Applications

For the construction of an integrated system in our environment based on the network-wide transaction, the following are assumed.

- Concerning the application program, the serialized execution of atomic actions must be guaranteed. (The implementation being based on the process model makes this assumption reasonable.)
- Each server is a transaction based closed system in terms of accessing a single kind of resource.

2.3 PROBLEM ANALYSIS

There are a lot of problems to be solved in constructing an integrated system based on the bottom up approach. One problem is affiliated with the concurrency control. In a closed environment, as the transaction is defined in it's single environment, concurrency control is inevitably affected by the life time of the transaction. There has been proposed many concurrency control techniques[10]. These algorithms usually assume that concurrently accessed data is inaccessible to other transactions until the end of transaction. At commit time, every resource accessed in the transaction is released for other transactions to access. From the view of the bottom up approach, this causes the problem of inaccessibility of the shared data from the network-wide transaction. In a traditional transaction system, transactions are prevented from interfering with one another if they access shared data concurrently. This leads to the deadlock phenomenon of the network-wide transaction.

The other problem is commitment control. The data committed by one of the members of a transaction, which belongs to a network-wide transaction, can never be rollbacked from other members.

The rationale of solving the above problem is to propagate the committed data of each transaction to the network-wide transaction. In a later section, we call the techniques which solve the above problems the "nested commitment control".

For the integration of several existing transaction oriented systems into one integrated transaction system, we insist that the following problems must be resolved.

- Communication delay should be transparent to the application program. The serialization of atomic actions in a transaction must be guaranteed across the network.
- Different transactions might be grouped together into one transaction without conflicts, in which the data may be shared.

3 IMPLEMENTATION TECHNIQUES

3.1 APPROACHES TO THE NETWORK-WIDE TRANSACTION

Two types of models are given to support the network-wide transaction in a server, which we call the "multi-bit-map oriented model". One is the model which inherits the accessed data from the previous transaction, and makes the committed data accessible(see Fig.3). This model makes possible the recovery of inherited data in case of failure. The other is the model which makes the non-shared data for cooperative transactions in a network-wide transaction to be safely committed(see Fig.4). Both models make the data accessed by the transactions recoverable to the consistent state one at a time.

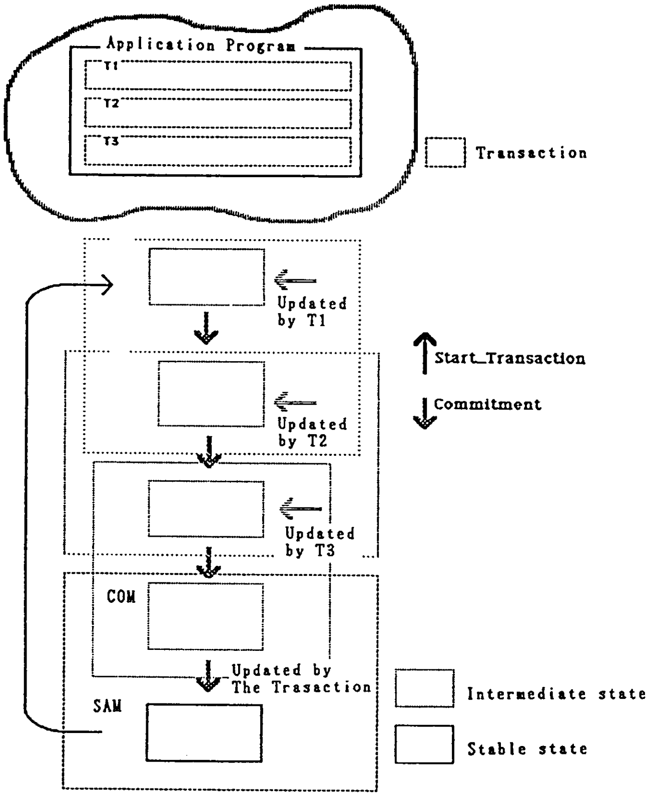

Figure 3. Nested Commitment Model for Shared Data

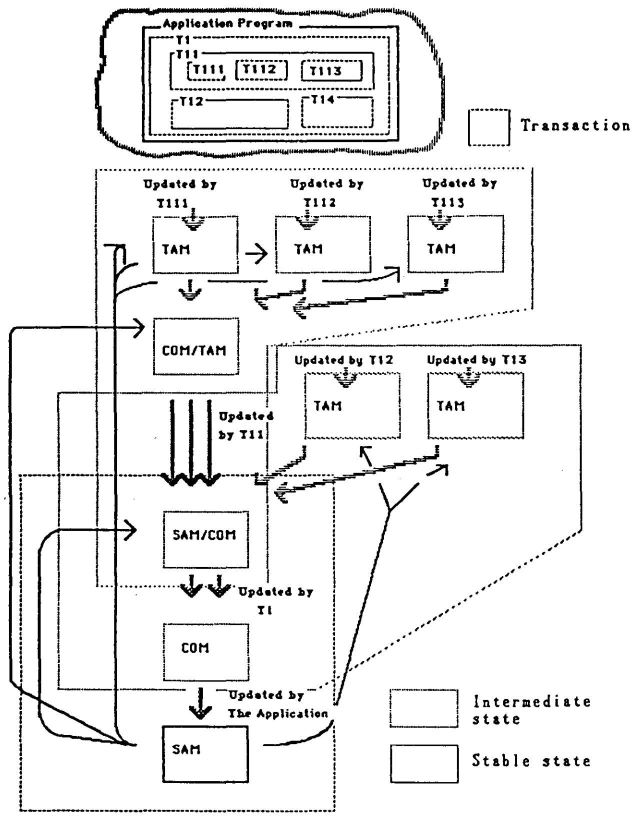

Figure 4. Nested Commitment Model for Non-Shared Data

3.1.1 Rules For Commitment

The following regulates the rules of the models. For integrated applications, either of these two models are applied on demand depending upon the ordered sequences of atomic actions in the server.

A) Rules For Shared Data In Nested Commitment For Network-wide Transaction

<Assumption>

1) The transaction's commit requests in a network-wide transaction must be ordered as presented by the application program, when these arrived at the server.

2) There exists some mechanisms which identify the network-wide transaction.

<Rules For Commitment>

When one of the members of the network-wide transaction commits the updated data, these data are inheritated to the next transaction step by step using the intermediate table until the network-wide transaction is committed(see Fig.3). The intermediate table is sequentially propagated to the next intermediate table from transaction to transaction.

B) Rules For Non-Shared Data Access For Network-wide Transaction

<Assumption>

1) Member transactions of a network-wide transaction may commit at any time during the life time of the network-wide transaction.

2) Member transactions of a network-wide transaction access data which are not shared by the same group of transactions in the network-wide transaction.

<Rules For Commitment>

The data accessed by the transactions in a network-wide transaction would not be committed until all of the members of the network-wide transaction commit. Iff all of the members of the network-wide transaction commit, the data committed might be propagated to the next group of transactions, in which the same analogy of the shared data in nested commitment is applied to the propagated data(see Fig.4).

In the above, two types of commitment control for the network-wide transaction were described. In a real environment, these two types of commitment controls are combined depending upon the serialized execution of the application program. In either case, all of the above mentioned properties are maintained.

The advantages of multi-bit-map oriented commitment control are summarized as follows.

- Transactions grouped in a network-wide transaction may commit or rollback at any time during the network-wide transaction's lifetime.
- Shared data can be accessed without interfering with other members of the transaction.

3.2 MULTI-BIT-MAP ORIENTED COMMITMENT CONTROL ALGORITHM

The algorithm which uses the multi-bit-map based boolean operations for commitment control is presented.

The basic multi-bit-map algorithm, indicated in Fig.5, uses three tables. The first COM(Common Table) indicates the intermediate state, and can be referenced from all transactions. The SAM(Stable Table) represents the committed area of the COM

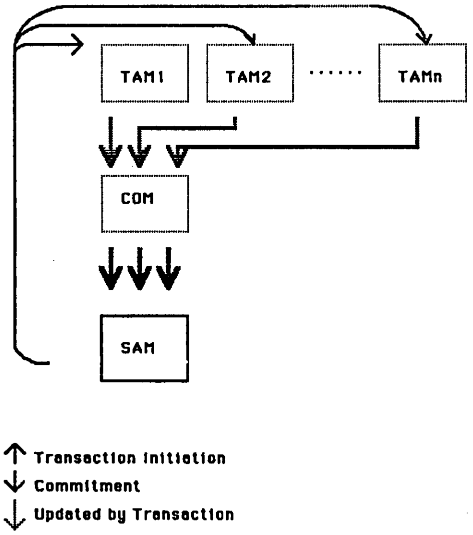

Figure5. Basic Multi-Bit-Map oriented Commitment Model

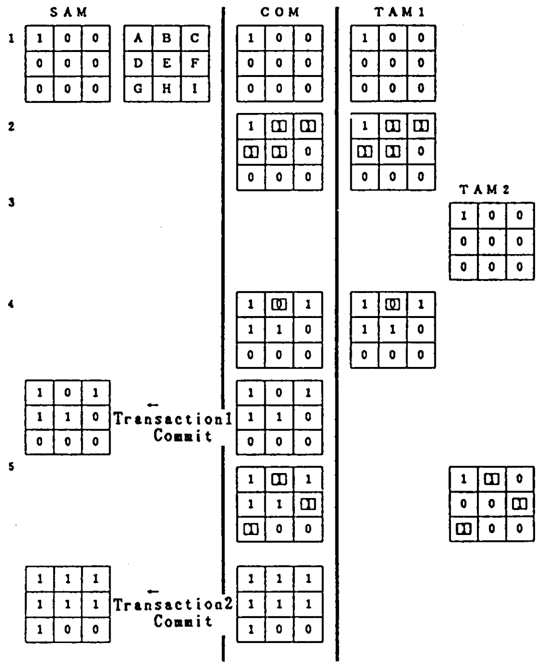
table. The TAM(Transaction Table) is defined for each transaction and indicates the transaction states. Several boolean operations on these three tables are defined, as illustrated in Table 1. TAM is created from SAM whenever the new transaction emerges(see Table 1-1). When the transaction is committed, the operation shown in Table 1-2 is performed and SAM is updated and the disk is also updated.

Fig.6 displays one example performed using these operations. In this figure, it is assumed that there are only nine areas, and one area has already been committed. The stepwise explanation is as follows.

When transaction 1 is initiated, TAM1 is generated by copying SAM (1). If transaction 1 acquires four data areas, the COM table is searched and the empty areas are assigned (2). After this, if transaction 2 is initiated, TAM2 is generated from SAM(3). If transaction 1 releases one area and commits, that area is assigned to empty areas and the operations in Table 1-2 are performed, and the area indicated by SAM table are updated(4). After this if transaction 2 acquires three areas, COM is searched again, and empty areas are assigned (5). If transaction 2 commits after this, the operations in Table 1-2 are performed and the areas indicated by SAM table are permanented(5).

This algorithm guarantees the freedom from failure in transaction processing.



A~I···storage address of pre-allocated
(1)···Initiation of Transaction1
(2)···4 areas request by Transaction1
(3)···Initiation of Transaction2
(4)···Release request by Transaction1(B:data area)
(5)···3 areas request by Transaction2

Figure6. Example

Table1. BIT MAP operations

Table1-1

1	1	0	1
1	1	1	1

Table1···Transaction Initiation

Table2···Trasaction Commitment

The multi-bit-map can be extended to the nested commitment by replacing the SAM to COM of the above algorithm. By replacing stable state with common state, nested commitment is easily supported. Stable state can be replaced with the common state propagatelly according to the depth of nest, as offered. And only one lowest stable table is affected by the committed action. The correspondence of this algorithm with the conceptual model is shown in Fig.4.

4 FILE SERVER SYSTEM

The experimental development of a multi-bit-map oriented file server system which reflects the nested commitment processing is described.

4.1 OVERVIEW OF THE FILE SERVER SYSTEM

We developed the network-based file server system with the following in mind,

- be able to store and access a large amount of data whose size is variable.
- include basic functions for shared data.
- support mechanisms for an integrated office environment.

Based on the requirements above, we constructed a three layered system model. It consists of a basic layer, an applied layer, and an integrated layer. Fig.7 indicates the system model designed.

The basic layer includes the functions which are commonly required for general applications. Included functions are concurrency control, commitment control, and directory services. The applied layer includes those functions which are specific to special applications. It also includes general functions which can be constructed by utilizing the basic layer. Functions include remote procedure call or message transmission. The integrated layer integrates the office environment utilizing the basic functions and applied functions. The explanation of each sub-systems in the model, and techniques applied to each one is shown in Table 2.

4.2 OVERVIEW OF THE FUNCTIONS

- INTERFACE

Two interfaces for the basic layer and two interfaces for the applied layer are supported. As for the basic layer interface, file access protocol which can be used from remotely located applications residing on the same node as the file server are supported. As for the applied layer interface, the remote procedure call and synchronous message transmission among applications are supported for integration.

- TRANSACTION

A transaction is supported by the specific command, START-TR and TR-END. By enclosing access commands with those commands, atomicity of a transaction is guaranteed. The method used for commitment is shadow management of file directory, in which the multi-bit-map technique is applied.

- REMOTE PROCEDURE CALL AND MESSAGE TRANSMISSION

The system supports a synchronized message transmission mechanism using SEND and RECEIVE commands that are used as a tool for integrated processing management in an office environment. These commands are implemented on the UD(user defined)command when transmitted to the network. The remote procedure call is an extension of message transmission.

The remote procedure call is supported as an applied layer command. To provide n-party conversation, and to support distributed applications, synchronous message transmission among applications, using SEND and RECEIVE commands, is supported.

5 CONCLUSION

This paper described the approaches to an integrated office environment .

Several cooperating application programs which use traditional atomic transaction systems, such as file servers and database servers, are operated consistently within a local network. The atomicity and the serialization problem of network-wide transactions are solved by introducing the transaction concept on the application itself, and by introducing the multi-bit-map techniques to the servers. The proposed multi-bit-map oriented commitment control solved the problem of concurrency control in a traditional atomic transaction system. It made possible the sharing of data from several transactions.

The experimental development of a multi-bit-map oriented file server system was also described to verify the correctness of our model. The current system is now operating in our company.

USE OF PETRI NET INVARIANTS
TO DETECT STATIC DEADLOCKS IN ADA PROGRAMS

B. Shenker, T. Murata, S.M. Shatz

Department of EECS
University of Illinois at Chicago

ABSTRACT

This paper presents a method for detecting static deadlocks in Ada tasking programs using structural and dynamic analysis of Petri nets. Automatic translation of the Ada programs into Petri nets which preserve control flow and message flow properties is described. Properties of these Petri nets are discussed and algorithms are given to analyze the nets to obtain information about static deadlocks that can occur in the original programs. Petri net invariants are used by the algorithms to reduce the time and space complexities associated with dynamic Petri net analysis (i.e., reachability graph generation).

1. INTRODUCTION

Over the past few years, a few techniques have been proposed for use in validation of Ada tasking programs. Taylor [1] has presented a general static analysis technique for Ada tasking and has shown that such analysis has an exponential time complexity (in terms of the number of tasks). German [2] has described an approach for detecting deadlocks in Ada tasking programs using dynamic analysis. Since the approach uses dynamic analysis, results are dependent on the supporting environment, especially on the scheduler characteristics. In this paper, we propose the use of a Petri net invariant method for detecting static deadlocks in Ada tasking programs. Our technique reduces to some extent the time and space complexities associated with the general state enumeration method used by Taylor.

Our deadlock analysis technique starts with translation of Ada tasking programs into Petri net models [3] and uses structural and dynamic analyses of these specific Petri nets, which we call Ada nets. Ada nets are abstract models of the source programs since an Ada net only models the Ada source program's control flow and message flow. As such, only those Ada statements which can alter the control flow (such as If, Loop, and Select statements) or which constitute a rendezvous (Entry calls and Accepts) contribute to the Petri net translation. Further details on the translation of Ada programs into Ada nets will be given in Section 2.

Unlike the previously reported techniques of Shatz and Cheng [4], which are concerned with both deadlock and general tasking analysis, our method is not entirely based on generation of the complete Ada net's reachability graph. Instead, we have been able to combine the specific properties of Ada nets with the Petri net concepts of place and transition invariants in order to reduce the complexity associated with generating the complete reachability graph.

Since the intuitive concepts and definitions of Petri nets are well known and to save space, we will follow the terminology and notations of Petri nets as defined in [5], unless otherwise stated. Since the concepts of Petri net invariants are not so widely known and since they play a key role in our subsequent discussion, we briefly discuss them now. In particular, we define an <u>S-invariant</u> (<u>T-invariant</u>) as an integer solution y (x) of the homogeneous equation,

$Ay = 0$ ($A^T x = 0$), where A is the transition-to-place incidence matrix of a Petri net [5]. The subset of places (transitions) corresponding to nonzero entries of an m-vector y (an n-vector x) is called the <u>support</u> and is denoted by $||y||$ ($||x||$), where m is the number of places and n is the number of transitions in a Petri net. A support is said to be <u>minimal</u> if no proper nonempty subset of the support is another support. An S-invariant (T-invariant) whose support is minimal is called a <u>minimal S-invariant</u> (<u>T-invariant</u>). We use only non-negative invariants.

2. OVERVIEW OF ADA TRANSLATION BY EXAMPLE

Automated translation from Ada programs into Petri net models produces what we call Ada nets. The process of Ada net generation can be simply described as follows. Whenever the right-hand-side of any Ada syntactic construct is recognized during parsing, the Ada actions associated with the construct are invoked. These actions generate a part of the Ada net - the part that models the given construct. Control then passes to the syntactic parent of the translated construct. The translation process continues until the root of the parse tree is reached. At that point, the input Ada program is then either recognized or rejected. If it is recognized, the Ada net corresponding to the program will have been success-

CH2345-7/86/0000/1072$01.00 © 1986 IEEE

fully constructed. The parts of the net that are generated are linked together into an Ada net that preserves the behavior of the input program. Consider the following fragment from an Ada program (statement numbers are for later reference only):

```
TASK BODY task1 IS          TASK task2 IS
1)  WHILE cond1 LOOP        0)  ENTRY entry2;
2)  task2.entry2;           END;
3)  END LOOP;               TASK BODY task2 IS
END;  -- task1              4)  ACCEPT entry2;
                            END;  -- task2
```

The Ada translation maps the program fragment into the Ada subnet illustrated in Fig. 1a. The dashed places, transitions and arcs represent connections to the parts of the program not shown. Place p6 represents a Loop statement. The Entry call statement 2 is represented by t3, t4, p5, p2, p3, and p4. The Accept statement 4 is represented by t5, t6, p7, p2, p3, and p4. Places p2, p3, and p4 represent the communication channel of entry2 in task2. In general, every entry in any Ada program is represented by three unique places (p_{mep}, p_{send}, p_{ack}) in the corresponding Ada net. Thus, for this example, the three places for entry "entry2" are p2, p3, and p4 respectively. Place p2 is initially marked and belongs to the set of mutual exclusion places. Such a place is referred to as p_{mep}. Execution of statement 2 is represented by firing transition t3. This firing is possible only if p_{mep} of entry 2 (place p2) is marked. When p2 is not marked, some Entry call of entry2 must be currently involved in a rendezvous with an Accept statement of entry2. When t3 successfully fires, places p3 and p5 become marked. This submarking of the Ada subnet represents the situation when the Entry call (statement 2) is trying to rendezvous with an Accept statement of entry2. When the Accept statement (statement 4) is ready to rendezvous, t5 fires and removes the token from p3. Note that if there exists more than one Accept statement for entry2, then p3 serves as an input place to multiple transitions. The place p3 is referred to as a sending place (p_{send}). Firing t6 represents the control of task2 exiting the Accept statement. After the Accept statement ends, place p4 enables transition t4. This means that the control of task1 may exit from the suspended state (due to the Entry call). Place p4 is referred to as an acknowledging place (p_{ack}). When t4 fires, p2 becomes marked. This means that no Entry call is now rendezvousing with any Accept statement of entry2.

The details of translation from an Ada program into an Ada net are fairly complicated and require syntactic analysis as well as some semantic analysis (for example, to distinguish package function calls from task entry calls). The major technique is to generate pieces of the net during each production rule reduction during parsing. We briefly describe the idea on the previous example. Since it is assumed that Ada task specifications precede task bodies, statement 0 is reduced first. Three communication places (p2, p3, and p4) for entry2 in task2 are generated, as illustrated in Fig. 1b. Statement 2 is reduced next. It causes t3, t4, and p5 to be generated and linked with the communication places of entry2, as illustrated in Fig. 1c. The dashed places and arcs are not yet generated. The reduction of the Loop statement in task1 creates the Ada subnet illustrated in Fig. 1d. Place p6 is substituted for both dashed places in Fig. 1c. Finally, statement 4 is reduced. Two new transitions, t5 and t6, are linked to the places p3 and p4 of entry2. The Ada subnet for the program fragment is then complete and is illustrated in Fig. 1a. A detailed discussion of the general Ada translation technique used here is found in [3]. Another approach to automated translation of Ada tasks into Petri net equivalent models is discussed in [4].

3. PROPERTIES OF ADA NETS

3.1. Definitions and Characteristics

Definition: A process-subnet is a state machine that models one of the processes (Ada tasks) in a distributed environment when communication between processes is ignored.

Fig. 2a illustrates two separate process-subnets. Note that each begins with a place and ends with a place. At translation time, we introduce two transitions into the Ada net - t1 (par-begin transition) and t2 (par-end transition) in order to give a cycle in the Petri net graph. These two transitions are connected through a place p1 (cycle place). In Fig. 2b, we have the two process-subnets of Fig. 2a structured as a distributed program with no communication. However, most useful distributed programs are characterized by some communication between the processes. In Ada, processes communicate through communication statements (i.e., Accept statements and Entry call statements). As discussed in Section 2, every communication statement is represented by two transitions and at least four places. Fig. 2c illustrates the distributed program of Fig. 2b with some communication.

A transition that represents a communication statement is referred to as an AE transition (Accept or Entry transition). Since every communication statement is represented by exactly two AE transitions in an Ada net, we will refer to one of them as "first" (e.g., t5 in Fig. 2c) and the other one as "last" (e.g., t6 in Fig. 2c), based on the order of their occurrences in a transition firing sequence starting with t1. A place in a process-subnet that is either an output place of some first AE transition and/or an input place of some last AE transition is referred to as an AE place (e.g., place p7 in Fig. 2c). The places generated by the translation of an entry specification are referred to as communication places (e.g., p2, p3, p4 in Fig. 2c). They are not considered to be a part of any process-subnet. All non-communication places are referred to as sequential places. Any arc connecting an AE transition and a communication place is referred to as a communication arc. A communication arc is not considered to be part of any process-subnet. All non-communication arcs are referred to as sequential arcs. Three communication places, p_{mep}, p_{send}, and p_{ack} (p2, p3, and p4 in Fig. 2c, respectively), are required for token (information) exchange between two or more process-subnets. The places may be thought of as a communication channel between potential "senders" and "receivers". The mutual exclusion place p_{mep} guarantees that only one process-subnet may send a token at any time to the receiving process-subnet. No other process-subnet will send a token to that receiver until the current sender is acknowledged by p_{ack}.

Definition: An Ada net is a strongly connected Petri net, APN, composed of process-subnets possibly interconnected with communications arcs and places. The strong connectiveness of APN is provided by p1 (cycle place), t1 (par-begin transition), and t2 (par-end transition).

3.2. Safeness of Ada Nets

The initial marking M_0 for an Ada net represents the situation when a program modeled by the net is ready to start executing. The marking M_0 consists of places p1 and every p_{mep} initially marked with one token. No other places have tokens initially. M_0 for the Petri net in Fig. 2c is $(1\ 1\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 0)^T$.

Theorem 1: An Ada net APN < P, T > is safe for M_0, i.e. $M(p) \leq 1$ for each place p in P and for any marking M reachable from the initial marking M_0.

Proof: Consider first an Ada net APN<P, T> consisting of n process-subnets with no communication involved. Since each process-subnet is a state machine, the sequential places of each process-subnet together with the cycle place p1 constitute the support of an S-invariant having exactly one token. There are n such S-invariants, and each place p in P belongs to one of these n S-invariant supports. Since the token content of each S-invariant support remains the same and is one for any marking M reachable from M_0, we have $M(p) \leq 1$ for each place p in P and for marking M reachable from M_0. Next, when there are communications between process-subnets of APN, by the construction of an Ada net, there are S-invariants whose supports consists of communication places, p_{mep}, p_{send}, p_{ack}, and some sequential places. Each of the supports of these S-invariants contains exactly one token (initially in p_{mep}). Thus every place p in P is in the support of at least one S-invariant having one token. Therefore, $M(p) \leq 1$ for each p in APN and for any marking M reachable from M_0. Thus, APN is safe for M_0.
q.e.d.

4. DETECTION OF STATIC DEADLOCKS IN ADA PROGRAMS

There is no commonly accepted definition of a static deadlock in a distributed programming environment. Traditional deadlock detection techniques (reachability tree or state graph analysis), using exhaustive search, label every potentially reachable deadlock as a "static deadlock". However, such techniques can generate some extra information. For example, a variable index loop containing communication statements always creates a potentially reachable deadlock. Since the number of times the loop executes is determined at execution time, any number of the loop iterations is assumed possible in this paper. Therefore, here we do not consider such a deadlock to be a static deadlock. Since Ada nets do not distinguish between the loops with variable and constant indices, potentially reachable deadlocks caused by Loop statements would not be reported by our static deadlock detection system. We would report any other deadlocks that can be predicted by static analysis of a program's source code. In the following sections, we define two classes of static deadlocks: inconsistency deadlocks and circular deadlocks.

4.1. Inconsistency Deadlocks

Some potentially reachable Ada program static deadlocks can be easily detected using only structural analysis of Ada nets. We call these deadlocks inconsistency deadlocks. In this section, we present an algorithm to detect such deadlocks.

An Ada program is called static executable when its corresponding Ada net has t2 (par-end transition) potentially enabled for M_0. We will refer to a set of linearly-independent T-invariants x of an Ada net such that $x(t) \geq 0$ for each t in the net and $x(t1) = x(t2) = 1$, where t1 is the par-begin transition and t2 is the par-end transition, as a set of Ada T-invariants of the net.

Theorem 2: A necessary condition for an Ada program Ap to be static executable is that its corresponding Ada net APN < P, T> has at least one Ada T-invariant.

The proof is obvious since there is always an Ada T-invariant in APN corresponding to the static execution path of Ap.

By Theorem 2, if an Ada net APN <P, T> modeling an Ada program Ap does not have an Ada T-invariant, then Ap is not static executable. Moreover, if some transition does not belong to the support of the linear combination of all Ada T-invariants of

APN, then the statement of Ap represented by the transition does not belong to any successful execution path. Such a situation indicates that Ap has at least one static deadlock, caused by a communication statement (or a group of communication statements). For example consider the following program fragment:

```
  task1:                      task2:

task2.entry2;          IF cond1
task2.entry1;            THEN ACCEPT entry2;
                         ELSE ACCEPT entry1;
```

The net corresponding to this Ada program would not have Ada T-invariants. Thus, the program is not static executable (it has a static deadlock) as can be easily checked. Note that removal of some communication statements (e.g., "task2.entry 1" and "ACCEPT entry1") could make the fragment static executable, since then every statement in the modified program would belong to at least one static execution path. Then, the support of a linear combination x' of all Ada T-invariants of the Ada net (for the modified program) would cover every transition in the net. Since the detection of these deadlocks depends on a test for T-invariants, we refer to them as inconsistency deadlocks. Now we present an algorithm that detects inconsistency deadlocks in an Ada program Ap (with its corresponding Ada net APN) and reports the minimal number of communication statements that need to be removed in order to remove the deadlock potential.

```
ALGORITHM INCONSISTENCY_DETECT

Input:
A - the incidence matrix of the net APN;
k - the number of communication
    statements in the program Ap;
S - the set of all possible subsets of
    communication statements in Ap.

Output:
The set of communication statements
"causing" inconsistency deadlocks

Method:
1) LOOP1: For i = 0 to k do
2) LOOP2: For each element s of S such
   that |s| = i do
3) A' := A;
4) Update A' to reflect the removal of
   all communication arcs associated
   with communication statements in s;

   For any entry, if the three columns of
   A' corresponding to $p_{mep}$, $p_{send}$, and

   $p_{ack}$ each have all zero entries,

   then remove the columns from A';
   Else if not every column of A' has
   both positive and negative entries,
   then return to Step 2;

   (* Some communication channels have *)
   (* lost all Accepts or Entry calls  *)
   (* -- but not both                  *)
5) Find the support ||x'|| of a linear
   combination of Ada T-invariants of the
   net APN' corresponding to A';
6) If every transition of APN' belongs to
   ||x'||, report the set s and exit.

   End LOOP2;
   End LOOP1.
END ALGORITHM INCONSISTENCY_DETECT
```

As an example, consider a modified version of the classical consumer-producer problem:

```
Producer:               Buffer:
BEGIN                   BEGIN
WHILE cond1 LOOP        WHILE cond2 LOOP
Buffer.produce;         SELECT
Buffer.msg_send;        WHEN
ACCEPT msg_ack;          buffer not full =>
ACCEPT msg_ack;          ACCEPT produce;
END LOOP;                Producer.msg_ack;
END;                     ACCEPT msg_send;
                        OR
Consumer:               WHEN
BEGIN                    buffer not empty =>
WHILE cond3 LOOP         ACCEPT consume;
Buffer.consume;         END SELECT;
END LOOP;               END LOOP;
END;                    END;
```

Note that after Producer supplies an item to Buffer, both tasks intend to exchange messages (msg_ send and msg_ack). Unfortunately, the programmer made a mistake in coding this exchange. The result is such that whenever Producer sends an item to Buffer, the program deadlocks.

The Ada net for the program is shown in Fig.3. The first iteration of Loop1 in the algorithm INCONSISTENCY_DETECT reveals two Ada T-invariants:
x1 = (1 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0)
and
x2 = (1 1 1 1 1 0 0 0 0 0 0 1 1 1 0 0 0 0 0 0 0 0).
Since some transitions do not belong to ||x'||, where x' = x1 + x2, the program has an inconsistency deadlock. During the second iteration of LOOP1 (with |s| = 1), we are trying to remove the deadlock. After we remove the communication arcs associated with the producer's first Accept statement, the algorithm reports three Ada T-invariants:
x1 = (1 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0),
x2 = (1 1 1 1 1 0 0 0 0 0 0 1 1 1 0 0 0 0 0 0 0 0),
and
x3 = (1 1 0 0 1 1 1 1 1 1 1 0 0 1 1 1 1 1 1 1 1 1).
Let x' = x1 + x2 + x3. Now, ||x'|| includes every transition of the net. Therefore, the Accept statement is reported as a "cause" of the inconsistency deadlock. Presumably, the programmer would then update the program by removing the extra Accept statement. The reader may note that

the new version would still suffer from a deadlock. This deadlock, however, is not an inconsistency deadlock; it is a circular deadlock and will be treated in the next section. The Ada net for the new program is illustrated in Fig. 4.

Algorithm INCONSISTENCY_DETECT is designed to find inconsistency deadlocks. In the best case (i.e., the program has no inconsistency deadlocks), when all the AE transitions belong to the support of a linear combination of the Ada T-invariants, only one execution of LOOP2 (LOOP1) is needed. Thus, the time complexity in this case is bounded by the time complexity of an integer programming algorithm (denote it by $C_{mn,}$ where m and n are the dimensions of the incidence matrix). which has been shown to be polynomial in the number of matrix columns (Petri net places) [6]. In the worst case, when all communication statements must be removed, Step 2 ("LOOP2") may execute upto 2^k times, where k is the number of communication statements. In a general case, when only two or three communication statements are causing the deadlock, the time complexity of INCONSISTENCY_DETECT is $O(k^2 \times C_{mn})$ or $O(k^3 \times C_{mn})$ respectively. Note that a general state enumeration technique would always require $O(n^T)$ time, where n is the number of concurrency related statements and T is the number of Ada tasks [1].

4.2. Circular Deadlocks

Even if an Ada program is free of inconsistency deadlocks, some statements may not belong to any static execution path of the program. In this section we discuss potentially reachable static deadlocks in Ada programs free of inconsistency deadlocks.

Definition: A circular deadlock is a deadlock (in a program free of inconsistency deadlocks) due to a set of communication statements, each in separate tasks, mutually suspending each other and, thus, also the control of flows of their respective tasks.

An Ada net dicircuit (directed circuit) which represents a circular deadlock is referred to as a C-type dicircuit (dicircuit of circular type). For example, the only circular deadlock for the program of Fig. 4 is represented by the C-type dicircuit (t18, t19, t20, t9, t10, t11). A C-type dicircuit possesses the following properties:
1) The dicircuit is composed of process-subnets' segments which start and end with communication transitions (e.g., [t18, t19, t20] and [t9, t10, t11] in Fig. 4. The starting transition of such a segment is referred to as a ready transition, and the ending transition as a last-executable transition. The last-executable transition of one segment is connected to the ready transition of another segment through a communication place (e.g., in Fig. 4, last-executable transitions t20 and t11 are attached to ready transitions t9 and t18, respectively). Thus, a C-type dicircuit has a set of ready transitions and a set of last-executable transitions.
2) A set of communication places representing at least two Ada entries belongs to the C-type dicircuit (e.g., p10 represents entry msg_ack and p7 represents entry msg_send in Fig.4). Otherwise, the dicircuit is called a single-entry dicircuit and is not a C-type dicircuit.
3) If more than one segment of a process-subnet belongs to the same dicircuit, such a dicircuit is called a multi-sequential-part dicircuit and is not considered a C-type dicircuit. It is easy to show that such a dicircuit does not represent any circular deadlock; for if it did, then in order to "enable such a dicircuit", we would need to have a marking which would enable all the ready transitions of the dicircuit. Since one of the process-subnets has more than one ready transition, reachability of such a marking would contradict to the safeness of Ada nets (Theorem 1).

Theorem 3: A sufficient condition for an Ada net to have a C-type dicircuit is that there is a minimal S-invariant y such that the places of its support $||y||$ have no tokens at M_0 and do not form either a single-entry or multi-sequential-part dicircuit.

Proof: If the support $||y||$ does not have any tokens at M_0, then the number of tokens in $||y||$ is 0 for any marking reachable from M_0 [5]. If the places of $||y||$ do not form either a single-entry or a multi-sequential-part dicircuit, then the places in $||y||$ form a C-type dicircuit. q.e.d.

The condition of Theorem 3 can be used to detect every circular deadlock in a program that has only one Entry call and one Accept statement per entry. The example of Fig. 4 shows an Ada net for which reporting of S-invariants provides complete information about is C-type dicircuits.

Finding circular deadlocks in general is a more complicated task. We attempt to detect C-type dicircuits by isolating them from any other possible dicircuits. It is important to first remove the dicircuits representing iterative statements, such as Loop statements. The procedure for that is illustrated in Fig. 5. We remove a dicircuit representing a Loop statement by replacing place p1 (representing the Loop statement) by two places pk and pm.

ALGORITHM CIRCULAR_DETECT

Input:
A - The incidence matrix of net APN.

Output:
The set of minimal supports of submarkings enabling all C-type dicircuits in APN. Communication places are not included in the supports.

```
Method:
1) Disconnect the dicircuits representing
   Loop statements;
2) Remove all initially marked places
   from A. The result is a new matrix A'
   for a new net APN'. Perform procedure
   PRUNE_TREE;
3) Perform procedure ALL_IN_DICIRCUITS;
4) Trace all dicircuits in A' and place
   them into a set C. Remove all single-
   entry and multi-sequential-part di-
   circuits from C. For each dicircuit
   in C, find the support of the minimal
   submarking enabling the dicircuit and
   place it into a set R (if not there).
END ALGORITHM CIRCULAR_DETECT
```

```
PROCEDURE PRUNE_TREE
(* Makes a Petri net connected *)

Repeat the following step until every
place and transition of APN' has at least
one input and at least one output arc;

If any place or transition of APN' has no
input or output arcs, then remove it from
APN'. The new incidence matrix of APN' is
still denoted by A'.
END PROCEDURE PRUNE_TREE
```

```
PROCEDURE ALL_IN_DICIRCUITS
(* Makes a net strongly connected *)

If APN' has n transitions and m places,
create a (m+n)x(m+n) matrix L for all
vertices of APN'. Initially L has all
entries set to 0. If there exists an arc
from a transition t to a place p in APN',
set L(t,p) to 1. By symmetry, an arc from
a place p to a transition t implies that
we set L(p,t) to 1;

For each entry of L, perform Dijkstra's
shortest path algorithm [7] to derive a
new matrix L;

For all vertices vi, if there is no
vertex vj such that L(vi,vj) > 0 and
L(vj,vi) > 0, and APN' has more than four
transitions and four places, then remove
vi from A' (from APN'), perform Procedure
PRUNE_TREE and go to the first step of
this procedure;

Return the resulting Ada net APN'.
END PROCEDURE ALL_IN_DICIRCUITS
```

A detailed stepwise discussion and analysis of the algorithm can be found in [3]. The time complexity of the algorithm can be shown to be polynomial in the number of places of an input Ada net. The following example illustrates the algorithm CIRCULAR_DETECT.

Consider the Ada net illustrated in Fig. 4. Step (1) disconnects Loop statements represented by places p25, p16, and p14. Step (2) removes all original places and transitions of the net, except for the ones with thickly drawn arcs (in Fig. 4) as their inputs and outputs. Step (3) has no effect in this example, since every place (transition) left has at least one input and at least one output thickly drawn arc. Step (4) traces the only C-type dicircuit of the net: (t18, t19, t20, t9, t10, t11). When the algorithm terminates, set R has only one element, the set {p28 and p20} (representing the communication statements that would block if the deadlock is reached).

In general not every circular deadlock is of interest to a programmer. Only the ones which are actually reachable by static execution paths should be detected and reported. Such circular deadlocks are referred to as potentially reachable circular deadlocks. Structural analysis (using structural restrictions and Petri net invariants) is necessary but not sufficient for detecting potentially reachable circular deadlocks. Dynamic (reachability tree) analysis must be used too. Algorithm CIRCULAR_REACHABLE, presented next, reports only the potentially reachable C-type dicircuits of an Ada net.

```
ALGORITHM CIRCULAR_REACHABLE

Input:
Ap  - An Ada program;
APN - The Ada net corresponding to Ap;
X   - The set of Ada T-invariants of APN;
R   - The set of the minimal supports of
      submarkings enabling the C-type di-
      circuit of APN.

Output:
The set R' of minimal supports of reach-
able submarkings enabling the C-type di-
circuits of APN.

Method:
(* T-invariant directed reachability *)
(* graph generation                  *)

If R is empty, report that Ap is cir-
cular deadlock-free and exit.

LOOP1: For each x in X perform
(* Select T-invariant as a firing *)
(* count vector                   *)
M:=$M_0$; x':=x; R':=Ø; STACK:=Ø;

LOOP2: Repeat
(* Perform selective reachability *)
(* graph generation               *)
If no tj with x'(tj) > 0 is enabled at M,
then do
   (* if x'=0 a static execution  *)
   (* path in Ap is found         *)
   If STACK is empty exit LOOP2;
   Retrieve the last saved marking of
   APN, firing count vector, and transi-
   tion in conflict, and store them into
   M, x', and tk, respectively;
```

```
Else if more than one transition is
enabled at M then do
   Assign one of those transitions to tk;
   For every other transition in con-
   flict, push current values of M and x'
   onto STACK;
Else assign the enabled transition of APN
to tk;

Fire transition tk to get new marking M;
Let x'(tk) := x'(tk) - 1;
If the current M was considered before,
then do
   If STACK is empty exit LOOP2;
   Retrieve the last saved marking of
   APN, firing count vector, and tran-
   sition in conflict, and store them
   into M, x', and tk, respectively;
Else if any element of R is a subset of
the support of M and the element does
not belong to R', then add the element
to R';

END LOOP2;
END LOOP1.
END ALGORITHM CIRCULAR_REACHABLE
```

An Ada program that is free of inconsistency deadlocks and free of potentially reachable circular deadlocks is referred to as a static deadlock-free program. Even though the program in Example 1 has a circular deadlock, it is a static deadlock-free program, since the circular deadlock reported by Algorithm CIRCULAR_DETECT is not reachable (as would be reported by Algorithm CIRCULAR_REACHABLE).

Algorithm CIRCULAR_REACHABLE is more efficient than "blind" tracing of the Petri net's reachability graph. CIRCULAR_REACHABLE uses the knowledge of Petri net's Ada T-invariants in order to reduce the time complexity of Petri net dynamic (reachability) analysis. As an example, consider the Ada net illustrated in Fig. 4. As noted earlier, the Ada net is free of inconsistency deadlocks and has three Ada T-invariants.
x1 = (1 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0),
x2 = (1 1 1 1 1 0 0 0 0 0 0 1 1 1 0 0 0 0 0 0),
and
x3 = (1 1 0 0 1 1 1 1 1 1 1 0 0 1 1 1 1 1 1 1).
T-invariant x1 indicates that the program may terminate (i.e., the Petri net may cycle) without any communication between the tasks Producer, Buffer, and Consumer. Ada T-invariants x2 and x3 correspond to the nets shown in Figs. 6a and 6b respectively. Generating the reachability graph for the net in Fig. 4 using x1 or x2 as a guiding firing count vector does not lead to a marking whose support would include both p28 and p20, the places previously identified by Algorithm CIRCULAR_DETECT. On the other hand, when the algorithm generates the reachability graph using x3 as the guiding firing count vector, we eventually reach marking M = (0 1 0 0 0 1 0 0 1 0 1 0 0 1 0 0 0 0 0 1 0 0 0 0 0 0 0 1 0 0). Since M's support includes both p28 and p20, CIRCULAR_REACHABLE reports the potentially reachable C-type dicircuit. Presumably, the user would then eliminate this deadlock by interchanging the order of the statements "Producer. msg_ack" and "ACCEPT msg_send" in task Buffer. If we were to use blind reachability graph analysis for the Ada net in Fig. 4, then we would generate a reachability graph of eighty two vertices. In contrast, our algorithm generates a two-node reachability graph when using x1 as the guiding T-invariant, a nineteen-node graph when using x2 as the guiding T-invariant, and a sixteen-node graph when using x3 as a guiding T-invariant. Thus, the static deadlock detection system is more time and space-efficient than unrestricted reachability graph analysis. In fact, for an Ada program Ap modeled by an Ada net APN, the more Ada T-invariants APN has, the more efficient the analysis of APN by CIRCULAR_REACHABLE. The number of T-invariants of APN depends on the number of conflict statements (IF, Select, and Case) that have nested communication statements.

The analysis can also be considered to be modular since a user interested in some particular statements may not have to deal with the whole reachability graph of the Ada net modeling his system. Only the Ada T-invariants whose supports include the transitions which represent the statements of interest need to be used in the algorithm CIRCULAR_REACHABLE.

5. SUMMARY

In this paper, we described a static deadlock detection method for Ada tasking programs. First, an Ada program is translated into a Petri net, called an Ada net, which properly models the communication patterns and control flow of the source program. Then, the Ada net is analyzed for existence of static deadlocks based on structural analysis and dynamic analysis (using the reachability graph). Here static deadlocks are considered to be either inconsistency or circular deadlocks. Algorithms for detection of both classes were presented and illustrated by examples. Due to the use of both structural and dynamic Petri net techniques, our static deadlock detection method is relatively time(space)-efficient and can support modular analysis of Ada tasks.

Abstract

This paper provides a description of a new CAD tool for Stochastic Petri Nets. The primary philosophy for the software is to maintain a flexible design environment while providing support tools to quickly and easily evaluate different aspects of the design. Several components of the software are innovative and are described in some detail. The user interface is graphical with highly interactive layout and editing features. The most significant feature is the inherent support for hierarchical modeling of systems.

Introduction

Over the last two decades, Petri Net [12] models have been used in a wide area of applications. More recently, Petri Net models have been extended to include the concept of time. These models fall into two basic classes, Timed Petri Nets (TPN) [14, 15, 18] and Stochastic Petri Nets (*SPN*) [7, 11, 8]. The TPN model has the concept of an underlying clock that clicks off time and can have synchronous transition firings. The Stochastic Petri Net model has the underlying notion of time as a random variable where events are asynchronous. The bridge between the two models is the discrete time Stochastic Petri Net model [9] with unit probabilities.

Several application areas have adopted one or more of these models. Research in flexible manufacturing, PERT analysis, computer architectures, system reliability, and network protocols are the most familiar examples.

There have been several modifications of these basic models, in addition to the the various semantic interpretations of firing rules. First, the Generalized Stochastic Petri Nets [6] extend Stochastic Petri Nets by adding the concept of instantaneous transitions. Second, the Extended Stochastic Petri Nets [2] add features to relax the exponential assumption on the transition firing rates. Third, the Generalized Timed Petri Net [5] adds a selection probability to groups of transitions but maintains the discrete time concept. Fourth, Stochastic Petri Nets with 'new better than used' distributions for firing times are being used to specify regenerative simulation models [4]. All of these models have had analysis software written to support their application.

All of these software packages provide similar features for general Markov analysis which were previously available for queueing network models, without the need to directly specify all of the possible states and state transitions. These include, analytical solutions where possible, and simulations when necessary. Since many new design problems are difficult or impossible to cast into a queueing network model, the need for user friendly Markov analysis tools, based upon a *SPN* representation, is clear. Unfortunately, the widespread use of such tools will require an improved user interface.

Stochastic Petri Nets

Recall the formal description of Petri Nets [13] where the model PN has places P, transitions T, input and output arcs A and an initial marking M.

$$\begin{aligned} PN &\triangleq (P,T,A,M) \\ P &= \{p_1,p_2,\ldots,p_n\} \\ T &= \{t_1,t_2,\ldots,t_m\} \\ A &\subset \{P\times T\}\cup\{T\times P\} \\ M &= \{\mu_1,\mu_2,\ldots,\mu_n\} \end{aligned}$$

The marking may be viewed as a mapping from the set of places P to the natural numbers N.

$$M:P\rightarrow N \text{ where } M(p_i)=\mu_i \text{ for } i=1,2,\ldots,n \tag{1}$$

Define for a Petri Net PN the set function I of input places for a transition t.

$$I(t)\triangleq\{p\,|\,(p,t)\in A\} \tag{2}$$

Define for a Petri Net PN the set function O of output places for a transition t.

$$O(t)\triangleq\{p\,|\,(t,p)\in A\} \tag{3}$$

As is common in practice, a Petri Net can be drawn using circles to represent places and bars (or boxes) to represent transitions. Tokens, to denote a marking, are represented as dots inside the circles (places). A five place, five transition Petri Net could look like the one shown in figure 1.

The continuous time stochastic Petri Net $SPN \triangleq (P,T,A,M,\lambda)$ is extended from the Petri Net $PN \triangleq (P,T,A,M)$ by adding the set of average, possibly marking dependent, transition rates $\lambda = \{\lambda_1, \lambda_2, \ldots, \lambda_m\}$ for the exponentially distributed transition firing times. These models are equivalent to continuous time homogeneous Markov chains. So, the *SPN* model may be considered as a concise representation, or generator, of the Markov representation a system.

The *SPN* model, by the nature of its being a generator, is very useful in the verification of the state space of the system. It has all of the formal mechanisms to verify that the model correctly represents the the system, before the performance analysis is attempted. Since the entire verification and analysis phase is automated, no errors are introduced as would be if a new model was described for the performance analysis phase.

Tool Description

This section describes the tool in some detail. The basic model of the Stochastic Petri is augmented with a new transition, called a subnet transition. This transition is used to represent an entire subnet defined (or about to be defined) in the library of nets on disk. The basic goal of the hierarchical model is to keep the size of the current net under design (representing some component at some level of abstraction) to a manageable size. We anticipate that a *SPN* model would be made up of a very high level description with lots of subnet transitions. Then, at the next level of abstraction, a successive refinement of those transitions would associate another net structure to that transition.

The following subsections describe each of the three major features of the tool that are unique and innovative. The first subsection describes the user interface, its philosophy, function, and use. The second subsection describes some of the special design features of the analysis components. The last subsection describes the current approach to hierarchical modeling along with some of the problems encountered with the approach.

The User Interface

The basic philosophy of the user interface is simple. The user interface should be flexible enough to let the designer be creative (even artistic) while removing any tedium from the activity. This is accomplished by adopting the following goals.

1. The user interface should provide very rapid, easily selectable options.

2. Anything that is repetitious or algorithmic should be done by the tool.

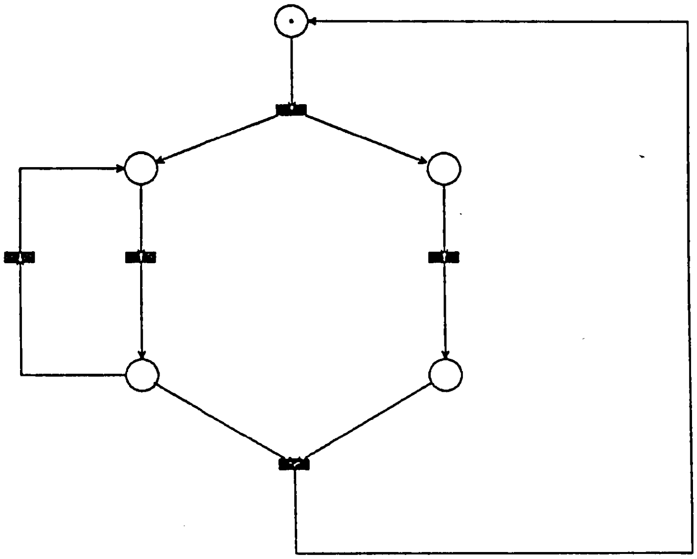

Figure 1.

3. All of the rules should be gently enforced by the tool.

4. Do not try to be smarter than the designer.

5. Anything that can be done, can be undone.

6. Options should be split into logical categories with different access for each.

7. Graphical representations of options are the best for the visually oriented human.

8. Both a top down and bottom up approach must be supported.

The user interface is constructed as a tool under the SUNTOOLS ® window management software. The tool has all of the features of a normal window. It can be moved, modified in size or shape, closed into icon form, and exist in multiple copies on the screen. The mouse is the primary input device. All drawing, menu selection, and analysis activities are initiated by mouse key clicks. The keyboard is used only in those cases when arbitrary text input is needed. The basic layout of the tool, the icons, and an example drawing can be seen in figure 2. The tool has three basic subwindows which make up three of the five functional user interface components.

Figure 2.

1. The menu subwindow (it can be on the left or right hand side) is a collection of icons representing drawing and editing features.

   a. Create a Place

   b. Create a Transition

   c. Create a Subnet Transition (a transition representing a subnet)

   d. Create an Arc

   e. Annotate a Transition (specify firing rate, etc.)

   f. Tag a Node (Place, Transition, or Subnet) with an ASCII string

   g. Add a Token

   h. Delete a Token (add an 'anti-token')

   i. Move a portion of the Net

   j. Delete an Arc

   k. Delete a Node

   l. Manually Fire a Transition or Subnet

2. The message subwindow on the top of the tool window which is used for error messages, comments, and text input to selections.

3. The canvas subwindow where all the actual drawing is done. The canvas subwindow represents a window into the drawing space. It may not show all of a particular *SPN*, but can be moved around or scaled to do so.

The basic idea of the tool is similar to the popular MacPaint for the MacIntosh computer. The menu icons are used to select an action. The selection is performed by pointing at the icon, and clicking the left mouse button. Once the selection is made, the cursor can be moved back to the drawing canvas, where it changes to represent the action selected. In the case of creating places, transitions, and subnet transitions, the cursor looks like the object to be created. Once a location is determined (pointed to by the cursor) the left mouse button is clicked to create an instantiation of the object. In a similar fashion, tokens can be added or removed from places, ASCII tags can be modified, and transition firing rates can be changed. In all cases, the user selects an option from the menu and activates the option by pointing and clicking the left mouse button. An English description of the option is displayed in the message subwindow and the icon is displayed in reverse video.

Since many drawing options are not semantically correct for Stochastic Petri Nets (such as connecting transitions to transitions), the tool enforces the rules. The user gets an error message in the message subwindow when an illegal action is taken, and the action is not be allowed to occur. There are several such rules.

1. An object can not be placed on top of another object.
2. Transitions and subnet transitions can only be connected to places.
3. Deleting a place, transition, or subnet transition deletes all the arcs associated with that node.
4. All locations are lined up with an invisible grid so that being close to lining up becomes exactly lined up.
5. Tokens and Anti-tokens can only be put into places.
6. Anti-tokens have no effect when there are no tokens present.
7. Only transitions and subnet transitions can be annotated with firing rates.

There are two additional functional components of the tool. These can be seen in figure 3. First, a popup menu (textual), activated by the right mouse button, provides options for the manipulation of the drawing environment. These include several commands (again activated by pointing).

1. Undo - undo the last drawing action (icon menu only)
2. Refresh - clear and redisplay the net.
3. Zoom In - magnify the image in the canvas subwindow with the cursor location as the new center.
4. Zoom Out - reduce the image in the canvas subwindow with the cursor location as the new center.
5. Clean Up - align a coarse drawing onto the imaginary grid points. (This is for files generated by other programs.)
6. Quit - abort the current session. A confirmation is required if any modifications have been made.
7. Exit - end the current session writing out the current net to the edit file defined when the tool was started.
8. Clear - clear the screen and destroy the current net. A confirmation is required if any modifications have been made.

Second, a popup menu (textual), activated by the middle mouse button, provides analysis options for studying the network currently designed.

1. Save - save the current design in a disk file. The file format is PIC compatible for inclusion in DITROFF documents.
2. Load - load the current design from a disk file.
3. Solve - generate the reachability set, construct the Markov matrix, solve the matrix for the steady state solution, and display the average number of tokens in each place.
4. Reachability - generate the reachability set, and send a printable copy of the reachability tree to the standard output.
5. Print - generate the reachability set, construct the Markov matrix, solve the matrix for the steady state solution, and display the average number of tokens in each place. Send a copy of the token probability densities for each place to the standard output.
6. Limit - solve for bounds on the throughput of the *SPN* using the bottleneck analysis technique [10].
7. Simulate - run a Monte Carlo simulation to animate the display of the *SPN* using a mouse controlled throttle for the clock rate.

Special Data Structures

Because maintaining information about the graphical representation needs to be flexible for ease of editing, it is not appropriate for analysis. Since analysis requires speed and compact size, an entirely different structure was used for nets when the analysis phase is initiated. Each of the basic structures are described below. The result of carefully selecting each of these data structures is the superior performance of the tool. Most of the design time went into selecting and coding these structures. All of the structures are allocated dynamically to increase the range of the tool. The allocation of the reachability set and Markovian structures is only done when an analysis is requested, and deallocated when it is complete. This philosophy has made it possible for this system to draw, edit and analyze *SPN* with a large number of nodes and at least 5000 states in the reachability set, in an interactive environment.

Figure 3.

Graphical Data Structures

The data structures for drawing are object oriented. A *SPN* is simply a collection of pointers to lists of objects. The lists of objects include, places, transitions, subnet transitions, arcs, and compound objects. Each element in the lists are data structures of a type for that list. All structures for places have information about the location of the place, its ASCII label, the number of tokens, etc. All structures for transitions have information about the location of the transition, its ASCII label, its firing rate, etc. All structures for subnet transitions have information about the location of the subnet transition, its ASCII label, its firing rate, the filename where the complete subnet description is (if any), etc. All structures for arcs have information about the sequence of points (arcs can be segmented) which make up the arc, the direction of the arc (to or from a place) and pointers to the specific place, transition, or subnet transition the arc connects. In addition to all of these, there is a backup net structure to save deletions for the undo of a deletion.

Reachability Data Structures

To speed up the response time for the analysis phase, a flexible structure for the net was not selected. Instead, the object oriented structure is translated into a packed structure for the generation of the reachability set.

The reachability set is maintained as a tree structure following the normal algorithms [13], but because of the significant lookup time in this graph structure, a second data structure was added. After the generation of a new marking from a current leaf in the reachability graph, the new marking is dropped into a binary search tree (which only contains pointers) to check for duplication. If it is found, it is not included in the reachability set. If it is not found, it is added to both the binary search tree and the reachability set.

Markov Data Structure

The end result of the analysis is the generation of the equivalent Markov chain. Since this tool is currently restricted to continuous time Stochastic Petri Nets, the resulting matrix tends to be very sparse. Therefore, the data structure used for the matrix is the uncompressed pointer storage structure defined for the Yale Sparse Matrix software package [3].

Approximations for Hierarchical Models

In order to facilitate the top-down and bottom-up design concepts, a hierarchical model is needed. It is clear that the state space explosion makes large models intractable. The idea is a simple one, and a heuristic. The addition of a subnet transition allows us to postpone the description of a detailed section of the net. This section is then described and analyzed separately. The load dependent behavior of the subsystem is then included as the behavior of the subnet transition in the higher level model.

In figure 8, we see an example of such a model. The drawing in the upper left is the complete model without a hierarchical description. The drawing in the lower left is the high level model for this complicated system, where each subnet transition represents the behavior of the subsystem models, one of which is shown in the upper right hand corner. The solution would not be even close if we just approximated the throughput of the subnet as a single transition. There are several reasons for this. First, the routing probabilities in a *SPN* depend on the relative firing rates of the contending transitions. Second, the throughput of a *SPN* is load dependent. Therefore, a pair of transitions and a holding place are used to model the subsystem in this approximation. The first transition fires at precisely the same rate as the selection transition would in the exact model. That means that the transition at the entry to the subsystem is simply duplicated. The second transition models the load dependent behavior of the actual subsystem. The firing rate of the that transition depends on how many tokens are in the subsystem (equivalently, the holding place).

Although this is clearly a heuristic approximation, it is similar to the techniques used in Non-Product Form Queuing networks [16]. The results so far are very promising, and we will continue to investigate this approximation, as well as others.

An Example - A Token Ring

In order to clearly demonstrate the use of the SPAN tool, a token ring was analyzed as an example. Token rings have been analyzed by others [1, 17] using other techniques, so this example can be compared to the other alternatives.

A token ring is a network for local communication which has a physical topology in the shape of a ring. The perimeter of the ring may follow some funny path rather than a direct line to the next station, but is still a direct physical connection. The access (i.e. permission to transmit) is controlled by circulating a single token which enables the station who possesses it to transmit. This gives access to the communication medium to stations in a round-robin fashion. Several token ring designs are currently available or soon to be available. IBM Corporation and Proteon Corporation have token ring designs for local area networks.

Manually fire transitions.

Figure 8

One of the performance measures for a token ring is the token latency time. That is the time it takes the token to return to a station since it was last forwarded. This latency has an fixed upper bound, since in heavy load, at most one message can be sent by each station. What the solution gives is the average value of the latency for a system under various, non-saturating loads.

The load parameters for this model are the same as used in the analysis given in Sethi's paper [17]. The time to pass a token is 50 microseconds. The time to send a packet is exponentially distributed with a mean of 400 microseconds. Messages arrive as a Poisson process if the station is idle with means 50, 100, 150, 175, 200, 300, and 1000 messages per second. Messages are assumed to be rescheduled if they arrive to a station with a message waiting.

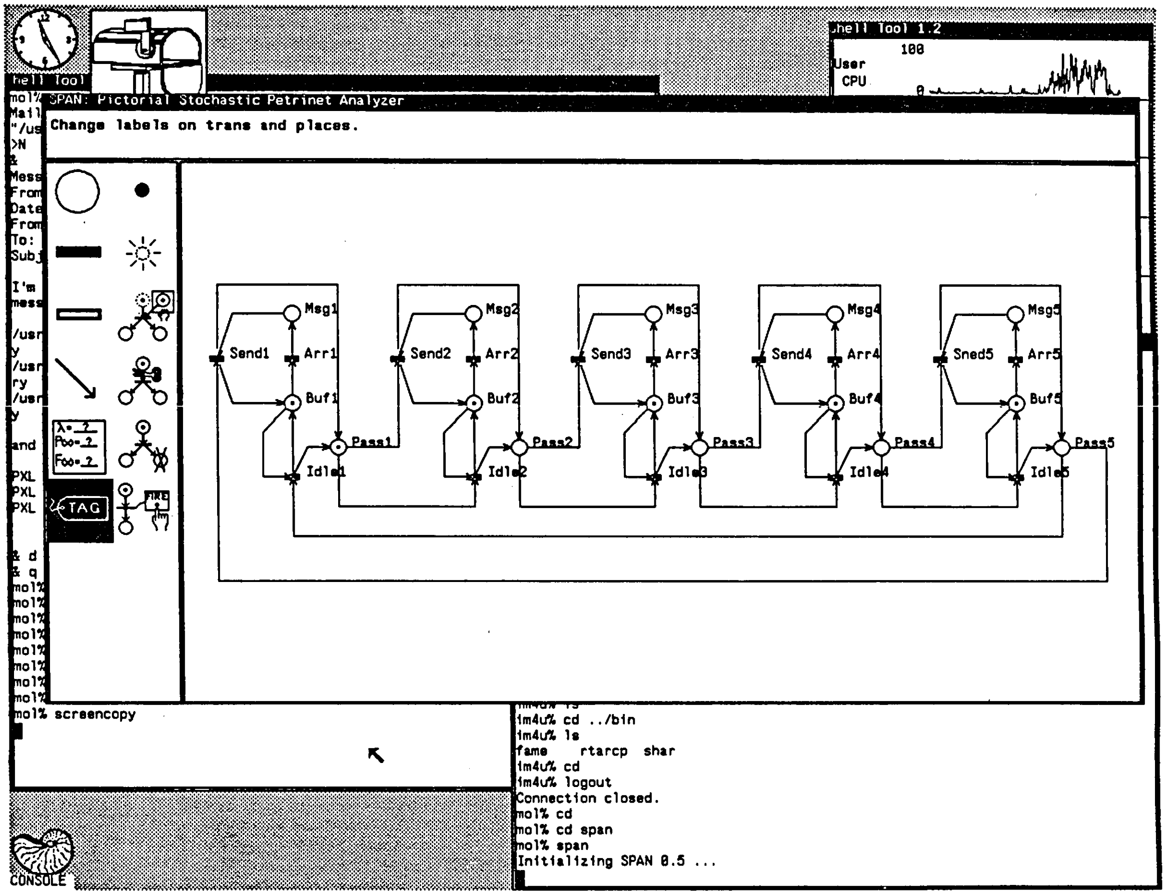
The Stochastic Petri Net model for the token ring is shown in figure 9. The various places represent whether a message is waiting to be sent (Msg), the message buffer is available (Buf), or the token is being passed to the next station (Pass). The various transitions represent the events of forwarding a token (Idle), sending a message followed by the token (Send), or having a message arrive (Arr). This particular model is for five stations spaced around the ring.

The model is then solved by SPAN to give the steady state probabilities of the number of tokens in each place. That gives the probability that each station is either idle or has a message to send. Knowing the average time to send a message or token, the average token latency (rotation time) can be calculated. In addition, since the Poisson arrival process is effectively turned off during the period of time a message is waiting, the actual offered load is the original rate times the probability the station is in the idle state.

The results of the analysis are shown graphically in figure 10. The curve starts at the minimum time to circulate a token around the five stations and increases as the rate of message arrivals increase. The curve shows the expected convexity, and would show the abrupt upper-bound at 2 milliseconds, if the system were pushed that far.

Conclusions

The CAD tool, SPAN, for the analysis of Stochastic Petri Models has proven to be very useful. The design goals of a highly interactive, user friendly, and high performance design aid have been attained. The system can handle large nets by breaking them down in a hierarchical manner and can solve medium size nets in a relatively short time (given the fact that the SUN 2/120 ® is poor at floating point). A summary of the timings for the standard example net with increasing reachability set size is given below.



```
Change labels on trans and places.
```

```
mol% screencopy
```

```
im4u% cd ../bin
im4u% ls
fame    rtarcp  shar
im4u% cd
im4u% logout
Connection closed.
mol% cd
mol% cd span
mol% span
Initializing SPAN 0.5 ...
```

Figure 9

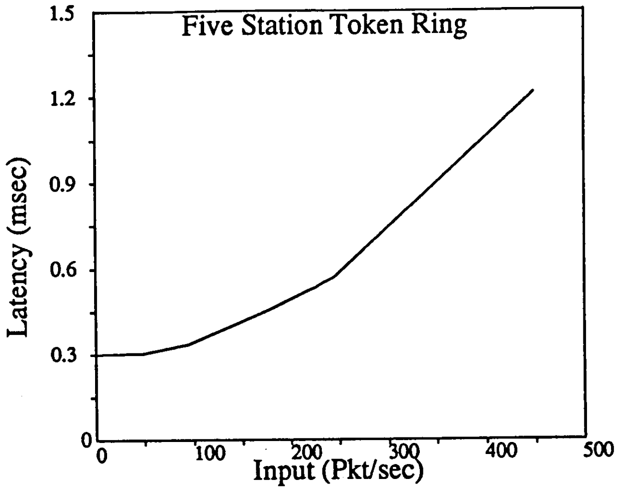


Figure 10

The sudden increase in processing time for the cases above 500 states is not completely understood. At this time, we believe that at 500 states, paging becomes a significant factor on our SUN 2/120 ® workstation since we have only 2meg of memory. This belief is supported by the timings on a 3meg SUN 2/120 ® which are shown in parentheses. The lack of data for the time on the Markovian analysis for large systems is due to the fact that those routines are currently in FORTRAN and can not do dynamic memory allocation. Therefore, if SPAN does not allocate enough space for the Yale package, the program aborts the Markovian analysis. This is currently under conversion to avoid the problem.

Tokens (#)	States (#)	Reachability (sec)	Markovian (sec)
1	5	<1	<1
2	14	<1	<1
3	30	<1	1
4	55	<1	4
5	91	1	6
6	140	3	19
7	204	6	45
8	285	10	110
9	385	18 (14)	283
10	506	27 (21)	---
11	2212	270 (130)	---
12	5322	1300 (862)	---

® SUN is a registered trademark of Sun Microsystmes Inc.

It is clear from even the small amount of use the package has seen, that several changes are needed. The human interface for reachability analysis must be changed to support some type of query-response dialogue rather than a long listing. In a similar vein, the Markovian results need to be represented differently. It would be much better to point at an arc, and get the throughput for that arc. Similarly, pointing at a transition would trigger the display of the utility of that transition. Finally, pointing at a place could give you the mean time until a token returns to that place.

Some of the drawing features need to updated. It would be nice to select and duplicate sections of a *SPN* in a fashion similar to the way we move sections of a net. The addition of a mouse activated keypad would further minimize the number of keyboard actions required.

Acknowledgements

This software could not have been written without the help of two outstanding individuals. First, a graduate student, Supoj Sutanthavibul, spearheaded all of our efforts by creating several tools on the SUN with such great style, that several sections of the SPAN code still bear his name. Second, Prentiss Riddle actually wrote half of the code with the author and provided exactly the right balance for the completion of this project in only 3 man-months.

petri - A UNIX[1] Tool for the Analysis of Petri Nets

Ira R. Forman

Microelectronics and Computer Technology Corporation
Austin, Texas 78759

ABSTRACT

An analyzer of Petri nets is described. Petri nets are a tool for modeling concurrent systems. The program supports three forms of analysis: simulation, reachability analysis, and invariant analysis. Simulation allows one to follow the behavior of the net in order to develop intuitions and correct the net. Reachability analysis computes all possible simulations and thus allows one to verify net properties. Reachability analysis is specialized for three forms of Petri nets (i.e., safe, bounded, and place/transition). Invariant analysis derives properties of nets by analyzing the incidence matrix, which implies larger nets can be analyzed. The combination of these forms of analysis yields an engineering tool that should be useful in many software engineering environments.

1. Introduction

The modeling of concurrent systems is becoming increasingly important; Petri nets are a excellent way of doing such modeling. The reader who is not familiar with Petri nets should consult Peterson [13] or Agerwala [1]. Greater detail is available in the texts by Brauer [5], Peterson [14], or Reisig [16]. Once the model is built, computer analysis is important in order to insure that desired system properties are achieved. This is especially true in those environments where the model must be modified intermittantly during development or maintenance in response to changing customer or market requirements. Computer analysis uncovers errors due to modification quickly and at a lower cost.

petri is a tool for manipulating and analyzing Petri nets. *petri* has a flexible interface that makes it usable in learning situations. In addition, *petri* provides reasonably rapid computations and has no storage limitations (other than operating system limits). Thus *petri* is a tool for doing serious analyses. Other tools for the display and analysis of Petri nets are also finding their way into industry and the classroom [3,9,12,15,17].

There are three modes of analysis provided by *petri:* simulation, reachability, and invariant. One can simulate the net with the aid of a two column display that shows the current marking and the firable transitions. One can compute the reachability graph of the net and display information about the reachability graph. One can compute the S- and T-invariants of the net and have them displayed.

For reachability analysis *petri's* preferred mode of operation is safe place/transition nets. In this case *petri* uses one bit per place to store markings, leading to a very efficient computation. *petri* also has modes for bounded nets and unrestricted nets.

2. A Description of the User Interface

This section describes the interface to *petri*. An evaluation of *petri* is given in Section 5.

2.1 Invoking petri

The *petri* program is invoked with the following UNIX command

```
petri [-s] [-b] [-g] [-q] infiles
```

If infiles are given, *petri* first reads commands from the infiles and then prompts the user. The four command line flags have the following meanings:

-s means that the user believes the net to be safe; *petri* uses this information to compute the reachability graph more efficiently. One bit is allocated per place to store markings for reachability computations. If the net is not safe, *petri* discovers this fact and terminates with an error message that contains a path (i.e., place/transition sequence) to the unsafe marking. The -s, -b, and -g flags are mutually exclusive with -s as the default.

-b means that the user believes the net to be bounded; in this mode *petri* does not do the ω search. If the user is mistaken, i.e., the net is not bounded, the computation of the reachability graph does not necessarily terminate.

[1] UNIX is a trademark of AT&T Bell Laboratories.

-g means that no assumptions are made about the net. In this case, the computation of the reachability graph does the ω search, which is a very expensive computation. (Formally speaking we are computing the coverability graph in this case; see Jantzen and Valk [8]).

-q implies the quiet mode; *petri* does not prompt the user after reading the file of commands. This flag is used for background analyses.

When used in interactive mode, the *petri* program prompts the user for commands. Output from a command may be redirected by adding a filename to the command to create a new file or by adding ">> filename" to the command to append to the file.

The *petri* commands can be partitioned into four groups; net manipulation, net display, interface support, and analysis. The following four subsections contain descriptions of the first three groups; the analysis commands are covered in Section 3.

2.2 Net Manipulation

Figure 1 depicts an example net that is used throughout this paper. The net represents two processes that share a resource. Each process requires exclusive access to the resource. Figure 2 contains the commands to build the net depicted in Figure 1. The meaning of the commands is given below.

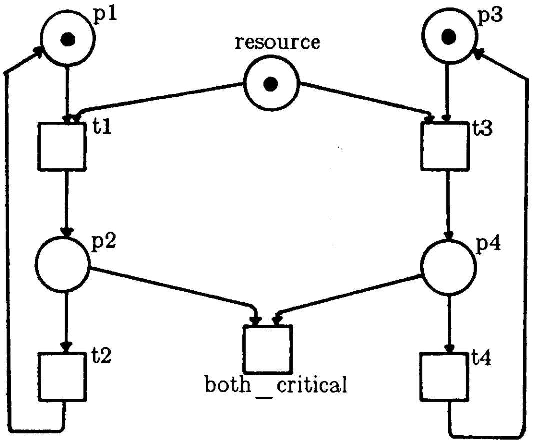

Figure 1. A sample Petri net.

add place *list_of_places_to_add*
Creates one new place for each item in the comma-separated list of the place names. The name of a place or transition is an identifier (a letter followed a sequence of letters, numbers, and underscores).

add transition *list_of_transitions_to_add*
Creates one new transition for each item in the comma-separated list of the transition names.

add arc *list_of_arc_groups_to_add*
Creates new arcs specified by each arc group in the comma-separated list of arc groups. An arc group is denoted as follows: node_a{successor1, successor2, ...}, which specifies an arc from node_a to each of successor1, successor2, ... The term "node" refers to either a place or a transition.

mark *list_of_places_to_mark*
Allows one to change the current marking of the net. The *list_of_places_to_mark* is a comma separated list of place names followed by an equal sign and a number. For example, place_a = 2, place_b = 0. If a place is mentioned alone (without an equal sign and number), this means "set the number of tokens to 1."

```
add place p1, p2, p3, p4, resource
add transition t1, t2, t3, t4, both_critical
add arc p1{t1}, t1{p2}, p2{t2}, t2{p1}
add arc p3{t3}, t3{p4}, p4{t4}, t4{p3}
add arc t2{resource}, t4{resource}, resource{t1, t3}
add arc p2{both_critical}, p4{both_critical}
mark p1, p3, resource
```

Figure 2. Commands for building the net in Figure 1.

It is not sufficient in an interface just to be able to build nets. It is also important to be able to compose them in such a way that the nets can be built by automatically translating from some language for distributed programming. For this purpose, the interface also contains the **merge, split, rename, reduce,** and **retain** commands, which are described below. The important point is that the commands facilitate the building of a net in pieces that can be subsequently composed. The **merge** command is the most important in this category. It should be noted that *petri* supports nodes that have multiple names, any of which are valid identifiers of the node. The result of the **merge** or **reduce** command is a node with multiple names.

merge *list_of_nodes*
Merges a list of transitions(places) into one transition(place) whose set of names is that of all the elements of the list. The predecessors of the resulting transition(place) is the union of the predecessors of the transitions(places) in the list. If a predecessor has arcs to multiple elements of the list, the resulting transition has multiple arcs from the predecessor. Similar actions hold for successors.

split *transition_name* **in** *number_of_parts*
Splits a transition into *number_of_parts* transitions; each transition has "#<an_integer>" appended to it beginning with 0. Each transition has the same set of

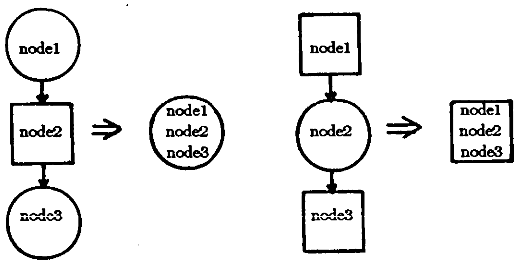
predecessor and successor places as the original transition.

rename *node_name* **to** *identifier*

Renames the node with name *node_name* with new name *identifier*.

reduce

Executes the following net reductions until there are no reductions possible.



Note that node1 has exactly one successor and node3 has exactly one predecessor. A list of the reductions is sent to the terminal or to a file with use of the same syntactic conventions as the **display** commands.

retain *list_of_nodes*

Sets a flag in each transition (place) in the list to indicate to the **reduce** command may not eliminate the transition (place). (The **reduce** command resets the flag.) This command is necessary to prevent the **reduce** command from removing the node in which interest lies when doing analysis.

2.3 Net Display

The five commands for displaying a net are described below. These commands are usually used for debugging a net (except for **display statistics**, which can contain reachability information).

display net

Displays a depth-first spanning tree of the net. States are enclosed in braces with the number of tokens (e.g., {place_p = 1}). Events are enclosed in brackets (e.g., [transition_t]).

display frame *node*

Displays the node and all its neighboring nodes.

display marking

Displays the names of the places with nonzero tokens and the number of tokens if greater than zero.

display statistics

Displays interesting statistics about the net. These are: the number of places, the number of transitions, the number of arcs. If the reachability graph has been computed already, the number of nodes, the number of terminal nodes, and the number of back arcs of the reachability graph are displayed also.

display firable

Displays the current list of the firable transitions.

2.4 Interface Support Commands

There are several commands to help interface with *petri* and UNIX. **save** *file* copies the net on the *file* in the form of *petri* commands. **source** *file* reads *file* as a source of commands. **alias** *id1 id2* allows *id1* to be used as an alias for *id2*. The purpose of this command is to allow the user to define short forms for the keywords. **!** is the shell escape. **help** displays a synopsis of the command set.

3. Types of Analyses

There are three forms of analysis provided by *petri:* reachability graph analysis, simulation, and invariant analysis.

3.1 Reachability Graph Analysis

The **compute rgraph** command computes the reachability graph and stores it in memory with no displayed output. The hitting of the interrupt character during the computation of the reachability graph causes the computation of the reachability graph to stop. In this case, some nodes are marked as type *frontier*, which means that these nodes may have successors that may not have been computed because the computation was stopped. The computation can be resumed with the **compute rgraph** command (there is a small possibility that the count of the number of arcs in the reachability graph might be off by 1 when doing this).

Once the reachability graph is computed, the **display bounds**, **display conflicts**, **display concurrent**, **display terminals**, and **display path** commands can be used to obtain information about the reachability graph. The reachability graph is automatically computed for these commands if it has not already been done.

The **display bounds** command lists the greatest number of tokens that may appear in any place. An ω indicates that the place has no finite bound. The **display concurrent** command lists pairs of transitions for which there is a reachable marking in which the pair of transitions are concurrent. The **display conflicts** command lists pairs of transitions for which there is a reachable marking in which the pair of transitions conflict. The **display terminals** command lists the terminal nodes of the reachability graph, that is, the reachable markings at which no transition is firable. The **display path to terminals** command lists for each terminal node in the reachability graph, one minimum length path from the initial marking to the terminal node. The **display path to (** *marking* **)** command lists one minimum length path from the initial marking to the marking in the reachability graph. The **display path to cover of (** *marking* **)** command lists one minimum length path from the initial marking to a cover of the marking in the reachability graph. The **display dead** command lists those transitions that can never be fired from the current marking. One analysis technique is to add to the net transitions that represent events that erroneous conditions. Then one can use the **display dead** command to verify that the erroneous transitions are never enabled. In Figure 1 *both_critical* is such a transition.

The set of commands is also intended to support the design process. The reachability computation implies an interleaving semantic model. In order to really verify the design one must show the noninterference of concurrent transitions. The **display concurrent** command exists for this purpose. In designing systems with nets, because conflict resolution is nondeterministic, the resolution is actually a choice that the designer leaves to the implementer. Designers should be able to easily enquire about these choices. The **display conflicts** command exists for this purpose.

It should be noted that once the reachability graph is computed, the **display statistics** command reports for the reachability graph on the numbers of nodes and arcs, the number of terminal nodes, and the number of back arcs. These numbers can be useful in the analysis of a net. For example, a back arc is an arc that completes a circuit. If the net is not supposed to have any cyclic behavior (as in checking for the absence of livelock), then the number of back arcs should be zero.

No matter how well displayed, a listing of the entire reachability graph is not an effective analysis tool because there is too much information. The **display** commands are provided to obtain useful information about the reachability graph. Figure 3 depicts sample outputs for some display commands for the Petri net in Figure 1. However, the number of possible display commands is endless and a method of forming ad hoc queries is needed. The answer to this problem is to view the reachability graph as a database about the behavior of the net. With this view one can see that a database query language would be useful. Now because we are interested in the behavior of the net, which occurs over time, temporal logic is an ideal query language. For this reason we have incorporated the interface to the Extended Model Checker, which enables one to form queries in temporal logic about the reachability graph. The reader should consult the paper by Clarke, Emerson, and Sistla for more information [6].

The **display emc** command displays the reachability graph as a LISP S-expression for input into the Extended Model Checker. The Extended Model Checker is a package with which one can make queries in temporal logic in terms of certain atomic propositions. The set of atomic propositions that we chose for the queries about the behavior of a Petri net are:

- the set of place names, where if *x* is a place name, then the atomic proposition *x* means "*x* is marked",
- the set of transition names, where if *x* is a transition name, then the atomic proposition *x* means "*x* is firable".

In analyzing the net in Figure 1 one could compose the temporal statement "sometimes p2 is marked and p4 is marked" and expect that the Extended Model Checker will reply false. This allows us to test the desired property of mutual exclusion directly (i.e., without going to the effort of adding the *both_critical* transition and checking that it is dead). Note that "x fires" is not an atomic proposition and one cannot enquiry about it directly. To make such a query, one may construct the nets so that the transition of interest has a unique post-state.

```
petri: display statistics
number of places = 5
number of transitions = 5
number of arcs = 14
number of rgraph nodes = 3
number of rgraph arcs = 4
number of rgraph terminals = 0
number of rgraph back arcs = 1
petri: display bounds
        1       resource
        1       p4
        1       p3
        1       p2
        1       p1
petri: display dead
both_critical
petri: display conflicts
(t1,t3)
```

Figure 3. Example of analysis commands for the net in Figure 1.

We mention above that nodes do not have just one name but a set of names. The extra names come from the use of the **merge** and **reduce** commands. The **display emc** command outputs all of the names of a node. (The other commands display only one of the names of a node.) This feature allows one to reduce the net and still make queries in terms of the original net.

3.2 Simulation

The **simulate** command presents the user with a two column display for simulation. The left column lists the marked places and the number of tokens in each place. The right column lists the firable transitions. The following keys are available as commands when looking at the simulation display.

k move the cursor up.

j move the cursor down.

f fires the transition named to the right of the cursor. The display is updated with the new marking and new set of firable transitions. (Note: currently the display shows only 22 marked places and 22 firable transitions.)

u undoes the firing of the last transition. (Repeated use undoes the entire simulation.)

p outputs the firing sequence to file *sim.path*.

q terminates the simulation with the last marking as the new net marking.

x terminates the simulation with no change to the net.

The command **simulate restart** continues the last simulation from where it was terminated.

The simulate command proved most useful when debugging nets that reachability analysis showed to have unsatisfactory behavior. The procedure was to simulate the net while moving tokens about a net picture. The advantage of having the program was that one could fire multiple transitions and the marking would be accurately kept. This was especially true when one wanted to back up and try another firing sequence. One opportunity that was missed in the implementation is the capability to execute the reachability graph analysis commands on the firing sequence of the simulation.

3.3 Invariant Analysis

The command **display invariants** lists the S- and T-invariants of the net. A T-invariant is an algebraic formula on a firing sequence that leaves the marking unchanged. An S-invariant is a algebraic formula on a subset of the places of a net such that the value of the formula remains constant for all firing sequences.

Invariants can be used to prove properties of nets. In Figure 1 the S-invariants are:

(1) p1 + p2
(2) p2 + p4 + resource
(3) p3 + p4

where the name of a place represents the number of tokens that the place contains. Based on the initial marking, it is easy to see that

$$p2 + p4 + resource = 1$$

for all reachable markings. This implies $p2 + p4 \leq 1$, which implies that mutual exclusion of p2 and p4 is a property of the net.

S- and T-invariants are explained in [11]. The algorithm of Martinez and Silva [10] is used; this algorithm produces the set of minimal support invariants. [4] contains an extensive explanation of how S- and T-invariants may be used to prove properties of protocols.

The advantage of invariant analysis is that it can be used on nets for which the reachability graph is too large to build. The disadvantage is that there is an additional step of proving net properties once the invariants are found. This can be quite difficult. Because *petri* can build very large reachability graphs, the direct route of using the display commands or the Extended Model Checker has been the one used in all problems. We have not done anything other than trivial examples with invariant analysis.

4. An Overview of Implementation

petri runs on Berkeley 4.2bsd UNIX on either a Sun Microsystems workstation, a Pyramid mainframe, or a DEC VAX. It is built with approximately 5100 lines of code that is either C, *yacc*, or *lex*. (*yacc* is a parser generator and *lex* is a scanner generator.) The program is structured like a compiler in that the input commands are parsed by a *yacc/lex* generated parser. This technique and the UNIX facilities for redirecting input and output account for our ability to achieve high capability with little software.

Figure 4 depicts a net schema that is used for a performance benchmark. This schema is chosen because it generates very large reachability graphs for small nets. Table 1 gives the time and space requirements for each of the three options for building reachability graphs when run on a Pyramid 90x. Time is given in hours, minutes, and seconds. Space is given in kilobytes. From this table one can see the importance of space to the construction of the reachability graph. In dealing with safe nets the storage consumption is measured in megabytes/minute. The use of a word instead of a bit for the marking vector (and the associated programming techniques) totally accounts for the difference between the performance for safe and bounded nets. The ω search totally accounts for the difference between the performance for bounded and general nets.

The high performance of the reachability algorithm is obtained by the following implementation techniques.

1. A reachability graph is computed rather than a reachability tree. This greatly reduces the amount of storage required to hold the structure. The number of nodes in the reachability tree is equal to the number of arcs in the reachability graph minus one. From the table above it is clear that for larger nets, the reachability graph provides large savings.
2. When a new marking is generated, the search for a duplicate (i.e., a node with an equal marking) is a costly part the computation. This search of the reachability graph is done by using a hash table with 10007 entries.
3. On the less intuitive side, the test for the firability of a transition is a very costly operation because it must be done for every transition at every reachable marking. The algorithm for computing the reachability graph uses the net itself to keep track of the current marking during the computation. This allows a quick check of firability because the predecessor places of a transition can be quickly accessed and usually the first predecessor has zero tokens because the transition is probably not firable.
4. The algorithm was specialized to compute the reachability graph for safe and bounded nets. This was done in two ways.
   a. Markings for safe nets are stored with one bit per state instead of one word per state. In turn, this allowed other optimizations such as increasing the speed of the equality test of marking vectors.
   b. The search of the frontier to discover ω's is omitted, because ω's cannot occur in safe or bounded nets.
5. All the memory for the storage of the net and its reachability graph is dynamically allocated. (For this reason there are no limits on the size of entities other than the operating system limit on storage allocated to a job.)
6. All of the display commands for reachability graph

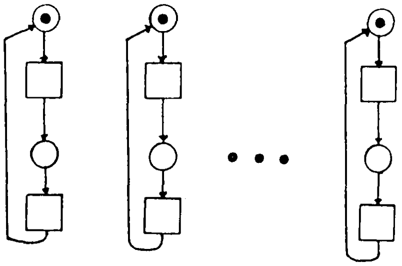


Figure 4. Net schema for performance benchmark.

Processes	Rgraph		-s		-b		-g	
	Nodes	Arcs	Time	Space	Time	Space	Time	Space

analysis involve a search of the graph. Usually searches are done with a marking bit at each node to indicate whether or not the node has been visited. This leads to the problem of resetting the marking bit at the beginning of each search, which implies two passes over the graph for each search. To avoid this problem, a global count of the number of searches is kept and for each node the number of times it is visited is kept in the node. At the beginning of a search the global count is incremented; when a node is visited during a search the local count is set equal to the global count. Therefore, unvisited nodes have a local count less than the global count. Although this technique requires more storage it is preferable to resetting bits because it yields faster searches.

5. Experience

The experience described was accumulated over by the author previous to his employment at MCC with a different net analyzer (which he also built). The analyzer described to this point is the one with a new architecture, while the experience is with the old analyzer. Although we have not yet had the opportunity to use the new analyzer, the experience with the old one is valid for discussion.

5.1 Synergy in the Tool Set

Originally net entry was conceived to be an interactive process. Net entry was never interactive; it didn't prove to be useful In dealing with larger nets. (In fact, a command was implemented to delete nodes and arcs, but it was never used.) Instead synergy among the available tools ran rampant during use. The synergy between *petri* and *emc* is just one example. The most used combinations were *petri* and tools for building nets like the *m4* macro processor.

One mode of using *petri* was as follows. One would build macros to generate pieces of a net that are repeated in a problem. For example, if one were modeling the dining philosophers problem, a philosopher macro and a fork macro would be written. This would be done carefully so that the generated net pieces could be merged with the **merge** command. The net was generated by writting the proper macro invocations and merge commands.

The second mode of use was to generate the net from a programming-like language. A language based on Holt's Role/Activity Diagrams [7] was designed and a translator to Petri nets was built. The **rename, merge,** and **split** commands were indispensable in this translation process. There are many reductions possible for Petri nets; however, for the analysis of the nets produced from this programming language, only the reduction that is described for the **reduce** command was found to be useful (which was why it was the only one implemented).

5.2 Reachability Graphs and Debugging Net Designs

The interactive analysis of a net is a very useful feature when showing that a net model satisfies behavioral requirements. When the analysis shows that the requirements are not met, a debugging process then proceeds. There are many subtlies of the command set that facilitate this process.

Let us consider how we might tackle one type of erroneous net. Imagine that we are designing with the intent of having a safe net. If the net is not safe, the analyzer reports on the shortest firing sequence to the unsafe marking (i.e., the shortest that exists in the partially built reachability graph when the unsafe marking is found). The use of the simulation facility with this information may be enough to correct the net. But if it is not, then the computation may be done with either the -s or -g option. This takes more time, but one can interrupt the computation and analyze the partially built reachability graph. This can be done until one has a reachability graph with enough information to correct the problem.

5.3 Actual Use

Despite the power of *petri,* experience shows that its use requires study and creativity. When modeling a system, it is easy to abstract away the properties in which one is truly interested. The model must be constructed accurately. The other side of the coin is that one can easily overwhelm the analyzer (remember the size of the reachability graph can be exponential in the size of the net). One must try to abstract as much a possible. This gives us a trade-off between two conflicting goals.

Two protocols were analyzed with *petri*. Let us call them A and B; space does not permit us to describe them other than to say that protocol A was for the run-time support of a distributed programming language and protocol B was for a packet switching telephony system. In both cases errors were found in the protocol. In the case of A, the protocol was abandoned for other techniques. In the case of B, the designers corrected the protocol. It is significant to note that the second analysis was not done by the author [2].

6. Conclusion

An analyzer for Petri nets was built and used on two protocols. This proved successful in that errors in the protocols were found that might have gone undetected until after the software was released. The analyzer tool fit well with other available tools leading to increased synergy in the tool set.

Another useful aspect of having an analyzer is that it supplies the impetus for people to learn about Petri nets. To an organization involved in the design of software, the benefit is a model of concurrency that is independent of any programming language.

Abstract

The GTPN (Generalized Timed Petri Net) is a performance model based on Petri Nets. The state space for a model of the system is automatically constructed and analyzed using results from Markov chain theory. We address some of the key computational issues involved in the Markov chain theory approach. In particular, we discuss two types of algorithms. The first type compute the *absorption probabilities* and *mean time to absorption.* The second type compute the steady state probability distribution for a single, possibly periodic, recurrent Markov chain class. We also describe the GTPN's user interface for input of the model description, execution of the tool, and the output of the performance results.

Section 1. Introduction

Petri Nets are a formal graphical model of asynchronous parallel computation [PET62, PET81]. Modifying Petri Nets so that time is represented has recently been an active research area [MOL81, NAT80, ZUB80, AJM84, HOL85a]. The goal of these models is to analyze system performance and/or reliability as an extension of the reachability analysis. Our model, Generalized Timed Petri Nets (GTPN) [HOL85a], associates firing frequencies and deterministic firing times with each transition in the net. For the purposes of performance analysis, we view the GTPN as a stochastic process. The time-in-state is a deterministic function for each state of the net. However, a probability distribution is defined over the possible next states based on the firing frequencies. Analysis of the embedded discrete-parameter Markov Chain yields performance estimates. [HOL85b and VER86] contain results for multiprocessor performance issues obtained using the GTPN analyzer.

We have used our GTPN analyzer to solve models with up to 45,000 states. An important issue is the computational efficiency of the performance analysis. An earlier paper [HOL85a] describes efficient methods we developed for building the state space for GTPN models. States in the automatically generated Markov Chain are grouped into *transient* and *recurrent* classes. This paper focuses on numerical methods we use for solving the very large (typically $20,000 \times 20,000$), but very sparse (typically 2-3 non-zero entries per row) matrix equations to get the absorption probabilities and equilibrium state probabilities for the recurrent classes in the Markov Chain. For computing absorption probabilities, we use the key observation that the classes in the Markov Chain form a directed acyclic graph (DAG). For computing equilibrium state probabilities, we use the Power Method, with some shifting and scaling of the probability matrix needed for periodic Markov Chains. A second important issue we address is the user interface of the tool.

The organization of the remainder of this paper is as follows. Section 2 presents an overview of the GTPN and outlines the equations which must be solved. Section 3 considers efficient methods of computing the absorption probabilities and mean times to absorption for the recurrent classes. Section 4 considers methods for computing the steady state probability distribution for each recurrent class. Section 5 describes the current user interface of the GTPN. Section 6 summarizes our experiences.

2. The GTPN Model

2.1. The Net

A GTPN is a Petri net which includes: 1) a deterministic firing duration associated with each transition, 2) a mechanism for specifying next state probabilities for conflicting transitions, and 3) a set of named resources associated with transitions and/or places which are used to calculate performance estimates. We plan to add transition *enabling times* [RAZ83] to support modeling behavior such as timeouts in network protocols. This will require some minor changes in the model definition and how the reachability graph is built.

Letting S denote the set of reachable states, $\Re^+$ denote the positive reals, and $\mathcal{P}$ denote the power set, the current GTPN is formally defined by the following tuple:

$$GTPN = (P, T, A, M_0, D, F, C, R)$$

where

$P = \{p_1, p_2, \ldots, p_n\}$	(places)
$T = \{t_1, t_2, \ldots, t_m\}$	(transitions)
$A: \{P \times T\} \cup \{T \times P\} \rightarrow \{0, 1, 2, ...\}$	(directed arcs)
$M_0: P \rightarrow \{0, 1, \ldots\}$	(initial marking)
$D: T \times S \rightarrow \Re^+ \cup \{0\}$	(firing durations)
$F: T \times S \rightarrow \Re^+ \cup \{0\}$	(firing frequencies)
$C: T \rightarrow \{yes, no\}$	(CntComb flags)
$R: P \cup T \rightarrow \mathcal{P}(\{r_1, r_2, \ldots, r_k\})$	(resources)

The first four components of the tuple are identical to the constructs in an untimed Petri Net (see [PET81]). The remaining four components are described below.

Figure 2.1 shows an example GTPN including the initial state distribution of tokens. Each transition is labeled with, from left to right, its firing duration expression, its frequency expression, its CntComb boolean flag, and its list of resources. There are no resources associated with places in this model.

This research was partially supported by the National Science Foundation under grants DCR-8402680 and DCR-8451405, and by grants from IBM and Cray Research, Inc.

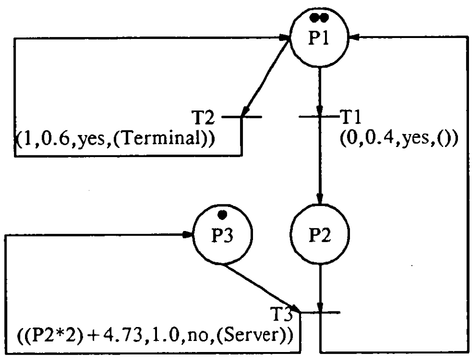

Figure 2.1. Example of a GTPN net

A transition's firing duration and frequency are expressions containing immediate values (real and integer), names of places (which represents the number of tokens in that place in the current state), names of transitions (which represents the value one if at least one firing of that transition is in progress in the current state and is otherwise zero), and arithmetic, relational, and logical operators. Thus, a transition's firing duration and frequency can be state-dependent, but for a given state they are deterministic.

The example in Figure 2.1 models users at terminals who, with a geometric think time, generate requests for a server. There is one token on place P1 for each user. Transitions T1 and T2 implement the think time. Note that the GTPN can represent geometric, as well as constant, holding times. Transition T3 implements a load-dependent server with a firing duration that depends on the number of tokens on P2.

2.2. The Reachability Graph

The *multiplicity* of an input place is the number of arcs from that place to that transition. An output place's multiplicity is defined analogously. An enabled transition ***starts firing*** by removing from each input place a number of tokens equal to its multiplicity. After start firing, the firing is ***in progress*** until ***end firing***. While the firing is in progress, the time to end firing, called the ***remaining firing time*** (RFT), decreases from the transition's firing duration to zero. At end firing a number of tokens equal to its multiplicity is put on each output place.

A marking together with the set of current RFT's defines a *state* of the net. State transitions in the GTPN are defined by maximal sets [1] of start firing or end firing events which occur at the same time. A state which has at least one transition enabled (e.g. the initial state in Figure 3.1), has zero duration, and leads to a set of next states defined by all possible combinations of start-firing events that can occur simultaneously. The new RFT's are set to their transitions' durations. If there are no enabled transitions, but there are some firings in progress, then there is one next state generated by the end firing of all firings in progress with the smallest RFT (*Tmin*). The time-in-state value in this case is *Tmin*. If there are no enabled transitions and no firings in progress, then the net remains in the current state forever.

For each state, a probability distribution is defined over the set of next states. In the nontrivial case, we need to assign a probability to each maximal set of transitions that can start firing together. Calculation of the next state probabilities for start firing events is complex, due to the possibility of conflicting transitions. We only outline our approach and quote the relevant formulas in this paper. The reader is referred to [HOL85a] for a more complete discussion.

Two transitions whose sets of input places intersect are in the same ***conflict set***. The transitive closure of the property of intersecting input places defines an equivalence relation on the set of transitions. This equivalence relation partitions the set of transitions into disjoint sets called ***generalized conflict sets***. A maximal set of start firing events which comprise a state transition is the union of a set of independent ***local maximals***, one from each generalized conflict set. The probability for the maximal is the product of the probabilities for the associated local maximals (since the local maximals are independent). Let *LocalMax[j,i]* denote the *j*th local maximal of the *i*th generalized conflict set. Let *NumComb* denote the ***number of combinations***, or the number of ways tokens can be removed from input places, in order to implement a local maximal. Our formula for *Pr{LocalMax[j,i]}* is

$$Pr\{LocalMax[j,i]\} = \frac{J * \prod_{\{k:k\in LocalMax[j,i]\}} f_k}{\sum_{\{m:m=1,\ldots,M\}} M * \prod_{\{k:k\in LocalMax[m,i]\}} f_k}$$

J is NumComb[LocalMax[j,i]] if *NumComb* is used and zero otherwise. M is NumComb[LocalMax[m,i]] if *NumComb* is used and zero otherwise. In some cases, the value *NumComb* is needed in order to derive an intuitively reasonable probability. The boolean flag CntComb (Count Combinations) associated with each transition specifies whether this should be done. Only if the flag is ***yes*** for all transitions in the maximal, is *NumComb* used.

In Figure 2.2 and Table 2.1 we show the reachability graph for the net in Figure 2.1, assuming there is only one user (i.e. one initial token in P1). The labels on the edges of the graph are the next state probabilities. The labels on the vertices of the graph are the values for time-in-state. The marking vectors

3	0	1	1	{}	{}
4	0	0	0	{(T3,6.73)}	{Server(1)}

[1] a set with property α is a ***maximal*** set with property α if it is not a proper subset of any other set with property α.

are shown in the table. The RFT sets are shown as a list of pairs with one pair per in progress firing of a transition. The first component of each pair is the name of the transition. The second component is the remaining firing time. The resources used and their number of uses are also shown in the table.

Section 2.3. Analysis of the Embedded Markov Chain

Our analysis is based on the key observation that the times at which state changes occur form an embedded, discrete-time, finite state Markov Chain. Consequently, we need to sketch some of the relevant terminology and theorems of Markov Chain theory. We are only concerned currently with analyzing models with finite state spaces. The strongly connected components of the state space (when viewed as a directed graph) are the *classes* of the Markov Chain. The condensed graph (one vertex for each class) is a directed acyclic graph with one root. In the case of a finite state space, the interior vertices of the condensed graph are called *transient* classes. The leaf vertices of the condensed graph are called *recurrent* classes. In a typical evolution of the system being modeled, the system starts in a state in the root of this condensed graph. It then filters through the transient classes until it is absorbed by one of the recurrent classes. Once absorbed it stays in that recurrent class permanently.

Since, in the GTPN, we are interested in long run behavior, there are two characteristics of the movement through the transient classes that are of interest. First, is the *absorption probabilities*, the probabilities of being absorbed by each leaf. Second, is the *mean time to absorption.*

The primary approach to computing the absorption probabilities is based on First Step Analysis [TAY84]. Consider a particular initial state, i. On the first state change, the process will move from state i to a state j that is in a transient class or in a recurrent class. If j is in class R, the future probability of being absorbed by class R is one. If j is in another recurrent class, the future probability of being absorbed by class R is zero. If j is in a transient class, then, by the memoryless property, the probability of being absorbed by class R is the same as if j were the initial state.

More formally, suppose that the states in all the transient classes are numbered $0, ..., n-1$ and consider a fixed recurrent class R and fixed initial state i. Let $U_{iR} = Pr\{\text{Absorption in class } R | X_0 = i\}$ for $0 \leq i \leq n-1$.

$$U_{iR} = \sum_{\{j \in R\}} P_{ij} + \sum_{j=0}^{n-1} P_{ij} U_{jR}, \qquad i = 0, 1, ..., n-1$$

This equation cannot be solved in isolation. However, if we consider all possible transient initial states, then we have a system of linear equations that can be solved for the U_{iR}'s.

Once absorbed in a particular recurrent class, the probability distribution over the states in the long run needs to be computed. This probability distribution exists for any recurrent class R in a finite state space as long as it is interpreted as the long run expected fraction of visits in each state. This stationary probability distribution is easy to find since it is the unique solution to the set of equations

$$\pi_R = \pi_R P_R \qquad \text{and} \qquad \sum_{j \in R} \pi_j = 1$$

The matrix P_R is $P_R = \{P_{ij} | i, j \in R\}$.

Section 2.4. Computing Performance Estimates

The embedded Markov Chain has allowed us to obtain, for each recurrent class, the long run expected fraction of visits in each state. We still need to obtain, for each recurrent class, the performance estimate for each resource. This is done in two steps. First, we obtain, for each recurrent class, the long run expected fraction of time, $RelTime(S_1)$, spent in each state S_1, (i.e. count time-in-state, instead of visits). Let S be the set of states in R. As shown in [HOL85a], $RelTime(S_1)$ can be computed by:

$$RelTime(S_1) = \frac{TimeInState(S_1)\pi_{S_1}}{\sum_{k \in S} TimeInState(k)\pi_k}$$

Second, the performance estimate for a resource in a given recurrent class is the long run expected number of usages of that resource in that class. Consequently, we simply take the expectation of the random variable ResUsages (again S is the set of states in R).

$$E[ResUsages] = \sum_{k \in S} ResUsages(k) Pr\{statek\}$$
$$= \sum_{k \in S} ResUsages(k) RelTime(k)$$

The probability distribution of the random variable ResUsages with respect to the number of usages of the resource is also computed. Computing this distribution is straightforward. We know the long run probability distribution of time over the states in the recurrent class. We also know the number of usages of the resource in question for each state. Simply summing the probabilities of the states that use the resource the same number of times generates the desired distribution. This distribution is very useful for reliability prediction (e.g. 90% of the time will at least 3 processors be working?).

Section 3. Absorption Probabilities and Mean Time to Absorption

As discussed in section 2.3, two of the characteristics of the system's performance that we need to determine are the absorption probabilities and mean time to absorption. First Step Analysis was proposed as the method for computing these characteristics. In this section we discuss the computational issues involved in determining those characteristics. Section 3.1 discusses some of the efficiency issues involved in implementing First Step Analysis for computing the absorption probabilities. Section 3.2 describes an optimization which can significantly accelerate solution of the First Step Analysis equations. Section 3.3 covers the analogous material for computing the mean time to absorption. In an important special case that arises frequently in GTPN models, an alternative to First Step Analysis can be used to compute absorption probabilities. Section 3.4 describes this still more efficient method.

Section 3.1. First Step Analysis

Direct application of First Step Analysis implies that r systems of n linear equations are solved where r is the number of recurrent classes, and n is the number of transient states in the Markov Chain. Solving one system of equations determines the absorption probability of interest for one recurrent class. Since the GTPN is intended to be a practical tool, an efficient solution method is important.

We write the systems of linear equations in matrix form as follows:

$$U_R = P_{TR} + P_T U_R, \tag{3.1}$$

where U_R is the $n \times 1$ vector of absorption probabilities for recurrent class R from transient states $0, 1, ..., n-1$, P_{TR} is the $n \times 1$ vector of one-step transition probabilities from transient state i to any state in R, and P_T is the $n \times n$ one-step transition probability matrix for the transient states.

The standard form for a system of linear equations is $Ax = b$ where A is $n \times n$, x is $n \times 1$, and b is $n \times 1$. Our form maps into the standard form by letting $A = (P_T - I)$, $x = U_R$, and $b = -P_{TR}$:

$$(P_T - I)U_R = -P_{TR}. \tag{3.2}$$

There are many methods of solving systems of linear equations. Gaussian elimination is the primary direct method. Iterative methods, such as the Gauss-Seidel method, are much more efficient for large matrices. Before selecting a solution method, however, we will discuss an important optimization that can be applied to First Step Analysis.

Section 3.2 Optimization of First Step Analysis

An optimization exists that can significantly accelerate solution of the linear systems of equations for First Step Analysis. This optimization is based on a key observation: by permuting the rows and columns of the matrix P_T, P_T can be put into block upper triangular form, where each diagonal block represents the transitions within one transient class of the Markov Chain. To see this, recall that the Markov Chain classes are the strongly connected components in the reachability graph. They thus form a directed acyclic graph (DAG), the condensed graph. As with any DAG, the vertices of the condensed graph can be numbered via a topological sort so that the number assigned to a vertex is always less than the numbers assigned to its children. This numbering defines the permutation that generates the block upper triangular form. We find the strongly connected components using Tarjan's O(n) algorithm, and perform the topological sort on the DAG using another linear-time depth-first search [SED83].

After the permutation, equation 3.2 is of the following form:

$$\begin{pmatrix} A_{11} & A_{21} & \cdots & A_{1N} \\ & A_{22} & & A_{2N} \\ & & \ddots & \vdots \\ & & & A_{NN} \end{pmatrix} \begin{pmatrix} U_1 \\ U_2 \\ \vdots \\ U_n \end{pmatrix} = \begin{pmatrix} -P_{1R} \\ -P_{2R} \\ \vdots \\ -P_{nR} \end{pmatrix} \tag{3.3}$$

where the elements are matrices, each diagonal block A_{ii} is square of order n_i and

$$\sum_{i=1}^{N} n_i = n.$$

The system (3.3) can be solved as a sequence of N smaller problems. Problem i is of order n_i and the matrix of coefficients is $A_{ii}, i = 1, 2, ..., N$. The procedure is as follows [PIS84]:

(i) Solve the last subsystem, with A_{NN} as the matrix of coefficients, for the last n_N unknowns. Compute the vector x_N of order n_N.

(ii) Subtract the products $A_{jN}x_N$ from the right-hand side for $j = 1, ..., N-1$. A block upper triangular matrix of order $N-1$ is obtained, and the procedure is repeated until the complete solution is obtained.

Note that the assumption must be made that the diagonal blocks in Equation (3.2) are nonsingular. The solution of each subsystem can be done by any method for solving linear equations, such as Gaussian elimination or the Gauss-Seidel iteration.

Section 3.3. Computing Mean Time to Absorption

The mean time to absorption can also be computed using a first-step analysis. One system of n linear equations is solved where n is the number of transient states. Each transient state i has one equation. Starting in state i, the mean time to absorption is the time-in-state for state i plus zero if the next state is in a recurrent class and plus P_{ij} times the mean time to absorption for state j if state j is transient. Note that the Markov property is again being used. Formally, each equation is of the form:

$$U_i = TimeInState(i) + \sum_{j=0}^{n-1} P_{ij}U_j, \qquad i = 0, 1, ..., n-1$$

If the integer 1 replaces the time-in-state, then the mean number of visits to transient states before absorption can be computed. The mean number of visits to a given set of transient states before absorption can be computed if the time-in-state is replaced by the integer 1 when visiting a state in the given set and is replaced by the integer 0, otherwise.

The discussion in Section 3.2 applies here also. In particular, the system of equations can be changed into the form $Ax = b$, permuted into block upper triangular form, and then solved as outlined.

Section 3.4. More Efficient Solution of an Important Special Case

In a special case that occurs frequently in GTPN models, an efficient alternative approach based on the condensed reachability graph (i.e. one vertex per strongly connected component) can be used to compute absorption probabilities. In this alternative, probabilities are assigned to the edges leaving each vertex in the condensed graph A depth first search is then done. During the depth first search the probability along each path to each leaf is determined by taking the product of the edge probabilities along the path. The absorption probability for a given leaf is then simply the sum of the path probabilities terminating at that leaf.

The difficulty with this approach is with determining the edge probabilities leaving a vertex in the condensed graph. If all the exit edges originate at the same vertex V_1 within the strongly connected component, then the probabilities are easily computed. Find all the edges of which V_1 is the parent that are exit edges. Sum their probabilities as edges in the original graph. The probability of each edge in the condensed graph is its probability in the original graph normalized by this sum.

The problem is when more than one vertex, say V_1 and V_2, in the original graph are parents of exit edges. Determining the probability that each of these parent vertices is the vertex from which exiting occurs is dependent on the detailed structure of the strongly connected component. Our current implementation uses the condensed graph approach when the special case of one parent vertex in the strongly connected component is met. When the special case is not met, first-step analysis with Gauss-Seidel iteration is used. We plan to implement the optimization described in section 3.2 with subsystem solution by Gauss-Seidel iteration.

Section 4. Stationary Probability Distributions

In this section we discuss the method we use to calculate the stationary probability distribution for each recurrent class in the Markov Chain. Let R denote a recurrent class with states $j = 0, 1, ..., n$, and let π_j represent the long run expected fraction of visits to state j, given that the modeled system is absorbed in class R.

Recall that the vector $\pi_R = (\pi_0, \pi_1, ..., \pi_n)$ is uniquely determined by the following equations:

$$\pi_R = \pi_R P_R \qquad \text{and} \qquad \sum_{j=1}^{n} \pi_j = 1, \tag{4.1}$$

where P_R is the $n \times n$ state transition probability matrix for R.

Because the matrix P_R is sparse, but potentially very large, iterative methods are more practical than direct methods. One of the most widely used iterative methods, the Power Method [JOH82], views equation 4.1 as an eigenvalue problem. In particular, π_R is the eigenvector associated with the unit eigenvalue of P_R. Applying the Power Method to iteratively solve for π_R, is done as follows:

$$\pi_R^{k+1} = \pi_R^k P_R.$$

Since our current implementation uses the Power Method, the remainder of this section focuses on issues related to it and, in particular, with ensuring convergence.

Section 4.1. Spectral Distribution

An eigenvalue, λ, of a real $n \times n$ matrix A, is *strictly dominant*, if its modulus is strictly greater than those of all the other eigenvalues of A. Direct application of the Power Method converges to an eigenvector corresponding to the dominant eigenvalue, if and only if the matrix has a simple, strictly dominant eigenvalue.

This constraint on the direct application of the Power Method can be expressed in terms of the periodicity of the recurrent class in the Markov Chain. In order to make that connection between the spectral distribution and the periodicity of the Markov Chain class, we need the theorems of Perron and Frobenius [CIN75,SEN84]. These theorems state the following:

> An irreducible non-negative matrix, A, has a real, positive, and simple eigenvalue, α, which is *greater than or equal to* all other eigenvalues of A in modulus. The eigenvector corresponding to the eigenvalue α is strictly positive. If A is *aperiodic*, (i.e. $A^k > 0$ for some k), then α is *strictly greater than* all other eigenvalues of A. A periodic matrix with period δ, has exactly δ eigenvalues with absolute values equal to α. These eigenvalues are all distinct and are given by:
>
> $$\lambda_k = \alpha[e^{2\pi i/\delta}]^{k-1}, k = 1, 2, ..., \delta, i = \sqrt{-1}$$

If A is a stochastic matrix (i.e. all rows sum to one), then $\alpha = 1$. An aperiodic stochastic matrix thus has a simple unit eigenvalue and all other eigenvalues are of strictly smaller modulus. A periodic stochastic matrix with period δ has exactly δ eigenvalues of unit modulus all of which are simple. These eigenvalues can be regarded as a set of points around the unit circle in the complex plane, which goes over into itself under a rotation of the plane by the angle $2\pi/\delta$.

Section 4.2. Ensuring Convergence

According to the above discussion, the Power Method can only be applied directly to find the stationary probability distribution when the recurrent class is aperiodic. To handle the case of a periodic recurrent class, the following theorem [STE74] concerning shifting and scaling the matrix becomes important:

Theorem: Let A be a complex $n \times n$ matrix, and let λ be an eigenvalue of A with eigenvector x. Then:

1. $a\lambda$ is an eigenvalue of aA with eigenvector x.
2. $\lambda - b$ is an eigenvalue of $A - bI$ with eigenvector x.

This theorem allows us to transform the matrix P_R to ensure that the unit eigenvalue is strictly greater than all other eigenvalues in modulus. In particular, we make the following transformations on P_R:

$$P_R' = \epsilon(P_R - I) + I = \epsilon P_R + (1 - \epsilon)I \qquad 0 < \epsilon < 1.$$

The first transformation, subtracting I, shifts all eigenvalues of P_R to the left by one in the complex plane. The eigenvector π_R now corresponds to the eigenvalue zero. The second transformation, multiplication by ϵ, shrinks all of the eigenvalues except the zero eigenvalue corresponding to π_R (the circle is now centered at $-\epsilon$ and is of ϵ radius). The third transformation, adding I, shifts all eigenvalues to the right by one, creating a unit eigenvalue corresponding to π_R whose modulus is strictly greater than that of all other eigenvalues. Thus, application of the Power Method using P_R' always converges.

Section 4.3. Convergence Rate

The convergence rate of this method is essentially the rate at which $\lambda_2'^k$ converges to zero, where λ_2' is the second largest eigenvalue of the matrix P_R' [JOH82]. The value of ϵ indirectly influences the rate of convergence by scaling all of the eigenvalues. Wallace and Rosenberg [WAL66] define a suitable value for ϵ to be $0.99 \times [max(|P_{ii} - 1|)]^{-1}$. We have used this value, which equals 0.99 for most GTPN models, in our implementation.

In general, the value of λ_2' depends on the size and structure of the particular GTPN model constructed, and convergence rates vary considerably. In particular, the convergence rate may be extremely slow. A recent paper by Stewart and Goyal [STE85], suggests that successive overrelaxation is a better method for solving steady-state equations for continuous time Markov chains. We plan to investigate whether this approach would also be more efficient for the GTPN.

Section 5. The GTPN Analyzer User Interface

This section describes the current user interface to the GTPN tool. This interface has three parts: the format of the model description input to the tool, the process of running the tool, and the format of the output of the performance results. We should note that the nature of this interface is largely independent of the rest of the tool.

Section 5.1. The Input Format

The model description is input in textual form. This text is processed by table-driven lexical and syntactic analyzers. In particular, we use two tools, Scangen and LLgen, that have been developed by others at the University of Wisconsin—Madison. Scangen accepts descriptions of tokens written as regular expressions and generates tables to drive a lexical analyzer. LLgen accepts a context-free grammar specification and generates tables for parsing sentences of the specified language. It generates tables for any LL(1) grammar. During execution of the GTPN tool, the tables generated by Scangen and LLgen are used in conjunction with the parser and semantic routines to construct the internal tables describing the net and its initial state.

```
NET
     P1(1) -- > P2(1): 0, 0.4, yes, ;
     P1(1) -- > P1(1): 1, 0.6, yes, Trans2;
     P2(1), P3(1) -- > P1(1), P3(1):
               (P2*2)+4.73, 1.0, no, Trans3;
RESOURCES
     Terminal: Trans2;
     Server: Trans3;
INITSTATE
     P1(2), P3(1)
END
```

Figure 5.1. Input Format for Example

The input format is quite simple. As an example, in Figure 5.1 is the actual input for the net which is shown graphically in Figure 2.1. There are four reserved words: NET, RESOURCES, INITSTATE, and END. These four words, in that order, divide the input into three sections.

The NET section is a sequence of entries, one for each transition. A transition's entry first lists the transition's input places, the token -- >, and the transition's output places. Each input place has a number in parenthesis which is the number of tokens removed by a single firing. Each output place has a number in parenthesis which is the number of tokens added by a single firing. After the colon, the transition has four remaining fields: its duration expression, its frequency expression, the CntComb flag, and an optional name. A transition needs a name if it is to be referenced in a duration or frequency expression or in the RESOURCES section.

The RESOURCES section has one entry for each resource (performance measure). A resource's entry names the resource and then lists a sequence of names of places and transitions. In a given state the number of usages of a resource are determined by these place and transition names. A place has as many resource usages as there are tokens on it. A transition has as many resource usages as there are firings in progress. A more general specification of performance measures would allow expressions containing arithmetic, logical and relational operators as well as place and transition names. We have not yet implemented this capability, but it appears straightforward.

The INITSTATE section lists the places which contain at least one token in the initial state. Each such place has the number of its initial tokens in parenthesis.

There will be some minor changes to this format when we introduce enabling times.

Section 5.2. Running the GTPN

The GTPN tool is a single executable file. It is invoked by the command line:

```
gtpna -[a-z] file
```

The net description comes from *file*. The results go to standard output. Various optional flags display aspects of the internal state of the tool and are useful for debugging.

Section 5.3. Output Format

The output is also textual. First, general information is listed. This includes the number of places, transitions, resources, and states. Second, for each leaf, the performance results for each resource are given as well as the number of iterations needed for the Power Method to converge. Third, the absorption probability for each leaf is listed. Fourth, for each leaf and for each resource, the probability distribution over the number of resource usages is given.

6. Conclusions

A careful study of implementation issues is essential to the successful development of a modeling tool. We have discussed some of the most important implementation issues in the Generalized Timed Petri Net modeling approach. The first general issue concerns using results from numerical linear algebra to aid in efficient analysis of the state space.

The two important transient characteristics of the state space are the absorption probabilities and mean time to absorption. We proposed using First Step Analysis to compute these characteristics. In this method several systems of linear equations are solved. Each system could be solved immediately by Gauss-Seidel. Alternatively, we suggested a more efficient solution based on permuting the matrix into block upper triangular form and then solving a sequence of smaller problems. In an important special case a still more efficient method based on the graph of strongly connected components can be used.

The important steady state characteristic is the steady state probability distribution within each recurrent class. This distribution is determined by another system of linear equations. We currently solve this system of equations by treating it as an eigenvalue problem and using the Power Method. A direct application of the Power Method, unfortunately, does not converge if the recurrent class is periodic. We discuss how scaling and shifting of the transition probability matrix can ensure convergence without changing the desired eigenvector. We briefly discuss the convergence rate. We plan to investigate whether other methods may be superior to the Power Method.

The second issue is the user interface to the GTPN tool. The most interesting aspect of this interface is the use of a table-driven scanner and a table-driven parser has greatly aided in the processing of the textual form of the input description.

Acknowledgements

Many people have made helpful comments and suggestions during our research. We would like to especially thank Klaus Hollig and Diane O'Leary.

SECURITY AND PRIVACY REQUIREMENTS IN COMPUTING

Rein Turn

California State University, Northridge
Northridge, CA 91330

ABSTRACT

Advances in computer technology are profoundly affecting and changing the functioning of societies worldwide, and are generating a variety of nontechnical concerns about computer applications. Among these are information security, privacy protection, and societal resiliency. This paper briefly describes the security and privacy requirements in system design and use, and surveys the current efforts for meeting these requirements. The paper points out that it is important to consider security and privacy issues in all phases of a system's life cycle, as well as to familiarize computer professionals with the societal impacts of computer uses.

I. INTRODUCTION

Recent advances in computer technology are making available, at acceptable cost, computer systems with virtually unlimited processing power, storage capacity, and capability for data communication. The very large scale integration (VLSI) technology permits placing on single chips tens of thousands of logic circuits or millions of bits of memory, and to mass-produce these for near-negligible cost[1]. It is economical, therefore, to maximize the use of computer technology in any system. Such use produces old products and services in new, digital form, and engenders new services or products. Examples include the digital telephone, expert systems[2], various electronic funds transfer systems (EFTS), smart cards[3], embedded microprocessors for controlling other systems, and computer vision[4].

The new computer technology and its applications are profoundly affecting and changing the functioning of societies worldwide. Dependence on computers is increasing, and they are becoming critical components in systems that will dirctly affect our future as well as the daily life. This means that the traditional computer system design requirements, such as high performance and reliability, software portability, system interoperability, and easy maintainability must be strengthened and augmented by new requirements such as system safety, system and data security, privacy protection for personal information, and preservation of societal resiliency. The purpose of this paper is to provide an overview of these requirements, and to discuss the design issues they raise.

II. SECURITY AND SAFETY REQUIREMENTS

A general concern of the users of any system, or of people directly affected by the operation of a system, is its trustworthiness: Is it available when needed? Will it function correctly and reliably? Is it safe to use? Is it protected against misuse or tampering? For a simple system such as a chain saw, it may be possible to answer these questions by inspection at the time of use. For complex systems, such as an air traffic control system, the designers and operators must be trusted to have implemented the appropriate safeguards and requirements.

The safety of computer-controlled real-time systems is receiving increased attention[5]. The principal goal is to prevent physical harm to the users of the system, to anyone or any property within the system's domain of operation, or to the system itself and its operators. Concerns here go beyond the reliability of the controlling computer system alone -- while the latter is recovering, the controlled system must not be unsafe. Thus, system safety encompasses the total system, including its human operators and users, and even other systems that may be encountered. Safety preservation techniques must be developed and integrated into all phases of the system's life cycle, especially the life cycles of the system's software, data bases, and interfaces with users or other systems.

Security requirements.

Computer security is usually defined as the: "protection of the system and the data stored therein against unauthorized access, modification, destruction or use, and against actions or situations that deny authorized access or use of the system." While accidental events that threaten security are included, the emphasis is on deliberate attempts to weaken security. The need for computer system security should be self-evident in view of the large body of evidence that attacks against computer systems or the information therein have occurred[6,7].

In general, the following are the principal reasons for providing access control and security in computer systems and applications[8]:

Protection of resources: The computer sytem, and more importantly, the data stored and processed therein, tend to be critically valuable

CH2345-7/86/0000/1106$01.00 © 1986 IEEE

to an organization's functioning. Some data in the system (e.g., financial accounts) directly represent tangible value and must be protected against unauthorized alterations.

Mandated by law: Several countries have enacted laws that require protection of certain categories of information, such as national defense information or personal information; other laws may require that the integrity of financial data be ensured.

Maintain management control: A goal for any organization is to be in full control of the computer resources and their use.

Ensure safety and integrity: Security is an essential prerequisite for the system safety and for the integrity of the data bases and processes being used (e.g., in computer-aided design or in computer-based modeling).

Operational advantages or economies: A secure computer system is important in organizations whose business depends on their customers' trust (e.g., financial institutions). It can increase the organization's advantage over competitors with less secure systems. It can also reduce operating costs such as insurance premiums.

Despite of the convincing rationale, many systems employ only a minimal set of security safeguards. One reason for this is that the operating system software provided by vendors is still not capable of preventing unauthorized access -- security has not been a design objective. While operating systems generally perform their intended functions correctly, experience has shown that they contain design or implementation flaws and shortcuts that permit any existing access control mechanisms to be bypassed and, thus, cannot prevent unauthorized access and use[9].

The theory of designing truly secure operating systems appears now to be well in hand and meaningful design criteria exist[10], but applying these in practice is a different matter. Secure operating systems will require radical changes in the currently used hardware and software architectures, and it will be very difficult to maintain compatibility with the existing systems and software. Vendors and their customers are reluctant to develop new systems which, even if they provide much better security, require expensive conversions of the existing software and data bases. Many users would accept the uncertainty of suffering large losses in the future due to lack of security rather than making even relatively modest expenditures for security now.

Managers who do want to improve security find a sparse market place: a few access control software packages for managing passwords[11], some devices for controlling dial-up access to thwart hackers, and various anchoring devices for personal computers. With a few exceptions (e.g., Honeywell's MULTICS and SCOMP[12]), there are no secure operating systems available.

Security Risks.

Not all systems require a high level of security, and different approaches can be taken to achieving a desired degree of secureness. The determination of security requirements for a given system, and the selection of appropriate security mechanisms are a part of the risk management activity. The basic steps are[13]: value and criticality analysis, vulnerability analysis, threat identification, risk analysis, risk assessment, security safeguards selection and implementation, development of contingency plans, and effectiveness reviews. Again, these steps may be difficult to apply in practice. For example, it is difficult to place value on information, discover all vulnerabilities, or develop threat scenarios for exploiting these vulnerabilities.

Security risk analysis requires establishing for each threat its probability of occurrence over a specified time period (e.g. a year) and the amount of loss that would be incurred. These quantities can be multiplied to obtain the annual loss expectancy (ALE), as described in[14]. However, since very little actuarial information is available about threats to computer systems, computations of the ALE's is usually based on the analyst's subjective judgement. A thorough review of risk analysis techniques is found in[16].

The operational environment is also taken into account. Thus, in general, security risks are higher in systems where: (1) the "distance" is large between the highest information sensitivity or processing criticality level in the system, and the lowest trustworthiness level of the users; (2) user capabilities in the system include assembly language programming rather than being restricted to higher-level language (HOL) programming only (systems where users are limited to predefined transactions are even less risky); (3) system architecture is complex, such as in the case of multiprocessors or in distributed data processing systems (the risk is even higher in computer networks); and (4) there is considerable uncertainty over the trustworthiness of the system software developers (the situation worsens when hardware developers' trustworthiness is also in doubt).

The result of risk analysis is a list of threats ordered by some severeness measure (such as ALE). In the risk assessment step, decisions are made about each threat: either to accept the risk due to that threat or to reduce the risk by selecting and implementing a set of additional security mechanisms. However, in practice the granularity of strengthening security is much more coarse and, correspondingly, security cost increases are also in much larger increments that might be expected. In addition, tradeoffs may need to be made with system design objectives or requirements other than cost, such as functionality, performance, resource sharing, reliability, and user-friendliness.

Security Policies.

The conceptual elements of a security system are: (1) a security policy which establishes the security framework for the system; (2) prevention mechanisms which provide isolation, identification and authentication, and access control; (3) active protection mechanisms which perform monitoring and response functions; (4) integrity assurance procedures for the security mechanisms; (5) backup and recovery mechanisms; and (6) deterrence provisions (e.g., the existing computer crime laws).

In general, a security policy of an organization or a system defines the data protection requirements, establishes the information sensitivity levels and access categories, defines access criteria and protection requirements, and establishes authorization and accountability systems. A formal model of the access control rules defined by the policy is developed to permit formal proofs of the correctness of the design, implementation, and enforcement of the policy in the computer system software[16]. This model is called the "reference monitor", and it is implemented in the operating system as the "security kernel"[17].

The security policy model of the U.S. Department of Defense (DoD) for protecting national defense information can be used as an illustration[18]. The objective is to permit multilevel secure (MLS) operation where the system permits concurrent storage and processing of information with different degrees of sensitivity (security levels and categories), and permits concurrent access by users with different authorizations (security clearances and categories), but prevents any unauthorized accesses. In this security mode, full resource sharing is possible and the system can be used efficiently. The cost is in developing a secure and trusted operating system. The DoD multilevel security model may be stated as follows.

The system contains protected entities, called "objects",0, and active entities that seek access to the objects, called "subjects", S. Each object is assigned a "security level", SL(0), and membership in a set of access control categories, CAT(0). Each subject has been granted a "clearance level", CL(S), and access to a set of categories CAT(S). The security and clearance levels form a hierarchical system. Top secret, secret, confidential, and unclassified (TS, S, C, and U, respectively) are used in the DoD. The access categories are unordered and may exist at any security level. Two main access modes of subjects to objects are defined: read (observation but no modification), and write (no observation, appending of new information only).

The policy has a mandatory (nondiscretionary) part, and a discretionary part. The latter is a need-to-know access control policy enforcement which applies after the mandatory policy requirements have been satisfied. A model of discretionary access control is based on the access control matrix and on access rules which may be implemented by using "capabilities" or "access control lists". The mandatory (nondiscretionary) security policy rules for granting access are: (1) the simple security condition -- a subject is granted "read" access to an object if and only if $CL(S) \geq SL(0)$ and $CAT(S) \supseteq CAT(0)$; and (2) the "star-property" (*-property) -- a subject is granted "write" access (without being able to read) if and only if $CL(S) \leq SL(0)$ and $CAT(S) \subseteq CAT(0)$. The purpose of the *-property is to prevent copying of information from objects at a higher SL into objects at a lower SL by untrusted software or users.

The mandatory access rules must be invoked by the reference monitor mechanism in the system each and every time access is sought to an object. In order to compare the security and clearance levels, every object and subject in the system must be labelled. Labels must be unforgeable and the labelling and label transfer mechanisms must be proven correct -- they must be trusted. An additional security requirement not explicit in the above model is "confinement" -- prevention of information leakage to unauthorized subjects via unconventional, "covert" information flow channels.

Security policies in the private sector are less precisely defined and tend to emphasize data integrity and denial of services rather than data disclosure. However, the DoD security policy and systems that implement it may also be suitable for use in commercial applications[8,19].

A recent development which may strongly influence security policies and practice in the private sector is the National Security Decision Directive 145 issued in 1984 by the President. This directive appoints the National Security Agency to be the lead agency for computer security on a national scale, and broadens the mission of the National Computer Security Center to provide security training and education, risk analysis assistance, and access to trusted system technology also to the private sector. It also defines two new sensitivity categories: "sensitive but unclassified government or government-derived information, and "sensitive non-government information."

Security Evaluation Criteria.

In 1983, the U.S. DoD Computer Security Center published the trusted computer system evaluation criteria[10] which have become a de facto framework for evaluating system security, especially the operating system software security. The criteria emphasize policy enforcement, users' accountability, correctness assurance, and system documentation. Based on these, the following system of security divisions is defined:

Division D, -- minimal protection: Systems in this class have been evaluated, but fail to meet any security requirements.

Division C, -- discretionary protection: Systems in this division provide discretionary protection and accountability of the subjects for their actions.

Division B, -- mandatory protection: In this division, all systems contain a Trusted Computer Base (TCB) that preserves the integrity of security labels and uses them to enforce the mandatory access control policy. The implementation of the reference monitor concept must be demonstrated.

Division A, -- verified design: Systems in this division have been subjected to formal verification to assure that the mandatory and discretionary security controls in the system can effectively protect sensitive information.

The concept of a "trusted computing base" is defined in the criteria document as follows: "TCB is the totality of protection mechanisms within a computer system -- including hardware, firmware, and software -- the combination of which is responsible for enforcing a security policy. It creates a basic protection environment and provides additional user services required for a trusted computer system. The ability of a TCB to correctly enforce the security policy depends solely on the mechanisms within the TCB and on the correct input by the system administrative personnel of parameters (e.g., a user's clearance level) related to the security policy."

Security Mechanisms.

Security policies can be implemented in several ways, using combinations of physical isolation, logical isolation in operating system design and in hardware architecture, or administrative procedures. This yields a hierarchy of systems that provide different levels of security at different levels of confidence as specified, for example, in the DoD trusted systems evaluation criteria. The standard modes of secure operation are: dedicated system, system-high security mode (all users are cleared to the highest security level of data or processing in the system), and multilevel secure (MLS) mode. In an MLS system, the operating system software is proven to be correctly designed and implemented to handle security and clearance level labels correctly and reliably, and to perform the reference monitor function correctly and reliably, such that no unauthorized accesses, overt or covert, can occur. The state of the art of operating system security, especially verification of design and implementation correctness, has not yet progressed to the point where general purpose MLS operating systems are available[20].

Security mechanisms are hardware or software features which implement the trusted computing base by providing isolation, identification and authentication, and access controls. In conventional operating systems they provide password validation, memory protection, memory management, and user/supervisor domains separation. In the future trusted operating systems they will implement the reference monitor model and features necessary for enforcing the system's security policy[21]: unforgable security labels, TCB protection (isolation of the TCB from subjects by use of privileged operating modes of the and virtualizing the system's resources), confinement of covert channels, and maintenance of security audit trails.

While the above are not all the architectural features necessary for the implementation secure operating systems, as per DoD security evaluation criteria, they do form an important set of design requirements that must be incorporated. In more complex architectures such as distributed systems, there are additional concerns regarding the security of interprocessor communications (typically using a local area network or LAN). Applicable security mechanisms include encryption[22], and architectural approaches for achieving MLS operation based on the use of a secure LAN and processors dedicated to specific security levels[23]. Security measures for computer networks are also based on the use of encryption[24] and secure protofor the various communications functions[25].

Finally, one must not overlook the interactions of security requirements and mechanisms with the other system design requirements. Of special interest is fault-tolerance[26], where certain software-based techniques for "corrective" redundancy may be incompatible with security requirements. In using corrective redundancy, errors in computation due to a hardware fault are corrected by repeating the computation. However, it may not be possible to correct a security violation in this manner.

III. PRIVACY PROTECTION

Privacy is a concept with many meanings. In this paper it is defined as the rights of individuals regarding the collection, storage, processing and use in decision making of personal information about themselves. It becomes an issue in computer applications in the context of computerized personal information record-keeping systems. While privacy was also a problem in manual systems, modern computer-communication technology makes it economical to store and process large volumes of data, permits complex correlations at high speed, allows high-speed access from distant locations and, thus, makes technically feasible for physically decentralized systems to become centralized "logically".

Centralization, whether physical or logical, lays the groundwork for integration of data records and assembly of personal information dossiers on individuals. This is viewed by the public as a threat to their liberties. There are other problems, too. Since information in stored and processsed in computers is not directly readable by humans, they cannot determine without the services of the record keeper what information about them is stored. Further, in the computer system, undetected hardware and software errors can cause information distortions, and information can be altered without detection by accident or deliberately.

Privacy Protection Principles.

Privacy protection is a societal policy and value which must be balanced with other policies and values and, in system design, with other requirements. It is clear that record-keeping on individuals is necessary when privileges are granted (such as the driver's license) or qualification for some benefits is determined. In these cases, the individual voluntariliy foregoes some of his privacy in order to receive the privilege or benefit. This is in the best interest of the society. On the other hand, the society must also protect the individual against excesses of the record keepers and against unfair decisions.

Since the government at its various levels from national to local is a major record-keeping entity, much of the concern about privacy protection centers on its activities. However, in the private sector, too, are large collections of personal information on education, health, employment, financial status, purchases, and life style[27,28]. On the international scale, operations of multinational corporations and international data processing service bureaus has resulted in transborder data flows (TDF) of personal information[29,30].

The principal mechanisms for ensuring privacy protection to individual data subjects are legislative and administrative, rather than technical. Often this distinction is misunderstood -- threats to individual privacy arise mainly from authorized users of the system, rather than from unauthorized users. Thus, privacy protection legislation is needed to keep the authorized users from making unauthorized use of personal information.

National level privacy protection legislation (or data protection, as it is commonly called in Europe) is now in force in a dozen countries: Austria, Canada, Denmark, Federal Republic of Germany, France, Israel, Luxenbourg, New Zealand, Norway, Sweden, United Kingdom, and the United States. Legislation is pending in several other countries (e.g., Australia, Belgium, Finland, Italy, Japan, the Netherlands, Portugal, Spain and Switzerland). Although the implementation approaches and protection scope tend to vary from country to country reflecting different cultural environments and legal traditions, the privacy rights granted are remarkably similar.

The principles for privacy protection have evolved over the last decade, beginning with several national studies, advancing with the early national privacy or data protection legislation (as in West German province Hessen and in Sweden), and arriving to the current form in the OECD Guidelines[31]. The Code of Fair Information Practices formulated by a U.S. Government advisory committee on privacy[32] was the initial foundation for these principles: (1) openness (no secret record-keeping systems, uses, or practices); (2) individual access (the right of individuals to know what data are kept about them, and how they are used); (3) individual participation (the right to correct or amend erroneous records); (4) collection limitation (restrictions on data types that may be collected, and on the collection methods); (5) use limitation (restrictions on the use of data for unannounced purposes); (6) disclosure limitation (restrictions on any external circulation of personal data); (7) information management (requirements to maintain data quality and confidentiaity); and (8) accountability (clearly fixed responsibility for compliance with privacy protection requirements).

Privacy protection efforts in the United States have developed along three lines: the federal government, state and local governments, and the private sector. Federal-level privacy laws, especially the Privacy Act of 1974, apply to the federal government agencies, but with law enforcement and intelligence communities exempted. They also apply to the private sector in financial credit reporting, to educational institutions that receive federal support, and to government access to individuals' banking transaction records. The states have enacted numerous privacy protection laws that cover government agencies and also some private sector business, addressing one or more of the following: employment records, financial credit reporting, insurance and medical records, law enforcement and criminal justice records, EFTS and cable television, and the use of polygraphs.

The future trend in the U.S. is for more extensive protection, even though it is not likely that any new federal-level privacy protection law will be enacted soon; states are likely to be more active. Thus, the private sector record-keeping systems are likely to remain unregulated on the federal level for some time, despite the Privacy Protection Study Commission's recommendations[33], and the general perception of the U.S. public that the threat to privacy is increasing. There is one exeption, however. The Electronic Communication Privacy Act of 1985 is likely to be enacted in 1986. This law would protect messages in electronic mail systems, and would limit the use of various electronic surveillance devices (e.g., as discussed in[34]).

The Impact of New Technologies.

The public concern over threats to privacy is further supported by the emergence of so-called "new technologies" based on the use of computers: computer networks, electronic mail, office automation, electronic funds transfer systems (EFTS), smart cards, interactive home services, and embedded microprocessors as controllers in other systems. Collectively, these applications tend to have a set of common attributes or modes of operations which may increase their potential for adverse impacts on privacy protection, since they potentially support: (1) automated services that generate large volumes of transactions involving individuals, and keep records on them; (2) automated techniques and systems for collecting and transmitting computer readable personal information; (3) direct or indirect integration of systems which handle personal information; (4) applications and services that allow inferring personal information; (5) automated decision-making based on personal information about individuals; (6) physical or information surveillance of individuals; and (7) overt or covert commercial markets for personal information.

The above features of the new computer technology applications set the stage for potential privacy protection problems. For example, computers are being connected into networks, and networks into super-networks, at a rapid rate. The benefits of this for data communication are obvious, even though the resulting systems contain multitudes of complex, hard-to-trace communication paths which contribute to problems in providing security, access control, and message integrity and authenticity.

From the privacy protection point of view, computer networks where personal information data bases are on-line can support de facto integration of record-keeping systems and, thus, the capability for "virtual dossiers" and extralegal exchanges of personal information. Networking will also enhance matching of personal information files in different systems for investigative purposes[35,36], increase the difficulty in monitoring compliance with privacy protection requirements, and render misuse of personal data bases more difficult to detect. Similar privacy protection problems arise in other applications of the new technology.

Privacy Protection and TDF.

Privacy protection is also an important transborder data flow (TDF) issue. Some countries with data protection laws are concerned that less privacy protection will be given to personal infomation about their citizens when transmitted abroad, especially to countries with less comprehensive data protection laws than their own. However, some countries that provide international data processing services or operate private networks tend to view these concerns as of little merit and, instead, promote the principle of "free flow of information". These countries, mainly the United States, are also aginst the concept of providing privacy protection to information about legal persons, such as corporations.

Standardization of privacy protection requirements, such as acceptance and implementation of the OECD privacy protection guidelines, is one approach to resolving these differences. The Council of Europe convention of privacy protection[37] is another effort in this durection among the European countries.

Technical Implications of Privacy Protection.

A technical consequence of the privacy protection requirements in the design and operation of computerized record-keeping systems is the incorporation of new functions not normally needed. These include: (1) preparing notifications of the system's functions and procedures in using personal procedures for inspections, challenges, reviews, information; (2) providing facilities and and submission of corrections or rebuttals by individuals; (3) accounting for, and auditing of the collection, use, and disclosure of personal information, and interactions with the data subjects; (4) maintaining data quality, confidentiality and security; and (5) demonstrating compliance with protection requirements.

Collectively, these technical requirements imply more computational tasks to be performed, and more data storage resources to be used. For example, the Privacy Act of 1974 requires that "...agencies shall maintain all records with such accuracy, relevance, timeliness, and completeness as is reasonably required to assure fairness to individuals in determinations". This calls for the following policy decisions: selection of data items to be used (relevance), the level of detail of information items (precision), the retention time (timeliness), and criteria for verifying accuracy of factual and evaluative information. In addition, mechanisms must be provided for assuring authenticity of the data items, for access authorization, and for revalidation or purging of data items.

The above, in turn, call for error control in data collection and entry, reliable identification of individuals, maintaining data integrity in the system, providing additional data fields in records for privacy protection purposes, operating privacy protection related audit trails, implementing in the systems data security safeguards and access control mechanisms, and adequate provisions for system backup and recovery.

Data security requirements in national data protection laws, and in international agreements, provide another example. The Council of Europe convention provides that: Appropriate security measures shall be taken " ... against accidental or unauthorized destruction or accidental loss, as well as against unauthorized access, alteration or dissemination". In addition, the convention requires that specific security measures be provided for every file; that the degree of vulnerability, need to restrict access, and requirement for long-term storage be considered; and that the current state-of-the-art security measures, methods, techniques be used.

Concluding this section, it may be observed that privacy protection continues as a concern in many countries, and that privacy protection principles are well-formulated and implementable. Since the technical aspects of privacy protection requirements are substantial, they must be considered early in the system's design phase and maintained throughout its life cycle.

IV. SOCIETAL RESILIENCY

In an information society, production and distribution of information is central to the economic, political, and social life. The benefits that accrue through the availability of information drive the society to obtain even more information. This leads to extensive automation of the information collection, processing, and dissemination

tion collection, processing, and dissemination functions. Examples are the decision support systems in business firms, computer-aided design and manufacturing systems, automated process control, office automation, electronic funds transfers, military command and control systems, and many others. It would be very difficult to operate in a modern society without computerized information systems.

As early as in the mid-1960s when the total computer population of the world was a few tens of thousands, concerns were voiced over the increasing dependence on computers[38]. Now, when the computer population of world is in tens of millions, and extensive computer networks exist, they are beginning to be regarded as a new, potentially serious technological vulnerability of the society.

In 1979, Sweden released a report of its Committee on the Vulnerability of Computer Systems (SARK)[39], which concluded that "vulnerability is unacceptably high in today's computerized society". Responding to this, the OECD held a workshop in 1981 on computer vulnerability[40]. Its conclusion was that there are sufficient reasons to justify concerns. In the United States, the American Federation of Information Processing Societies (AFIPS), reacted to the Swedish report by establishing a panel to examine the applicability of SARK conclusions to the United States. The panel observed that the SARK findings were not representative of the situation in the U.S., and that this country still appears to be adequately resilient[41].

An analysis of societal vulnerabilities and potential hazards due to massive use of computers is similar to performing a technology assessment or a risk analysis. Vulnerabilities and threats are identified and their effects are postulated. Among the effects identified by the AFIPS panel as sufficiently severe to cause society-wide problems were: (1) severe disruption of the national economy, and large losses; (2) large decline in the productive capability of an important industrial sector, or massive wasting of scarce resources; (3) severe erosion of citizens' rights and freedoms, (4) sharply increased dependence on foreign powers in economy, finance, or politics, and (5) a coup d'etat, conventional war, or a nuclear conflict.

If it is not possible for computer systems in a given country to directly cause, or to contribute to the occurrence of such harmful effects as listed above, then it would appear that there are no serious computer-related vulnerabilities in that country. On the other hand, some computer application may contribute indirectly by creating potential vulnerabilities which then may cause harmful societal effects. Examples are command and control systems, real time process control systems, systems for distributing goods and services, personal information record-keeping systems, elevctronic funds transfer systems, and management information systems.

Through a sudden unavailability of a sufficient number of computer systems a societally paralyzing chain of events may be triggered. For example, a coordinated attack on computer systems may be launched by terrorists, anti-social elements may embark on a long-term effort of subversion or sabotage, or computers may be damaged through some natural or man-made event (e.g., radiation or electromagnetic pulse from a nuclear accident in earth orbit[42]). A paralyzing situation may also develop gradually, such as the accumulation in data bases of erroneous information which results in wrong decisions and, over time, renders important computer systems unusable. Deliberate contamination of data bases or software could result in similar problems.

Resiliency is the ability to absorb disruptions and damages without suffering long-lasting or irreversible ill effects. In the present context, it is the ability to recover from computer system failures or from their misuse without society-wide harms. Resiliency may be due to certain intrinsic attributes of the society in question, or it may be achieved by deliberate actions of the users, the system designers, and the governmental agencies which may be involved. The following factors appear to affect resiliency: (1) geographic and demographic aspects of the society (large countries are likely to be more resilient); (2) degree of multiplicity and redundancy in providing critical services to the society; (3) degree of service-level and society-level preparedness, contingency planning, and backup; (4) extent of preservation of the "corporate memory" of how functions were performed and supported prior to automation; and (5) existence of legal safeguards against misuses of computer systems (e.g., such as privacy violations or computer crime).

Some of the factors listed above are depend on the size, location, culture, history, and the geopolitical situation of a country. Others are controllable and achievable by appropriate policies. Thus, a computerized country is not necessarily a vulnerable one. On the other hand, resiliency cannot be expected to be a permanent condition. Deliberate efforts are required by all sectors of the society to preserve resiliency. For example, public awareness of the capabilities as well as limitations of computer technology must be increased, industry associations must assume a role in maintaining resiliency in their specific functional areas, and the government must promote resiliency as a part of its national information policy. Individual organizations that are dependent on automated systems must plan for quality control in their data processing operations, provide for adequate security, establish and test contingency plans, and take steps to maintain the corporate memory of how to perform critical functions without computer support.

V. CONCLUDING REMARKS

This paper has striven to show that the traditional technical requirements must be augmented with nontechnical requirements in the development of computer systems for applications that impact public safety and individual rights. Information security and protection of individual privacy are

Information security and protection of individual privacy are two such requirements. Providing these protections involves a number of technical and administrative measures which may reduce the computer system's performance, limit user access, and add to the overhead in general. However, this is the price that must be paid in designing, implementing and operating systems in a societally responsible way. Warnings about the increased societal vulnerability due to massive computerization must also not be taken lightly, since the potential for highly disruptive threats is increasing. For example, international terrorism is likely to be directed against computer systems in the future at a much greater scale than in the past.

Analyzing the Security of an Existing Computer System

Matt Bishop

Research Institute for Advanced Computer Science
NASA Ames Research Center
Moffett Field, CA 94035

ABSTRACT

Most work concerning secure computer systems has dealt with the design, verification, and implementation of provably secure computer systems, or has explored ways of making existing computer systems more secure. The problem of locating security holes in existing systems has received considerably less attention; methods generally rely on "thought experiments" as a critical step in the procedure. The difficulty is that such experiments require that a large amount of information be available in a format that makes correlating the details of various programs straightforward. This paper describes a method of providing such a basis for the "thought experiment" by writing a special manual for parts of the operating system, system programs, and library subroutines.

Introduction

Published work in the security of computer systems tends to take one of two directions. The work may center on a new, secure (possibly provably so) computer system, and discuss its design, implementation, and verification, or the techniques used to do any (or all) of these steps. Less commonly, the work may report ways of improving the security of an existing system by discussing the known problems and methods to counter these threats. Only a few papers[1] deal with how to analyze an existing computer system in order to locate security problems

At this point, we should remind ourselves what we are trying to do. Users who have legitimate access to the system are *authorized users.* If the permissions on the system are set to allow someone to perform an action, that action is an *authorized action*; if the action is performed in the absence of such permission, it is an *unauthorized action.* A *secure* system is a system which allows only authorized users to perform only authorized actions. For example, if a user is not known to the system administrator (by an entry in the password file), he is not an authorized user and hence should not be able to access the system. Similarly, a *breach of security* occurs whenever an authorized user performs an unauthorized action, or when an unauthorized user obtains access to the system.

There are several reasons to check existing programs. The most important is that the design, implementation, and verification of new code takes quite some time, during which the new code could not be used. When one realizes that most operating systems were not designed with security as the primary consideration, the magnitude of such a task becomes apparent. Existing code, on the other hand, could be used for increasingly privileged tasks as it is examined in stages for security flaws. Second, given that there is already enough existing code to keep a nonsecure system functioning, it may be more cost-effective to check the code for security holes rather than rewriting it completely. Finally, once it is written, new software can be treated like existing software.

Unfortunately, lack of formal verification poses problems. The best way to reduce the number of security problems is "to use formal security verification methods to assure that the mandatory ... security controls employed in the system can effectively protect ... sensitive information stored or processed by the system."[2] To do this, the developers must state their security policy, the axioms used to implement the security policy, and using these axioms present a mathematical proof that the system satisfies the security policy. Then, they must show the implementation of the operating system conforms to the design. (LOCUS[3] and PSOS[4] are examples of proposed operating systems for which mechanisms of formal verification have been described.) Throughout this procedure is an assumption that the system is designed with this type of verification in mind. To submit an existing system to this procedure, one must first decide on a security policy, and then model the system mathematically and show that the system not only satisfies the security policy, but also is accurately represented by the mathematical model. Abstraction of a mathematical description from the operating system is far more difficult than implementing the operating system from the mathematical description.

It is important to realize that no method will provide the same degree of security as formally verifying a system; however, less rigorous methods can reveal security flaws, and make the writing and checking of secure system software easier and less prone to error.

The Starting Point

Given that mathematical verification is not suitable, let us look at other methods of testing, and improving, system security. The most obvious is an *ad hoc* approach of trying types of attacks that have proven successful on this, or

Work reported here was supported by the National Aeronautics and Space Administration under contract NAS2-11530.

CH2345-7/86/0000/1115$01.00 © 1986 IEEE

other, operating systems in the past. Although doing so is very effective in discovering specific security problems, it does not provide a broad, systematic approach for discovering flaws in the security of computer systems, or for testing new components.

A generalization of this method will provide a foundation for analyzing security problems. One technique for penetrating operating systems involves a formal strategy called the "Flaw Hypothesis Methodology."[5] It consists of four parts: knowing how the target operating system interacts with users, hypothesizing a flaw in that interaction, confirming that the flaw exists (through "thought experiments" and actual testing), and generalizing the flaw, and similar flaws, to a design or implementation deficiency in that operating system. Clearly, the most difficult part is taking the first step, from the knowledge of the operating system to the supposition of flaws.

Before discussing ways to make this easier, let us try to categorize the main areas in which problems arise, to gain some insight about where to look. Bisbey, Carlstedt, and Hollingsworth at the University of Southern California's Information Sciences Institute have identified several categories of system flaws which can produce security violations. The following list summarizes them by listing main areas, each broken into sub-areas:*

(1) Improper protection (initialization and enforcement):

(1a) improper choice of initial protection domain; for example, an incorrect choice of a protection domain or security partition leading to a user being able to access and change an audit trail;

(1b) improper isolation of implementation detail; for example, allowing users to bypass operating system controls and write to absolute input/output addresses;

(1c) improper change; for example, allowing data to be inconsistent while still in use, by letting one process change a database file while another, different process is accessing that file;

(1d) improper naming; for example, allowing two different programs to have the same name;

(1e) improper deallocation or deletion; for example, leaving old data in memory deallocated by one process and reallocated to another process, enabling the second process to access the information used by the first;

(2) Improper validation; for example, not checking critical conditions and parameters, leading to a process' addressing memory not in its memory space by referencing through an out-of-bounds pointer value;

(3) Improper synchronization:

(3a) improper indivisibility; for example, interrupting atomic operations such as locking;

(3b) improper sequencing; such as allowing race conditions among processes vying for resources;

(4) Improper choice of operand or operation; such as using unfair scheduling algorithms that block certain processes or users from running.

Although certainly not complete, this list provides a means of classifying most security problems, and is quite suitable as an outline of areas in which problems of security will arise.

Now that we have guidelines on where to look, we must consider how to go about looking. Unfortunately, there is no way to do this other than by trial and error. (There has been some discussion of problems leading to, and attacks taking advantage of, security flaws in operating systems generally[4,6], as well as discussions of the security of specific operating systems[7,8,9].) Such methods may be made more effective if the trials are done systematically rather than at random. One technique to systematize the search is to use a dependency graph of the control objects in the operating system to study their interaction and look for possible problems that may enable an attacker to breach security. Among the difficulties with this are the generation of the graph, and its being understood by those not familiar with the layout of the graph.

Before examining another technique, let us analyze the problem of finding security holes a bit further.

Laying the Groundwork

The key point in looking for security flaws is recognizing that the security problems we are dealing with arise from interactions between the user and the operating system. Specifically, the user creates a condition using one or more programs and then executes another program or programs which cause the operating system to ignore specific protections. For example, to copy a protected file, the user must force the operating system to ignore or override this protection (for example, by running a program at a level of privilege sufficient to cause file protections to be ineffective.)

Unfortunately, any list of methods to do this will contain only a subset of all possible methods, since any new system program would add many new ways to evade protections. Even if such a list could be made, it would be very different for each operating system, because each operating system has its own design and implementation philosophy, and the latter often differ in ways that affect very subtle points of interaction. Similarly, programs perform different tasks, and the work needed to catalogue all of the possible jobs programs may do will be endless. Indeed, the required level of security differs, too; programs executed with special powers (such as *root* or *operator* privileges) must be checked for security violations that need not be looked for in other nonprivileged programs.

But the problems that arise come from the interaction of users with the operating system, as we have said. The only two ways for a user to interact with the operating system are through programs (software) and through equipment attached to the computer (hardware), in the latter case the interface being the kernel. So, in order to examine the way users interact with the operating system, we must study how the programs interact with the operating system, and the device drivers and other routines through which the equipment interacts with the kernel.

Let us deal with individual programs first. To study how they interact with the kernel, we shall try to abstract the functionality of the program from the actual code. This will have two effects. First, it will separate security problems introduced by the coding of the program from those introduced by the design of the program. Then, the design of the program can be checked, both for internal security problems

* This organization is from Peter Neumann[6].

and for security problems arising from interaction with other programs. Once this is done, the implementation can be examined to ensure that it does not introduce other security problems.

The first step, therefore, is to figure out what the program does, and how it goes about doing it. For the first part, system documentation will provide some guidance, but because documentation very often is incorrect, incomplete, or imprecise, it is not always good to rely on it; hence, for both learning what the program does, and how it does it, one must go through the program code. Second, one must document all interaction with the operating system (such as the files looked at, and how the program uses them.) In particular, one must document all error checking and recovery (or the lack of it.)

As an outline, the following organization for this document would be appropriate:

Name

This is the name of the program. If the program may be invoked by any of several names, all should be listed.

Actions

Although similar to a specification, this section should conform to the code and not to what the program is supposed to do. This section requires that the implementation be examined and written out in such detail that someone not familiar with the code could understand not only the action of the program, but how it works, and what side effects it has. If library routines or programs already documented in this fashion are used, it is often useful to refer to the appropriate pages rather than recapitulate the actions of those routines or programs.

Apparent Assumptions

This presents any inherent assumptions. For example, if a file is assumed to be in a specific format, this should be noted here. If an assumption about the meaning of an error condition is made, list it here.

Files Used

This section names the system and user files used. It also contains a short description of each, any assumptions made about format, and the system calls used to access each.

System Calls

This lists all the system calls used.

Execution Modes

This is most useful for programs; it describes who may execute the program and with what privileges the program executes.

Known Bugs

Any known security problems are listed here. As security holes are found, they should be added. Note that suspicions should be listed (but marked as suspicions) until they are proven or disproven.

Error Handling

This describes what happens if errors occur. For example, suppose an index into an array is out of bounds; does the program dump core? Suppose a file is not in the correct format? Are there checks to ensure any reading or writing succeeds?

Library Functions Used

List the names, versions, and dates of any library functions used.

Manual Page Version

Give the author, date, version of the program, and system for which this document was prepared.

We shall call this document the *security manual page* to distinguish it from the usual manual page. (A sample page, for the UNIX* library routine *getlogin*, follows the references.)

Of course, in the Known Bugs section, one should document any discovered security problems.

This documentation should not be confined to the program only. Very often system programs need to perform a task such as looking up a name in a table to obtain associated data. These functions are performed so often that they have been collected into a set of library routines. Since these routines affect the function of each program in which they are used, it would save time and work to document these routines as described above. This would provide one reference for each library routine, rather than having the same routine be checked once for each program in which it is used (and risking a security hole being overlooked once). Similarly, new programs should use library routines whenever possible, and rather than duplicating code amongst several programs, the code should be changed into a library routine which the programs then call.

As an example of why documentation that describes the implementation of a program or library routine is necessary, consider the *getlogin*() bug, which exists on many UNIX systems. According to the manual[10], "[g]etlogin returns a pointer to the login name as found in */etc/utmp*." Although accurate, this description is very imprecise. *Getlogin* actually returns the login name of the user whose terminal is associated with the input, output, or error streams; this may or may not be the same as the login name of the person who executed the program. The security manual page should make this final statement, even though the manual page states *getlogin*'s function as indicated.**

Because of its complexity and function, the kernel must be checked differently than system programs and libraries. The principle is the same – analyze the code and document those parts which interact with other programs and equipment – but many security manual pages, not just one, will be written for it. Specifically, at least one page per system call and device driver will be necessary, stating error conditions and precisely how they are handled, as well as how the system calls and device drivers are accessed. Main components of the kernel – the initialization routines, the scheduler, and so forth – must also be documented, as must any routines that rely on files or specific memory locations or any other external factors.

Hence, the first step to checking the security of programs and the operating system is:

> *Document each program, system call and device driver, and library routine thoroughly, not just as to purpose but also as to its side effects and error handling.*

* UNIX is a Trademark of Bell Laboratories.

** See the sample security manual page that follows the references.

Hypothesizing the Flaws

Once a manual page or set of manual pages have been written, the process of locating security flaws begins. Unfortunately, the only known approach to doing this is largely *ad hoc.*

There are analogies in other fields. For example, the only way communications analysts can assess vulnerabilities of communications systems is to study the system thoroughly, and then draw on their knowledge of that system, their experience, and their knowledge of attacks that worked with other systems, to hypothesize security problems. They then test for these suspected flaws. The situation is precisely the same for computer security.

As with analyses of the vulnerability of communications systems, we can draw on past experience. There have been a number of studies of operating system security in general and of specific penetrations of various operating systems (some of these have been referred to earlier.) These studies provide knowledge of attacks that worked with many different systems. Combined with the knowledge gleaned from mathematical analyses of other systems and the weaknesses uncovered using those tools, all this experience provides a very solid background for hypothesizing security flaws.

The security manual described in the previous section will provide both the means of studying the system thoroughly and a reference guide useful in formulating hypotheses. As each program or routine algorithm is considered by itself, flaws may become apparent. (In fact, this happened with the *getlogin* manual page attached to this report. The second of the Known Bugs section was found by noticing the assumption made in step 4 of the algorithm, comparing it to step 3, and wondering what would happen if the assumption was invalid.) Correlating programs which use the same system files may reveal that the interaction of some such programs presents attackers with opportunities to subvert the system, or that these programs make inconsistent assumptions (or invalid assumptions) about the data in the file, or the way the file is used. A similar comment holds for programs and system calls; special attention should be paid to those system calls used to access and manipulate system files. The section on error handling should be quite fruitful for hypothesizing flaws. Many error conditions are not adequately handled, not handled correctly, or simply ignored. Very often this produces unusual situations that may present security holes which a clever attacker can exploit[11,12].

Hence, the second step to checking the security of programs and the operating system is:

> *Drawing on the documentation, past experience, and general knowledge of operating system vulnerabilities, hypothesize security flaws in the computer system, and test either to confirm or to deny that those flaws exist.*

Summary

When checking an existing computer system for security, both the operating system kernel and the system libraries and privileged programs must be examined. (If none of these has security flaws, applications programs will not be able to breach security.) They should be examined in the above order; note that this will ensure that the operating system calls, which are the basis for system library routines and system programs, will be examined before the code using them is examined.

Within each of these aspects, the steps of the "Flaw Hypothesis Method" as described in sections 2, 3, and 4 should be used to locate security flaws, paying special attention to the problem areas described in section 2. For each aspect, a security manual of the sort described in section 3 should be written and used as the basis for examining the interaction of the various components of the kernel, the libraries, and the system programs as discussed in section 4.

While this method will not ensure perfect security of a computer system, it will significantly increase the difficulty of an attacker penetrating the system.

Appendix – Sample Security Manual Page

NAME

getlogin – get login name

INVOCATION

char *getlogin();

ACTIONS

Getlogin returns the user believed to be using the controlling terminal. It does this as follows:

1. Find the first of the file descriptors 0, 1, 2 associated with a terminal by running an *ioctl*(2) on each and seeing which one succeeds; if all fail, return 0.
2. Find the device/inode pair corresponding to that terminal by using *fstat*(2), and scan the files in the directory */dev/* until one is found with that device/inode pair. If none is found, return 0.
3. Search the file */etc/ttys* for that file name, and count the number of lines *N* skipped before it is found. If not found, return 0.
4. Read the *N*th record in */etc/utmp*; this corresponds to the user currently using that terminal. It is in the format of *utmp*(5).
5. Return the contents of the *ut_name* field of that record. Note it is kept in a static area, and is overwritten the next time *getlogin* is called.

APPARENT ASSUMPTIONS

The first of the file descriptors 0, 1, and 2 that is associated with a terminal is associated with the terminal the user logged in on.

The number of the (text) line in */etc/ttys* describing a terminal corresponds to the offset into the file */etc/utmp* for that terminal.

FILES USED

/etc/ttys List of terminal names, one per line; *open*(2), *read*(2), *close*(2)

/etc/utmp List of logged-in users; assumes each record corresponds to a line in */etc/ttys* and that the records have the same order; *open*(2), *lseek*(2), *read*(2), *close*(2)

/dev/ Directory containing files corresponding to terminals; used to determine the name of the controlling terminal; *open*(2), *read*(2), *close*(2)

SYSTEM CALLS

close(2), *fstat*(2), *ioctl*(2), *lseek*(2), *open*(2), *read*(2), *sbrk*(2), *stat*(2)

EXECUTION MODES

This is a system library function.

KNOWN BUGS

If the first file descriptor found to be associated with a terminal is not associated with the controlling terminal, the name of the user at the associated terminal will be returned, and not the name of the user at the controlling terminal.

If a line is added to or deleted from */etc/ttys*, the algorithm used to associate users with their terminal names fails miserably. This problem can be corrected by looking in the *ut_term* field of the record and comparing it with the name obtained from */etc/ttys.*

ERROR HANDLING

On error, it is supposed to return 0.

No error check to be sure the *lseek*(2) to the record in */etc/utmp* succeeds.

No error check to be sure the record in */etc/utmp* corresponds to the name of the terminal.

Silently assumes names which are shorter than the space allocated in the record for user names are blank padded.

ABSTRACT

In an environment where copyrighted programs are shared by numerous independent users via a network configuration (e.g., a local area network), security research efforts have focused primarily on program security or on data security, but not both. In this paper we are concerned with achieving both types of security and characterizing the communication cost of doing this. We survey existing security techniques for the environment of concern and present a radically new technique. We analyze and simulate the communication cost of each technique to demonstrate their relative merits. It is shown that the technique requires nominal communications overhead while achieving both program and data security.

1. Introduction

This paper deals with three issues - securing user-data, securing program-logic, and reducing communications traffic. The securing of user-data has been widely studied and many effective techniques exist (see, for example, [DENN82]). By program-logic, we mean the set of all executable paths of a program. The securing of program-logic in a network environment is an issue not commonly studied or even mentioned in the literature. Achieving security of program-logic, in conjunction with securing user-data, will have an effect on communications traffic in a network environment.

Security in computer networks is hampered by the requirement that the application program and the portion of the database it manipulates must be physically resident on the same processor node at program execution. This may require transmission of programs or data over wire, microwave, or satellite links with resulting vulnerability to interception, decryption, and analysis. Since database management systems are the most widely used applications in main frame sites with information centers [KNIG85], we feel that a way which minimizes the shipment of program-logic and user-data (with special emphasis on database applications) would increase overall security within network environments.

Proprietary software and sensitive data are two assets, each of which have value [PARK81]. Our work to secure these two assets in a network environment has been influenced by the following additional concerns:

(1) Software updates: Information systems inherently require periodic software upgrading. Dispersion of a change to all users can be expensive and may never result in a complete upgrade among all the users.

(2) Communications traffic: The volume of communications traffic and the communications rate affects the performance of the network.

(3) Number of users serviced: The number of users serviced by a single copy of a program can determine main storage requirements. A processor servicing a large number of users could very easily require a large I/O buffer space.

(4) Volume of user-data: The volume of user-data determines the amount of secondary storage required. The issues are cost and responsibility for that storage.

Section 2 uses an example to motivate and describe two prevalent techniques for the network environment of concern and then describes a new, more secure, technique. Our descriptions allude to the above concerns. Section 3 outlines an approach for implementing the new technique, and Section 4 presents performance results for a simulation of this approach. In Section 5, we provide an analysis to help verify our simulations. Section 6 concludes our paper by discussing the significance of our work and presents alter-

CH2345-7/86/0000/1120$01.00 © 1986 IEEE

native approaches for implementing our new technique.

2. Interface Techniques

In this section, we present a commercial example to motivate and describe the characteristics of two prevalent techniques for the program-logic and user-data security problem when these two assets do not have the same owner or do not have the same node residency during execution. It will be seen that each of these techniques causes a compromise of either program-logic or user-data, and neither one provides an acceptable solution to the four security related concerns listed in Section 1. We then introduce a radically new technique which is applicable when generalized database management systems are considered for the program-logic environment. It will be seen in Sections 4 and 5 that this new technique provides a viable alternative to existing techniques for the defined environment.

2.1 Commercial Application Example

Let a person's house be an environment. (A business could just as well be used here for an environment.) Consider the Internal Revenue Service. The IRS requires, essentially, annual reports from people. People should have access to standardized application programs which enable them to maintain IRS acceptable records for completing IRS forms (management information). It is easy to imagine that, in the near future, a company like H & R Block would make convenient IRS applications programs available for people to maintain IRS acceptable bookkeeping records so that IRS forms can be automatically completed. The conditions here are the following:

(a) People insist on keeping their data in-house, so they will insist on having their own copy of H & R Block's application program.

(b) H & R Block will not provide a copy of any of their application programs to people for fear that the programs would be passed on without reimbursement. H & R Block will insist that any person who desires to use programs submit their data to H & R Block.

(c) The application programs developed by H & R Block will need to be modified periodically to reflect annual changes, such as new tax tables, alternations in computation procedures, and new formats for printing. H & R Block will insist that, at any particular time, every person must use the same application programs. This requirement will be impossible to enforce unless the programs "run" at computer installations controlled or owned by H & R Block.

We will refer to this example to help explain the security techniques described in the following subsections.

2.2 Data Secure Technique

This technique is characterized essentially by the fact that the user purchases the database management system software and data storage hardware. Since the user executes the program in his environment and the data is not transmitted, absolute data security is insured. However, protection of proprietary software is of concern since the software may be plagiarized. Software updates involve additional expense to the software vendor. The cost of the processing hardware and software may be of concern to the user. The weakest security mechanism here is the software licensing agreement [PARK81].

Referring to the commercial example in Section 2.1, H & R Block would have to allow users to purchase their application programs which violates condition (b). Consequently, the Data Secure technique is not a realistic technique for this example.

2.3 Program Secure Technique

This technique is characterized essentially by the fact that the database management system runs on one machine (the program node), while all the user-data originates on another machine (the data node) and must be transmitted to the program node for processing. Assuming the data traffic contains sensitive information, effective data protection mechanisms [ABRA85, DENN82, HOFF77, MCMA85, WOOD86] are essential. But, since data is transmitted in some form, it will always be vulnerable; absolute data security is not provided. However, software maintenance is simplified and proprietary software is protected. The volume of data and the communications transfer rate impact system performance. The communications traffic may be a problem. For some techniques of this type, the user-data is transmitted and then resides at the program node for processing (e.g., Martin Marietta Data Systems of Orlando, Florida); for others, it is repeatedly transmitted for processing and resides at the data node. The number of users serviced is of concern for the program node. Volume of user-data may be of concern to either the program node or the data node.

Referring to the commercial example in Section 2.1, people would have to transmit their data to H & R Block which violates condition (a). Consequently, the Program Secure technique is not a realistic technique for this example.

2.4 Program and Data Secure Technique

Absolute protection of proprietary software and sensitive data can be accomplished. This is true when the program-logic environment is defined by a generalized data base management system. The configuration shown in Fig. 1 provides a solution by keeping the program-logic separate from the user-data [CHES85, DRIS84].

Execution of a DBMS occurs on the program node. The user-data resides on the data node. This technique employs a signal/response method to accomplish DBMS execution. A signal packet is generated by the program node and transmitted to the data node for interpretation. The data node has processing and storage abilities. Interpretation of the signal packet requires some software interface to exist on the data node. The intent of this configuration is to keep this interface simple and compatible with various data nodes so that any off-the-shelf personal computer can act as a data node. The data node performs the requested signal operation and transmits a simple response back to the program node if necessary. Thus, the number of users serviced will not be a concern. Since the user-data is never transmitted across the communications link between the two nodes, absolute data security is insured. Thus volume of user-data is of concern only to the data node. The DBMS is resident on the program node and its program-logic is never transmitted; only data manipulation instructions are transmitted. Thus, software maintenance is simplified and proprietary software is protected. The volume of signals and responses and the communications traffic rate impact system performance. Communications traffic may be a problem and needs to be studied.

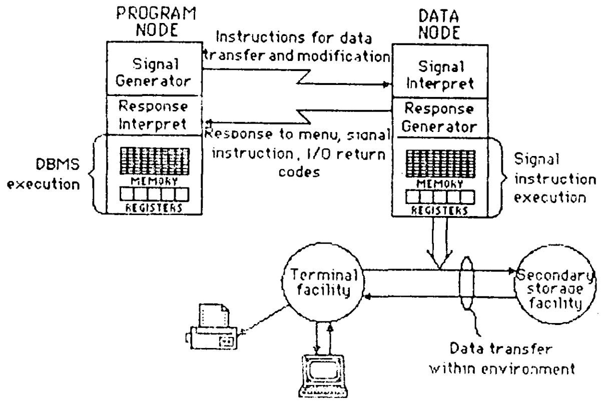
Referring to the commercial example in Section 2.1 and the configuration shown in Figure 1, the processing facility of the program node would be owned by H & R Block. People would buy personal computers of their choice and each person's equipment would represent a data node. A person would select commands offered by the H & R Block application programs. The application programs would issue commands to cause data movement or modification within the person's system. The financial records of the person do not move outside the person's system. Each person would establish and maintain their private financial records during a year. At the end of a year, each person would produce their own income tax return on their printer. H & R Block application programs are used but not seen by the people. H & R Block can easily alter or update their programs to comply with IRS whims. Consequently, all the conditions (a), (b) and (c) of Section 2.1 are satisfied by this technique.

The primary purpose of this paper is to present evidence which demonstrates that this new technique is a viable alternative to existing techniques. This is done in Sections 4 and 5. In the next section, we outline a method of implementing this new technique.

3. The Ship-Bit Method

In this section we describe a low-level hardware method of implementing the Program and Data Secure technique. We consider only generalized database management systems for the program-logic environment. This method involves shipping machine language data manipulation instructions with the generalized database management system to the data node for execution. This is accomplished by extending the machine's instruction opcode field to include a special bit identifying an instruction for shipment. This method requires additional storage for the shipping bits, interpretation logic for instruction type identification, and modified compilers which identify the instructions that need to be shipped.

If an instruction directly references data which exists on the data node, the instruction must be marked as an instruction to be shipped to the data node. Clearly, I/O operations using peripheral devices residing on the data node (i.e. printer or terminal) must also be marked



PROGRAM NODE
DATA NODE
Instructions for data transfer and modification
Signal Generator
Signal Interpret
Response Interpret
Response Generator
Response to menu, signal instruction, I/O return codes
DBMS execution
MEMORY
REGISTERS
Signal instruction execution
Terminal facility
Secondary storage facility
Data transfer within environment

Fig. 1. The Program and Data Secure Configuration.

for shipment to the data node. Since the DBMS executes on the program node, instructions which control the execution flow of the DBMS are never shipped to the data node for execution. An example of this type of instruction is a branch instruction.

Automation of the process of identifying the data manipulation related DBMS instructions poses an interesting problem. A likely solution is to design a compiler capable of distinguishing between data node and program node variables. If there is a mix of program node and data node variables in an instruction, then the compiler must decide as to where the instruction is best executed at that instant. An alternative solution is to have a preprocessing software which would flag those instructions that need shipping and replace them by the appropriate calls to shipping routines. We are not concerned with the design of such a software in this paper.

4. Simulation Results

Our concern here is to show by experimentation the feasibility of the method described in Section 3. It is true that the messages passing via the link between the program and data nodes need be encrypted and authenticated [DENN82]. The overhead associated with encryption would be proportional to the length of the message and do not alter our results mentioned here. All software overheads are ignored as the slow communication link speed will dominate the execution times

A simple DBMS was written using IBM 370 assembly language. The DBMS was capable of defining up to four files, inserting and deleting records, printing files, deleting files, and displaying directory contents. The DBMS was not designed for storage of real data as we were more interested in writing a DBMS capable of performing a reasonable test of basic data manipulation operations. Consequently, the DBMS was not complex; it offered only basic file-handling capabilities which served our purpose.

The data manipulation instructions of the DBMS were identified and the DBMS was executed on an ISPS [BARB81] simulation of the three techniques corresponding to Data Security, Program Security, Program and Data Security. The ISPS simulator ran on VAX 11/730 operating on VMS. The DBMS operations performed under the simulator consisted of three stages of testing:

(I) Define DBMS Schema
-Define 1 File
-Define 2 Files
-Define 3 Files
-Define 4 Files

(II) Mass Load DBMS Data
-Insert Records in Random Order
-Insert Sorted Records

(III) Typical DBMS Operations
-Display Directory Contents
-Print Files
-Delete Files
-Delete Records
-Insert Records
-Search Records on Key Field

A more efficient DBMS design in which the directory data is read once per session is also considered. This reduces the communications traffic in the Program and Data Secure technique because an instruction to read directory data is shipped only once. In the original DBMS design, an instruction to read directory data was shipped to the data node for each query.

The statistics resulting from each stage of testing are now summarized. The communications traffic overhead incurred by each technique is presented in terms of both volume and transmission delay time.

Stage I involved the definition of the database files. This activity involved mostly disk directory operations. The timing delay graph for each technique in Fig. 2 shows the transmission delay due to communications traffic volume plus I/O delay occurring in each technique. This graph does not indicate the effects of a more efficient DBMS design since detailed peripheral activity was not collected by the simulator.

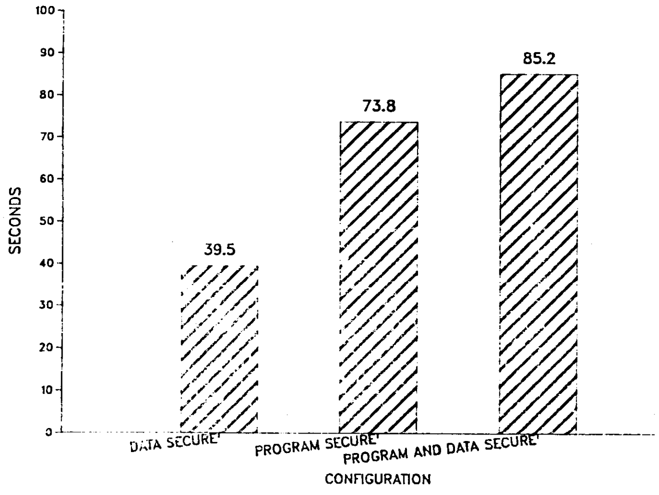


Fig. 2. Communications Plus I/O Traffic Delay for Stage 1.

The increase in communications traffic for each file defined is linear as shown in Fig. 3. The graph clearly indicates the increase in communications traffic of the Program and Data Secure technique over the Program Secure technique. The projected traffic for a more efficient DBMS design substantially reduces this increase for the new technique. The Program Secure technique is unchanged because there is no communications traffic in this situation that results from disk I/O operations. The residency of the disk causes the DBMS design change to have no effect on communications traffic in that technique.

Stage II testing involved a mass load of the database. This type of activity references the disk frequently. Therefore, the residency of the disk data will dictate the volume and types of communications traffic. The timing delays due to communications traffic plus I/O traffic in each technique is presented in Fig. 4 for the Stage II testing. The more efficient DBMS design would have reduced these values since the communications traffic volume would be reduced. The timing delay for the Data Secure technique is the time required to perform the peripheral I/O operations. The delays for the other two techniques involve this I/O delay plus communications traffic delay.

Stage III involved a collection of typical DBMS operations. For Stage III testing, Fig. 5 summarizes the communications traffic delay for each technique. This timing delay is directly related to the communications traffic volume plus I/O activity which occurs for this testing stage in each technique. The timing delay in the data secure technique results only from I/O activity. The same amount of I/O activity occurs in all the three techniques. Because the detailed peripheral I/O activity was not collected by the simulator for a more efficient DBMS design, an accurate display of timing delays for that DBMS design could not be presented.

The overall communications traffic volume is compared in Fig. 6 for the Program Secure technique and the new technique. The communications traffic volume resulting from a more efficiently designed DBMS is presented. The Program and Data Secure technique reflects a significant savings in traffic volume with the more efficient DBMS. This graph illustrates that for a more efficient DBMS, the new technique has an overhead of only 3.7% over the communications traffic volume for the Program Secure technique. To achieve absolute program and data security, this overhead expense is minimal.

5. Estimates of Query Execution Times

We present here a simplified model to estimate the query execution times for the Data Secure, the Program Secure and the Program and Data Secure techniques. Parametric values used for the simulation will be plugged into this model and the results obtained will be compared with those of Section 4 to illustrate the validity of our model.

We list below the various parameters that are included in the model:

C Number of bytes of control instructions in the program to answer a user query.

I_d Number of bytes of data manipulation instructions executed in the program to answer a user query.

R Number of bytes of data that need to produced and transmitted between the data and program nodes in the process of answering a user query.

B Baud rate of the transmission line (in bits/sec.).

b Number of bits transmitted per byte (byte + start and stop bits).

T_d Total time for all data accesses between the disk, the main memory and the processor, to answer a user query.

T_i Total time for transferring the program from the disk to the main memory to answer a user query.

T_e Total execution time for the program to answer a user query excluding any disk accesses.

l Average length (in bytes) of a data manipulation instruction.

T_m Time to access a single byte from main memory.

Note that $(C + I_d)$ indicates the total number of bytes of the program-logic to answer a user query.

5.1 Query Execution Time in the Data Secure Technique

This technique will be the fastest. However, this technique offers no program-logic security whatsoever. Assuming that the results are transmitted to the user terminal via Direct Memory Access

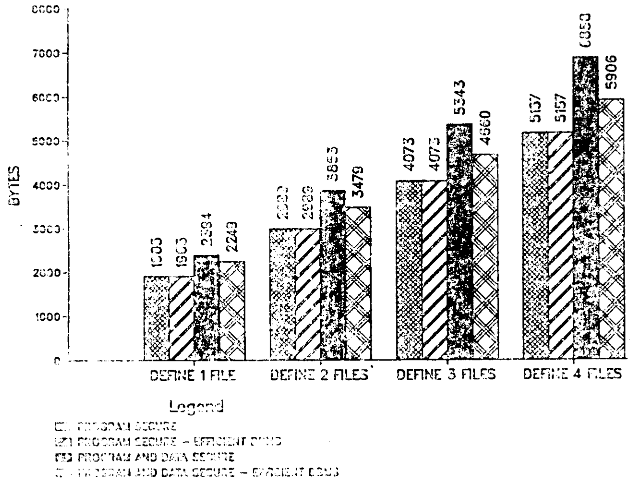

Fig. 3. Communications Traffic Volume for Stage I

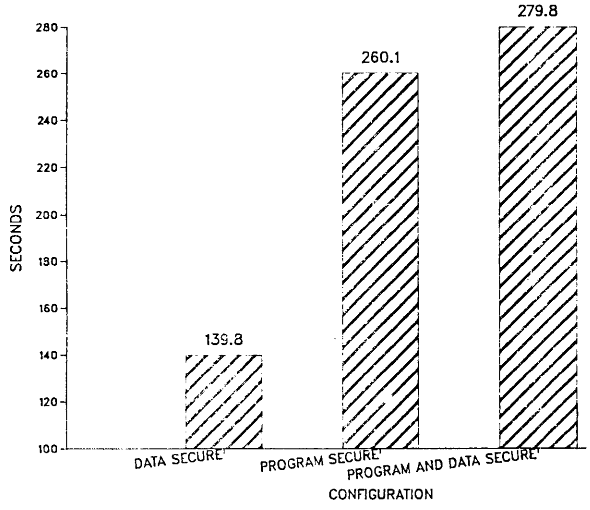

Fig. 4. Communications Plus I/O Traffic Delay for Stage II.

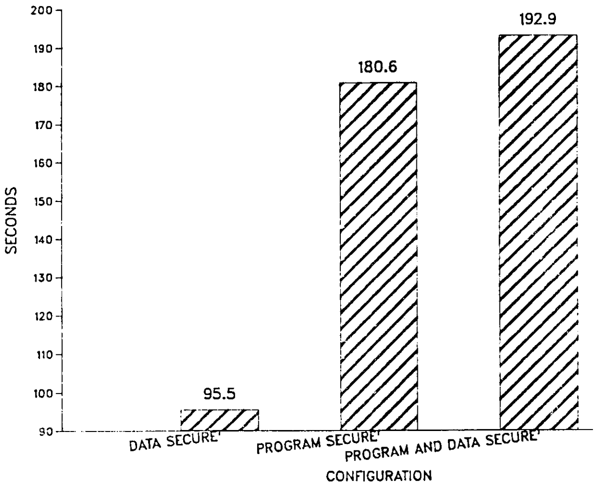

Fig. 5. Communications Plus I/O Traffic Delay for Stage III.

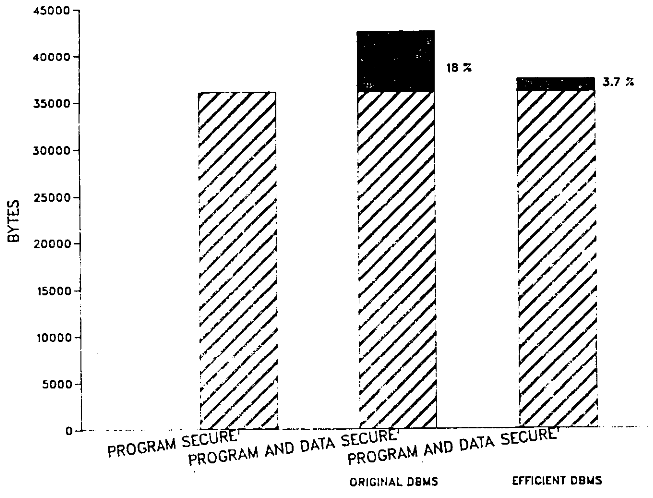

Fig. 6. Overall Communications Traffic Volume.

(DMA), the total query execution time is

$$T_{DS}=T_i+T_d+T_a+T_m(C+I_d)+T_mR \qquad (1)$$

where T_mR is the time to store the result bytes in main memory. There is no communication cost in this technique.

5.2 Query Execution Time in the Program Secure Technique

This technique offers only program-logic security and experiences a penalty in shipping the menu and the result bytes R from the program node to the data node. As in Section 5.1, we assume that the results are accessed in a DMA fashion for transmission to the data node. The total query execution time is

$$T_{PS}=T_{DS}+(b/B)R+T_mR \qquad (2)$$

of which

the communications cost=(b/B)R. (3)

5.3 Query Execution Time in the Program and Data Secure Technique

This technique provides the security for both program-logic and user-data, but suffers the penalty in shipping the data manipulation instructions to the data node. We assume here that we have to transmit a control byte with each transmitted instruction. The control byte instructs the data node as to the contents of the signal packet and the type of response (or no response) expected. As before, we assume that the result bytes are transmitted to the user terminal in a DMA fashion. The total query execution time is

$$T_{PDS}=T_{DS}+(I_db/B)(1+1/l)+T_m(2I_d+R)+(b/B)R' \qquad (4)$$

of which

$$\textit{the communication cost} = (I_db/B)(1+1/l)+(b/B)R' \qquad (5)$$

The factor $2I_dT_m$ accounts for the receiving, storing and fetching of the data manipulation instructions at the data memory. The factor $I_d(1/l)$ accounts for the number of control bytes that get transmitted with the data manipulation instructions. The value of R' in this case would be lower than the value of R in Section 5.2 because only menu but no query results need be shipped to the data node.

5.4 An Example

We illustrate below an application of our model to validate the simulation results of stage III of the testing described in Section 4. A comprehensive testing of typical DBMS operations, seems to be appropriate as our example. The following parametric values were used for or obtained from the simulation:

T_m 1 Microsecond.

B 1200 bits/sec.

b 8 bits(ignoring start and stop bits).

l 3(majority of data manipulation instructions being the RR, the SI and the RX instruction types of IBM370).

C 1248 bytes.

I_d 3354 bytes.

R 12383 bytes for the Program Secure technique; 9824 bytes for the Program and Data Secure technique.

From equations (3) and (5), the communications costs are 82.55 seconds and 95.23 seconds for the Program Secure technique and the Program and Data Secure technique, respectively. The corresponding values from Fig. 5 are 85.1 seconds and 97.4 seconds, respectively, after eliminating I/O delays. The model agrees fairly closely with the simulation results. The small disparity is accounted in that the above parametric values do not take into account transmission of directory data or condition code responses between the program node and the data node.

6. Conclusions

In this paper we considered an environment where copyrighted programs are shared by numerous independent users via a network configuration. We were concerned with achieving both program and data security and characterizing the communication cost of doing this. We surveyed existing security techniques for the environment of concern and presented a radically new technique. We analyzed and simulated the communication cost of each technique to demonstrate their relative merits. We showed that our new technique requires nominal communications overhead while achieving both program and data security.

The new technique discussed in this paper achieves security by controlled shipment of flagged instructions at the assembly level. Two other approaches are possible:

(1) The Software Trap Approach which consists of software flagging of code sections that need to be shipped via a software trap instruction. This approach requires a special handler for shipping instructions invoked by execution of a software trap instruction, and modified compilers which identify sections of code that are to be shipped. The compiler will insert the trap instruction and the number of bytes to be shipped prior to the

section of code that will be shipped. Upon execution of the trap instruction, the appropriate number of bytes will be shipped by the trap handler.

(2) The Software Macro Call Approach which consists of software macro calls to the data node which make use of the data node's operating system. This approach requires modified compilers which identify what can be invoked as a system call to the node's operating system or a call to a receiver subroutine at the data node.

Of the above two approaches, the Software Macro Call approach seems promising in improving the communication costs as the number of instructions that need to be shipped are considerably reduced. The performance of our new technique using this approach is expected to considerably excel the other techniques. We are studying the Software Macro Call approach by implementing it on a demonstration system consisting of two Intel system/310 microcomputers obtained under a grant from the Intel Corporation.

From RIG to Accent to Mach: The Evolution of A Network Operating System

Richard F. Rashid

Computer Science Department
Carnegie-Mellon University
Pittsburgh, Pa. 15213

Abstract

This paper describes experiences gained during the design, implementation and use of the CMU Accent Network Operating System, its predecessor, the University of Rochester RIG system and its successor CMU's Mach multiprocessor operating system. It outlines the major design decisions on which the Accent kernel was based, how those decisions evolved from the RIG experiences and how they had to be modified to properly handle general purpose multiprocessors in Mach. Also discussed are some of the major issues in the implementation of message-based systems, the usage patterns observed with Accent over a three year period of extensive use at CMU and a timing analysis of various Accent functions.

1. Background

Mach is a multiprocessor operating system kernel currently under development at Carnegie-Mellon University. In addition to binary compatibility with Berkeley's current UNIX 4.3 bsd release, Mach provides a number of new facilities not available in 4.3, including:

- Support for tightly coupled and loosely coupled general purpose multiprocessors.
- An internal symbolic kernel debugger.
- Support for transparent remote file access between autonomous systems.
- Support for large, sparse virtual address spaces, copy-on-write virtual copy operations, and memory mapped files.
- Provisions for user-provided memory objects and pagers.
- Multiple threads of control within a single address space.
- A capability-based interprocess communication facility integrated with virtual memory management to allow transfer of large amounts of data (up to the size of a process address space) via copy-on-write techniques.
- Transparent network interprocess communication with preservation of capability protection across network boundaries.

As of May 1986, Mach runs on most uniprocessor VAX architecture machines: VAX 11/750, 11/780, 11/785, 8200, 8600, 8650, MicroVAX I, and MicroVAX II. Mach also runs on two multiprocessor VAX machines, the four (11/780 or 11/785) processor VAX 11/784 with 8 MB of shared memory the VAX 8300 (with up to 4 processors). Mach has already been ported to the IBM RT/PC and work has begun on ports to the uniprocessor SUN 3 and multiprocessor Encore MultiMax. The current version of the system, Mach-1, includes all of the features listed above and is in production use by CMU researchers on a number of projects including a multiprocessor speech recognition system called Agora [5] and a project to build parallel production systems.

Mach is the logical successor to CMU's Accent [16, 17] kernel -- an operating system designed to support a large network of uniprocessor scientific personal computers. The design and implementation of Accent was in turn based on experiences gained during the development of the University of Rochester's RIG system [3, 14], a message-based network access machine. Both RIG and Accent have seen considerable use over the years. RIG provided a variety of functions including terminal support and remote file access within the Rochester environment until early this year when the last RIG machine was decommissioned. Accent continues in use at CMU as the basic operating system for a network of 150 PERQ workstations and has seen commercial use in printing and publishing workstations as well as engineering design systems. As a third generation network operating system Mach, benefits from the lessons learned in over ten years of design, implementation and use of RIG and Accent. This paper summarizes the lessons of those systems and their impact on the design and implementation of Mach.

2. The Evolution of Accent from RIG

Implementation of RIG began in 1975 on an early version of the Data General Eclipse mini-computer. The first usable version of the system came on-line in the fall of 1976. Eventually the Rochester network included several RIG Eclipse nodes as network servers and a number of Xerox Altos acting as RIG client hosts. RIG provided clients network file services, ARPANET access, printing services and a variety of other functions. Active development continued well into the 1980's but obsolescence of its Data General Eclipse and Xerox Alto hardware base eventually dictated its demise in the Spring of 1986.

2.1. The RIG Design

The basic system structuring tool in RIG was an interprocess communication (IPC) facility which allowed RIG processes to communicate by sending packets of information between themselves. RIG's IPC facility was defined in terms of two basic abstractions: *messages* and *ports*.

CH2345-7/86/0000/1128$01.00 © 1986 IEEE

A RIG port was defined to be a kernel-provided queue for messages and was referenced by a global identifier consisting of a dotted pair of integers *<process number.port number>*. A RIG port was protected in the sense that it could only be manipulated directly by the RIG kernel, but it was unprotected in the sense that any process could send a message to a port. A RIG port was tied directly to the RIG abstraction of a *process* -- a protected address space with a single thread of program control.

A RIG message was composed of a header followed by data. Messages were of limited size and could contain at most two scalar data items or two array objects. The type tagging of data in messages was limited to a small set of simple scalar and array data types. Port identifiers could be sent in messages only as simple integers which would then be interpreted by the destination process.

Due largely to the hardware on which it was implemented, RIG did not allow either a paged virtual memory or an address space larger than 2↑16 bytes. RIG did, however, use simple memory mapping techniques to move data [3]. The largest amount of data which could be transferred at a time was 2K bytes.

2.2. Problems with RIG

The RIG message passing architecture was originally intended more as a means for achieving modular decomposition (much like Brinch-Hansen's RC4000) rather than as the basis for a distributed system. It was discovered early on, though, that RIG's message passing facility could be adapted as the communication base for a network operating system. Unfortunately, as RIG became heavily used for networking work at Rochester a number of problems with the original design became apparent:

- **Protection**

  The fact that ports were represented as global identifiers which could be constructed and used by any process implied that a process could not limit the set of processes which could send it a message. To function correctly, each process had to be prepared to accept any possible message sent to it from any potential source. A single errant process could conceivably flood a process or even the entire system with incoherent messages.

- **Failure notification**

  Another difficulty with global identifiers was that they could be passed in messages as simple integers. It was therefore impossible to determine whether a given process was potentially dependent on another process. In principle any process could store in its data space a reference to any other process. The failure of a machine or a process could therefore not be signaled back to dependent processes automatically. Instead, a special process was invented which ran on each machine and was notified of process death events. Processes had to explicitly register their dependencies on other processes with this special "grim reaper" process in order to receive event-driven notifications.

- **Transparency of service**

  Because ports were tied explicitly to processes, a port defined service could not be moved from one process to another without notifying all parties. Transparent network communication was also compromised by this naming scheme. A port identifier was required to explicitly contain the network host identifier as part of its process number field. As the system expanded from one machine to one network to multiple interconnected networks this caused the port identifier to expand in size -- usually resulting in considerable reimplementation work.

- **Maximum message size**

  The limited size of messages in RIG resulted in a style of interprocess interaction in which large data objects (such as files) had to be broken up into chunks of 2K bytes or less. This constraint impacted on the efficiency of the system (by increasing the amount of message communication) and on the complexity of client/server interactions (e.g., by forcing servers to maintain state information about open files).

2.3. The evolution of RIG

CMU's Spice [8] distributed personal workstation project provided an oportunity to effectively "redo" a RIG-like system taking into account that system's limitations. The result was the Accent operating system kernel for the PERQ Systems Corporation PERQ computer.

The Accent solution to the problems present in the RIG design was based on two basic ideas:

1. **Define ports to be capabilities as well as communication objects.**

   By providing processes with capabilities to ports rather than a global identifier for them, it was possible to solve at one time the problems of protection, failure notification and transparency:

   - Protection in Accent is provided by allowing processes access only to those ports for which they have been given capabilities.

   - Processes can be notified automatically when a port disappears on which those processes are dependent because the kernel now has complete knowledge of which processes have access to each port in the system. There is no hidden communication between processes.

   - Transparency is complete because the ultimate destination of a message sent to a port is unknown by the sender. Thus transparent intermediary processes can be constructed which forward messages between groups of processes without their knowledge (either for the purpose of debugging and monitoring or for the purpose of transparent network communication).

2. **Use virtual memory to overcome limitations in the handling of large objects.**

   The use of a large address space (a luxury not possible in the design of RIG) and copy-on-write memory mapping techniques permits processes to transmit objects as large as they can directly access themselves. This allows processes such as file servers to provide access to large objects (e.g., files) through a single message exchange -- drastically reducing the number of messages sent in the system [9].

The first line of Accent code was written in April 1981. Today Accent is used at CMU in a network of 150 PERQ workstations. In addition to network operating system functions such as distributed process and file management, window management and mail systems, several applications have been built using Accent. These include research systems for distributed signal processing [10], distributed speech understanding [5] and distributed transaction processing [18]. Four separate programming environments have been built -- CommonLisp, Pascal, C and Ada -- including language support for an object-oriented remote procedure call facility [12].

3. The Accent Design

Accent is organized around the notion of a protected, message-based interprocess communication facility integrated with copy-on-write virtual memory management. Access to all services and resources, including the process management and memory management services of the operating system kernel itself, are provided through Accent's communication facility. This allows completely uniform access to such resources throughout the network. It also implies that access to kernel provided services is indistinguishable from access to process provided resources (with the exception of the interprocess communication facility itself).

3.1. Interprocess communication

The Accent interprocess communication facility is defined in terms of abstractions which, as in RIG, are called *ports* and *messages.*

The *port* is the basic transport abstraction provided by Accent. A port is a protected kernel object into which messages may be placed by processes and from which messages may be removed. A port is logically a finite length queue of messages sent by a process. Ports may have any number of senders but only one receiver. Access to a port is granted by receiving a message containing a port capability (to either send or receive).

Ports are used by processes to represent services or data structures. For example, the Accent window manager uses a port to represent a window on a bitmap display. Operations on a window are requested by a client process by sending a message to the port representing that window. The window manager process then receives that message and handles the request. Ports used in this way can be thought of as though they were capabilities to objects in a object oriented system(Jones78). The act of sending a message (and perhaps receiving a reply) corresponds to a cross-domain procedure call in a capability based system such as Hydra [2] or StarOS [11].

A *message* consists of a fixed length header and a variable size collection of typed data objects. Messages may contain both port capabilities and/or imbedded pointers as long as both are properly typed. A single message may transfer up to 2↑32 bytes of by-value data.

Messages may be sent and received either synchronously or asynchronously. A software interrupt mechanism allows a process to handle incoming messages outside the flow of normal program execution.

Figure 3-1 shows a typical message interaction. A process A sends a message to a port P2. Process A has send rights to P2 and receive rights to a port P1. At some later time, process B which has receive rights to port P2 receives that message which may in turn contain send rights to port P1 (for the purposes of sending a reply message back to process A). Process B then (optionally) replies by sending a message to P1.

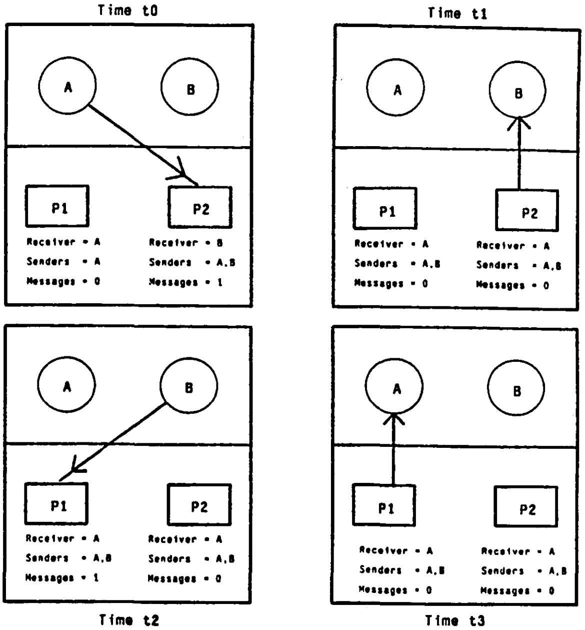

Figure 3-1: Typical message exchange

Should port P2 have been full, process A would have had the option at the point of sending the message to: (1) be suspended until the port was no longer full, (2) have the message send operation return a port full error code, or (3) have the kernel accept the message for future transmission to port P2 with the proviso that no further message can be sent by that process to P2 until the kernel sends a message to A telling it the current message has been posted.

3.2. Virtual memory support

Accent provides a 2↑32 byte paged address space for each process in the system and a 2↑32 byte paged address space for the operating system kernel. Disk pages and physical memory can be addressed by the kernel as a portion of its 2↑32 byte address space. Accent maintains a virtual memory table for each user process and for the operating system kernel. The kernel's address space is paged and all user process maps are kept in paged kernel memory. Only the kernel virtual memory table, a small kernel stack, the PERQ screen, I/O memory and those PASCAL modules required for handling the simplest form of page fault need be locked in physical memory, although in practice parts of the kernel debugger and symbol tables for locked modules are also locked to allow analysis of system errors. The total amount of kernel code and symbol table information locked is 64K bytes [9].

Whenever large amounts of data (the threshold is a system compile-time constant normally set at 1K bytes) are transmitted in a message, Accent uses memory mapping techniques rather than data copying to move information from one process to another within the same machine. The semantics of message passing in Accent imply that all data sent in a message are logically copied from one address space to another. This can be optimized by the kernel by mapping the sent data copy-on-write in both the sending and receiving processes.

Figure 3-2 shows a process A sending a large (for example 24 megabyte) message to a port P1. At the point the message is posted to P1, the part of A's address space containing the message is marked copy-on-write -- meaning any page referenced for writing will be copied and the copy placed instead into A's virtual memory table. The copy-on-write data then resides in the address space of the kernel until process B receives the message. At that point the data is removed from the address space of the kernel. By default, the operating system kernel determines where in the address space of B the newly received message data is placed. This allows the kernel to minimize memory mapping overhead. Any attempt by either A or B to change a 512 byte page of this copy-on-write data results in a copy of that page being made and placed into that process' address space.

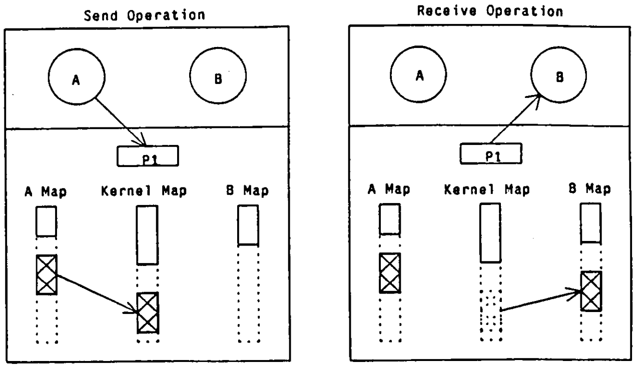

Figure 3-2: Mapping operations during message transfer

3.3. Network communication

The abstraction of communication through ports permits the distinction between access to local and remote resources to be completely invisible to a client process. In addition, Accent exploits the integration of memory management and IPC to provide a number of options in the handling of virtual memory, including the ability to allow memory to be sent copy-on-reference across a network. Each entry of an Accent virtual memory table maps a contiguous region of process virtual memory to a contiguous portion of an Accent *memory object*. A memory object is the basic unit of secondary storage in Accent. Memory objects can be contiguous physical memory (as used for the PERQ screen or I/O buffers) or a randomly addressed disk file. A memory object can also be backed not by disk or main memory, but by a process through a port. Initial references to a page of data mapped to a port are trapped by the kernel and a request for the necessary data is forwarded in a message on that port. This feature allows processes to provide the system with virtual memory that they themselves maintain (either locally or over a network connection to another machine). In this way network communication servers can provide copy-on-reference network transmission of pages in a large message.

4. Key Implementation Issues in Accent

Many of the implementation decisions made in Accent were based on experiences with RIG. Nevertheless, the addition of virtual memory and capability management to the RIG design made it unclear how the RIG experiences would extrapolate to the Accent environment.

4.1. IPC Implementation

The actual implementation of the message mechanism relied on several assumptions about the use of messages:

- the average number of messages outstanding at any given time per process would be small,
- the number of port capabilities needed by a process could vary from two to several hundred, and
- the use of simple messages (meaning messages which contained port capabilities only in their header and which contained less than a few kilobytes) would so dominate complex messages that simple messages would be an important special case.

Each of these assumptions had held true for RIG [4, 14]. It was hoped that although Accent provided a substantially different application environment than RIG, the RIG experiences would provide a reasonable prediction of Accent performance.

Given these expectations, the implementation was optimized for anticipated common cases, including:

- The assumption that there would seldom be more than one message waiting for a process at a time led to an implementation in which messages are queued in per-process rather than per-port queues.
- To allow large numbers of ports per process and fast lookup, port capabilities are represented as indexes into a global port record array stored in kernel virtual memory. Port access is protected through the use of a bitmap of process access rights kept per port (the number of processes is much less than the number of ports).
- The assumption that simple messages would be an important special case led to the addition of a field to the message header so that user processes can indicate whether or not a message is simple and thus allow special handling by the kernel.

These usage assumptions did in fact prove true for Accent. Table 4-1 demonstrates the properties of Accent message passing as measured during an active day of use.

1.01	Average probes to requested message
33.42	Average port rights held per process
14.38	Average ports owned per process
0.094	Ratio of complex to simple messages

Table 4-1: Message use statistics

4.2. Virtual Memory Implementation

The lack of sophisticated virtual memory management in RIG (and in fact in nearly all message-based systems of that era) meant that Accent could not benefit from previous experience with virtual memory use resulting from message operations. Instead, the design of Accent's virtual memory implementation grew out of simple assumptions based purely on intuition. These initial assumptions influenced the design of the Accent virtual memory implementation:

- process maps had to be compact, easy to manipulate and support sparse use of a process address space,
- the number of contiguously mapped regions of the address space would be reasonably small, and
- large amounts of memory would frequently be passed copy-on-write in messages.

The Accent process virtual memory map is maintained as a two-level indirect table terminating in linked lists of entries (see Figure 4-1). Each entry on the linked list maps a contiguous portion of process virtual memory into contiguous regions of Accent memory objects. The map is organized so that large portions can be validated, invalidated or copied without having to modify the linked lists of map entries. This is accomplished by having valid, copy-on-write and write-protect bits at each level of the table. During lookup, these bits are "ored" together. Thus all of memory can be efficiently made copy-on-write by just setting the copy-on-write bits of valid entries in level one of the process map table. Figure 4-1 illustrates the translation of a virtual address to an offset within a memory object.

Physical memory in Accent is used as a cache of secondary storage. There are no special disk buffers. Access to all information (e.g., files) is through message passing (and subsequent page faulting if necessary).

This scheme is flexible enough to be used internally by the kernel to remap portions of its own address space. An entire process virtual memory map, for example, is copied in a fork operation without physically copying the map by using Accent's copy-on-write facility. To reduce map manipulation overheads, changes caused by copy-on-write updates are recorded first in a virtual to physical address translation table (kept in physical memory) and are not incorporated into a process map until the relevant page must be written out to secondary storage.

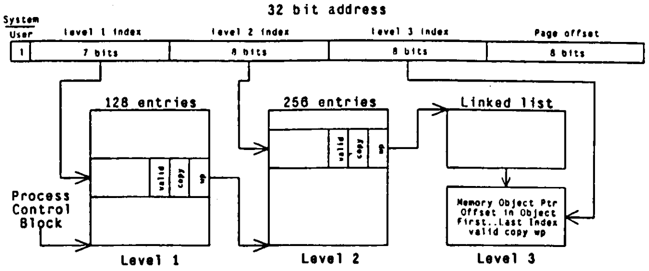

Figure 4-1: Mapping a virtual address in Accent

Copy-on-write access to memory objects is provided through the use of *shadow* memory objects which reflect page differences between a copied object and the object it shadows (which could in turn be a shadow). Disk space for newly created pages or pages written copy-on-write is allocated on an as-needed basis from a special paging area. No disk space is ever allocated to back up a process address space unless the paging algorithms need to flush a dirty page. See figure 4-2.

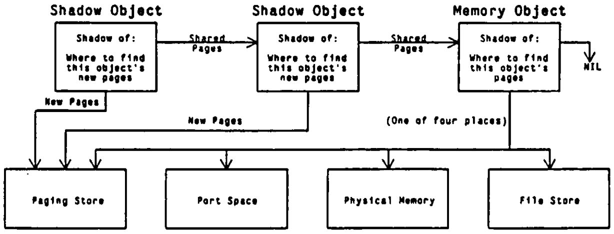

Figure 4-2: An example of memory object shadowing

Most shadow memory objects are small (under 32 pages). Most large shadows contain only a few pages of data different from the objects they shadow. These facts led to an allocation scheme in which small shadows are allocated contiguously from the paging store and larger shadows use a page map and are allocated as needed.

Overall, the basic assumptions about the use of process address space in Accent appear to hold true. The typical user process table:

- is between 1024 and 2048 bytes in size,
- contains 34-70 mapping entries, and
- maps a region of virtual memory approximately eight megabytes in extent (in PERQ PASCAL each separately compiled module occupies a distinct 128K byte region of memory) and about one to two megabytes in size.

Although all memory is passed copy-on-write from one process to another, the number of copy-on-write faults is typically small. A typical PASCAL compile/link/load cycle, for example, requires only slightly more than one copy-on-write fault per second. Clearly most of the data passed by copy in Accent is read and not written. The result is that the logical advantages of copy-on-write are obtained with costs similar to that of mapped shared memory [6].

4.3. Programming issues

One of the problems with message based systems has traditionally been the fact that existing programming languages do not support their message semantics. In RIG, a special remote procedure call function was provided called "Call" [13] which took as its arguments a message identifier, a process-port identifier, and operation arguments along with their type information. One of the early decisions in the implementation of Accent was to define all interprocess message interfaces in terms of a high-level specification language. The properties of ports allow them to be viewed as object references. The interprocess specification language is defined in terms of operations on objects. Subsystem specifications in this language are compiled by a program called Matchmaker into remote procedure call stubs for the various programming languages used in the system -- currently C, PASCAL, ADA and Common LISP. The result is that all interprocess interfaces look to the programmer as though they were procedural interfaces in each of these languages. In PASCAL, for example, the interface procedure for writing a string to a window of the screen would look like:

```
WriteString(window,string-to-be-written)
```

All Matchmaker specified calls take as their first argument the port object on which the operation is to be performed. The remote procedure call stub then packages the request in a message, sends it to the port, and waits for a reply message (if necessary). Initial access to server ports is accomplished either through inheritance (by having the parent process send port rights to its children) or by accessing a name server process (a port for which is typically passed to a process by inheritance). A complete description and specification of Matchmaker can be found in [12].

Matchmaker's specification language allows both synchronous and asynchronous calls as well as the specification of timeouts and exception handling behavior. It supports both by-value and by-value-result parameters. It allows types to be defined as well as the specification of their bit packing characteristics in the message. For the server process, Matchmaker produces routines which allow incoming messages to be decoded and server subroutines automatically invoked with the proper arguments.

The support provided by Matchmaker is similar to some of the features which have been introduced in modern languages for managing multiple tasks such as the ADA rendezvous mechanism [1]. Matchmaker, however, supports a number of different programming languages and provides a much greater range of options for synchronous and asynchronous behavior in a distributed environment.

Despite the obvious simplicity of simple "remote procedure call" style interfaces, a suprisingly high percentage of network operating system interfaces take advantage of the asynchronous form of Matchmaker interfaces. Of 225 system interfaces:

- 170 (approximately 77 percent) are synchronous,
- 45 (approximately 19 percent) are asynchronous and
- 10 (approximately 4 percent) represent exceptions.

Runtime statistics show that over 50 percent of messages actually sent during normal system execution are sent as part of asynchronous Matchmaker specified operations -- normally due to the behaviour of I/O subsystems (such as handlers for the PERQ keyboard and display) or basic system servers (such as network protocol servers).

Matchmaker server interfaces account for approximately 10 percent of the total network operating system code -- roughly 75.5k bytes out of 757k bytes. For the Accent kernel itself, the Matchmaker interface is 10280 bytes out of approximately 115k bytes. Runtime costs are considerably less. During a PASCAL compilation, for example, less than 2 percent of CPU time is due to Matchmaker interface overheads.

4.4. Key Statistics

4.4.1. Hardware and basic system performance of Accent

Table 4-2 compares the relative performance of PERQ and VAX-11/780 CPUs. Timings were performed in PASCAL on the PERQ and in C on a VAX running UNIX 4.1bsd.

PASCAL programs written for the PERQ range in overall speed from 1/5 to 1/3 the speed of comparable programs on the VAX 11/780, depending on whether 16-bit or 32-bit operations predominate. In fairness to the PERQ hardware, the underlying microengine is much faster than the PASCAL timings in table 4-2 would indicate. Microcoded operations often run as fast as or faster than equivalent VAX 11/780 assembly language. Note, for example, the relative speeds of the microcoded context switch and kernel trap operations. Moreover, instruction sets better tuned to the PERQ hardware, such as the Accent CommonLisp instruction set, run at speeds closer to 50 percent of the VAX. Nevertheless, for the purpose of gauging the performance of the Accent kernel code, which is written in PASCAL and makes heavy use of 32-bit arithmetic, pointer chasing and packed field accessing, the CPU speed of a PERQ is about 1/5 that of a VAX 11/780.

Perq	Vax	Ratio	Operation
2300ns	720ns	.31	Tick (32-bit stack local)
12us	4us	.25	Simple loop (16-bit integer)
20us	3us	.17	Simple loop (32-bit integer)
35us	20us	.57	Null procedure call/return
75us	25us	.33	Procedure call with 2 arguments
80us	400us	5.00	Context switch
132us	264us	2.00	Null kernel trap
30s	9s	.30	Baskett Puzzle Program (16-bit)
50s	10s	.20	Baskett Puzzle Program (32-bit)

Table 4-2: Comparison of Perq and Vax-11/780 operation times

4.4.2. IPC Costs

Table 4-3 shows the costs of various forms of message passing in Accent. As was previously described, Accent distinguishes between *simple* and *complex* messages to improve performance of common message operations. Simple messages are defined to be those with less than 960 bytes of in-line data that contain no pointers or port references (other than those in the message header). Other messages are considered complex. The times for complex messages listed in the table were measured for messages containing one pointer to 1024 bytes of data. The observed ratio of simple to complex messages in Accent is approximately 12-to-1.

Time	IPC Operation
1.15	Simple message send
1.35	Simple message receive
10.	Complex message send (1024 bytes)
10.	Complex message receive (1024 bytes)

Table 4-3: IPC operation times in milliseconds

The average number of messages per second observed during periods of heavy standard version use (e.g., compilation) is less than 30. There were 67378 simple messages and 4279 complex messages sent during one measurement of three hours of editing, network file access, and text formatting, an average of less than eight per second [9].

4.4.3. Accessing file data

One of the reasons for the relatively low message rate of message exchange in Accent is the heavy reliance on virtual memory mapping techniques for transferring large amounts of data in messages. A process making a request for a large file typically receives the entire file in a single message sent back from a file server process. As a result, all file access in Accent is mediated through the memory management system. There are no separate file buffers maintained by the system or special operations required for file access versus access to other forms of process mapped memory. By contrast, in RIG the same operation would have required as many message exchanges between client and server as there were pages in the file.

Table 4-4 shows the costs associated with reading a 56K byte file under UNIX 4.1bsd on a VAX 11/780 with a 30 millisecond average access time Fujitsu disk and under the standard version of Accent with a 30 millisecond average access time MAXSTORE drive.

The measured cost of a file access in Accent as shown in table 4-4 is due, in part, to the cost of a disk write to update the file access time. This disk write is unbuffered in Accent and thus is included in the file request time. The Unix disk write associated with an open is buffered and is excluded from the open/close time.

Accent file access speed is limited by the basic fault time of about four milliseconds (see table 4-5), the average number of consecutive file pages on a disk track and the cost of making new VP entries. Its page size is only 512 bytes, in contrast to 1024 bytes for 4.1bsd and 4096 or 8192 for 4.2bsd.

System	Time	Operation
Accent	66	Request file from server
UNIX 4.1	5-10	Open/close
Accent	5-10	Read a page (512 bytes)
UNIX 4.1	16-18	Read a page (1024 bytes)
UNIX 4.2	16-18	Read a page (4096 bytes)

Table 4-4: File access times in milliseconds

Once mapped, file access in Accent ranges from somewhat faster than 4.1bsd to slightly slower, depending on the locality of file pages. 4.2bsd file access [15] is considerably faster than either 4.1bsd or Accent. This increase in speed appears to be due almost entirely to the larger (typically 4096 byte) file page size. The actual number of disk I/O operations per second under 4.2 is almost identical to 4.1, about 50-60 per second, and appears to be bounded by the rotational speed of the disk (60 revolutions per second).

4.4.4. Fault handling and copy-on-write

Table 4-5 summarizes the results from test programs that caused 100,000 instances of a variety of memory fault types. It shows the average total times required to handle single faults.

Total	Type of fault
0.623	Null fault
3.355	Read fault, zero fill
3.704	Write fault, zero fill
3.760	Read fault, memory fill, small file
4.504	Read fault, memory fill, large file
3.833	Write fault, CopyOnWrite copy

Table 4-5: Fault handling times in milliseconds

Overall, the costs of copy-on-write memory management are nearly identical to that of by-reference memory mapping. Less than 0.01 percent of the total time associated with an entire rebuilding of the operating system and user programs from source is used to handle copy-on-write faults [9].

5. Mach: Adapting Accent to Multiprocessors

Accent went beyond demonstrating the feasibility of the message passing approach to building a distributed system. Experience with Accent showed that a message based network operating system, properly designed, can compete with more traditional operating system organizations. The advantages of this approach are system extensibility, protection and network transparency.

By the fall of 1984, however, it became apparent that, without a new hardware base, Accent would eventually follow RIG into oblivion. Hastening this process of electronic decay was Accent's inability to completely absorb the ever burgening body of UNIX developed software both at CMU and elsewhere -- despite the existence of a "UNIX compatibility" package.

Mach was conceived as an Accent-like operating system which would provide complete UNIX compatibility. It was also designed to better accommodate the kind of general purpose shared-memory multiprocessors which appear to be on their way to becoming the successors to traditional general purpose uniprocessor workstations and timesharing systems.

5.1. The design of Mach

The design of Mach differs from that of Accent in several crucial ways:

- The Accent notion of a process, which like RIG is an address space and single program counter, was split into two new concepts:
    1. a *task*, which is the basic unit of resource allocation including a paged address space, protected access to system resources (such as processors, ports and memory), and
    2. a *thread*, which is the basic unit of CPU utilization.
- A facility for handling a form of structured sharing of read/write memory between tasks in the same family tree was added to allow finer granularity synchronization than could be achieved with a kernel provided mechanism.
- The Mach IPC facility was further simplified. This came about as the logical result of using thread mechanisms to handle some forms of asynchrony and error handling (much as was done in the V Kernel [7]).
- The notion of memory object was generalized to allow general purpose user-state external pager tasks to be built.

These design modifications are a consequence of handling shared-memory multiprocessor architectures. Accent provided no tool for fine grain synchronization or lightweight processes. Both are important for effective use of multiprocessor cycles in a variety of applications.

Despite these changes, the basic features which allowed Accent to provide uniform access to both local and network resources are still in place. This allows networks of multiprocessors or of multiprocessors and uniprocessors to be built using the same basic system abstractions. As in Accent, operations on all Mach objects other than messages are performed by sending messages to ports which are used to represent them. For example, the act of creating a task or thread returns access rights to the port which represents the new object and which can be used to manipulate it. A thread can suspend another thread by sending a suspend message to that thread's *thread port*, even across a network boundary.

Tasks are related to each other in a tree structure by task creation operations. Virtual memory may be marked as inheritable to a task's children. Memory regions may be inherited read-write, copy-on-write or not at all. A standard UNIX fork operation, for example, takes the form of a task with one thread creating a child task with a similar single thread of control and all its memory shared copy-on-write.

The notions of multiple threads of control within a task and limited sharing between task allows Mach to provide three levels of synchronization and communication: fine grain, intra-application interprocess communication and inter-application interprocess communication.

Fine grain communication is performed on memory shared either within a task or between related tasks. Mach provides a library to support synchronization on shared memory to avoid the cost of kernel trap operations on short-term locks. Network read/write shared memory is not provided by the kernel, but is potentially implementable by a user-state process acting as an external object pager (see discussion of object pagers below).

Intra-application inter-thread communication is performed using the standard Send and Receive ports primitives but can be implemented more efficiently in the presence of shared libraries and memory. By the nature of the abstractions, threads can ignore the difference between intra-application communication and inter-application communication.

Inter-application communication requires the intervention of the Mach kernel to provide protection. As in Accent, large amounts of data in messages may be mapped copy-on-write from one address space to another rather than copied. Data forwarded in messages over the network can be transmitted on reference rather than all at once at the discretion of the network server.

5.2. Implementation

5.2.1. Virtual memory modifications

While system analysis indicated that the basic Accent virtual memory scheme worked well, it also demonstrated that the data structure used to represent an Accent process map -- a two-level indirect table terminated in linked lists of mapping descriptors -- was unnecessarily complicated. Because nearly all operations on maps are sequential and maps seldom get very large, Mach implements task address maps as simple ordered lists of mapping descriptors. Each descriptor maps a range of virtual addresses to a range of bytes in a memory object. The only non-sequential operation -- lookup events due primarily to memory faults -- is sped by the use of hints based on previous lookup requests.

Another innovation of Mach over Accent is in the use of *sharing maps* to represent read/write shared regions between tasks. A Mach mapping descriptor may point either directly to a memory object (which can then only be shared copy-on-write) or indirectly to memory objects through a sharing map. A sharing map is simply an address map which maps a range of virtual addresses shared by at least two task address maps. All operations on tasks maps in a shared range of addresses are performed through indirection on sharing maps.

Overall, the Mach data structures are simpler, more compact and more expressive than those of Accent. A Mach address map can be thought of as a simple run-length encoding of a process address space. A typical UNIX-style process can be expressed in less than 100 bytes.

5.2.2. Mach IPC

The introduction of the notion of tasks and threads into Mach necessitated some changes to Accent's basic IPC facility. Port access rights in Mach are owned by a task. All threads within a task may therefore send or receive messages on that task's ports.

ՙhe availability of threads to manage asynchronous activities simplified handling of software interrupts. Moreover, several message options, such as message priorities and the ability to preview the contents of a message before it had to be received, had been found to be largely unused for their intended purpose in Accent and have been removed.

5.2.3. Managing hardware diversity

Mach was intended from the outset to handle a wide diversity of both uniprocessor and multiprocessor hardware. For example, Mach provides a task memory sharing and a thread memory sharing model for multiprocessor memory synchronization. This allows Mach to support both multiprocessors which support full memory sharing with cache consistency as well as machines with only partial sharing or explicit memory caching. In practice, the system already is configured to handle a wide range of uniprocessor and multiprocessor VAX configurations. The same binary kernel image is used on both uniprocessor and multiprocessor systems.

Mach also handles another form of diversity. Messages, because they contain tagged data, are transformed from one machine data format to another by network servers. Properly typed Matchmaker interfaces allow programs written on an RT PC to communicate with VAX applications despite different byte ordering, data packing and data format conventions. There are, however, limits on this form of machine independence. For example, no attempt is made to preserve precision of floating point numbers converted from one form to another.

5.2.4. Confronting UNIX

One mechanism for ensuring Mach's survival in the face of a flood of UNIX based software is to make certain that it is compatible with an existing UNIX environment. This was achieved by building Mach to allow UNIX 4.3bsd system calls to be handled in much the same way they would be handled in a completely native system. The Mach kernel effectively supplants the basic system interface functions of the UNIX 4.3bsd kernel: trap handling, scheduling, multiprocessor synchronization, virtual memory management and interprocess communication. 4.3bsd functions are provided by kernel-state processes which are scheduled by the Mach kernel and share communication queues with it. Work is now underway to remove non-Mach UNIX functionality from kernel-state and provide these services through user-state processes.

6. Conclusions

The evolution of network operating systems from RIG through Mach was, in a sense, driven by the evolution of distributed computer systems from small networks of minicomputers in the middle 1970s to large networks of personal workstations and mainframes in the early 1980s to networks of uniprocessor and multiprocessor systems today. Not suprisingly, the basic software primitives of Mach -- task, thread, port, message and memory object -- parallel the hardware abstractions which characterize modern distributed systems -- nodes, processors, network channels, packets and primary and secondary memory. Experiences, both good and bad, with RIG and Accent have played an important role in determining the exact definition of the Mach mechanisms and their implementation.

7. Acknowledgements

In addition to anything the author may have done, the heroes of the RIG kernel development were Gene Ball and Ilya Gertner. Jerry Feldman was in large part responsible for the initial RIG design and the system's name. The Accent development team included George Robertson and Gene Ball as well as the author. Keith Lantz and Sam Harbison made notable contributions to the design. Mary Shaw contributed the name. Others contributed greatly to Accent's evolution: particularly Doug Philips, Jeff Eppinger, Robert Sansom, Robert Fitzgerald, David Golub, Mike Jones and Mary Thompson. Matchmaker could not have come into existence without the aid of Mary Thompson, Mike Jones, Rob MacLachlin and Keith Wright. Mach was the brainchild of many including Avie Tevanian, Mike Young and Bob Baron. Dario Giuse came up with the name.

LOAD BALANCING IN NEST: A NETWORK OF WORKSTATIONS

Ahmed K. Ezzat

Computing Systems Technology Research Department
AT&T Bell Laboratories
Murray Hill, New Jersey 07974

ABSTRACT

This paper describes a fully distributed load balancing model for scheduling processes in a distributed system. The model consists of two modules, information policy module and control policy module. These modules are replicated at every host and they cooperate together to provide a network-wide objective function. The model takes into consideration the imperfect knowledge about the system state, and assumes no a priori knowledge of the new processes description. The scheme is fully distributed, and the algorithm is adaptive and stable. The remote execution phase of the model has been implemented in the NEST distributed system. We give the essential details of the implementation and initial results on its performance. The scheme was tested under a realistic environment using an adapted version of an internal benchmark. The results confirm the feasibility and effectiveness of a simple policy to reduce the response time by dynamically taking advantage of load differences in the network.

1. INTRODUCTION

One of the interesting problems in the design of any distributed computing system is how to improve the overall system performance (i.e., throughput, response time, etc.) by dynamically distributing the load over the entire system. This should be done in a transparent way so that physical boundaries between resources on different hosts are hidden from system users. Optimal load balancing is expensive computationally, and would require a priori knowledge of the run-time characteristics of the workload in the system. Alternatively, it is desirable to have a suboptimal algorithm which requires less information about the workload, can deal with the imperfect knowledge about the system state, and is inexpensive to use.

In this paper, we present an implementation of a decentralized control dynamic load balancing algorithm in NEST [1, 2, 12], a multiprocessor system consisting of a network of AT&T 3B2 computers interconnected with AT&T 3BNET (which is an Ethernet compatible 10 megabit/second local area network). The purpose of this work is to validate the assumptions made in our scheduling model; furthermore, a prototype implementation would give us more insight into the feasibility, effectiveness, and performance of load balancing algorithms under sophisticated and realistic environment. We report our experience on both of these counts.

In the following section we review related research on load balancing. Section 3 gives an overview of our scheduling model. Section 4 discusses the load balancing algorithm in detail. Section 5 presents a brief background about the NEST system. Section 6 describes the benchmark used in evaluating the algorithm. Section 7 discusses the algorithm implementation considerations and gives an initial performance evaluation and its implications. We compare our work to other related systems in Section 8, and give some concluding remarks in Section 9.

2. BACKGROUND

Numerous studies have addressed the problem of load balancing in distributed systems. We found it convenient to review previous work in load balancing by dividing the problem into its three fundamental components and discussing the different approaches for each one individually. These components are namely load balancing mechanism, policy, and cost function formulation. In general these

CH2345-7/86/0000/1138$01.00 © 1986 IEEE

approaches for the different components are not mutually exclusive.

Load balancing can either have a centralized or a decentralized mechanism. In centralized mechanism schemes, the decision making process of assigning processes to different hosts in the network is done at a central controller where the system state is maintained. Stone [28] presented a centralized resource allocation algorithm based on the Ford-Fulkerson maxflow-mincut algorithm in order to maximize flow in commodity networks. Chow and Kohler [8] used a central dispatcher to allocate processes to hosts in order to minimize the mean response time in the network. In decentralized mechanism schemes, processes are scheduled at the arrival host. This approach is faster in making decisions, however it requires more communication overhead to update all hosts with the system state. Also, the policy in such a scheme has to be able to handle inconsistent hosts' view of the system state as a result of communication delays [13,16]. Stankovic [27] presented a heuristic for the effective cooperation of multiple decentralized components of a process scheduling function. The heuristic itself is based on the application of Bayesian decision theory as a systematic approach to complex decision making under conditions of imperfect knowledge.

Load balancing policy can be either static or dynamic. In static load balancing policies, assignment of processes to hosts are done based on a predetermined average behavior of the network and not on the current system state. Tantawi and Towsley [29] presented two decentralized static algorithms. The load balancing scheme is formulated as a nonlinear programming problem. Alternatively, in dynamic policies assignment of processes are done based on the current estimate of the system state. These policies would assign the process upon creation or external arrival permanently to what appears to be the best host at that time. A non-preemptive dynamic policy does not move a process even though its run-time characteristics may prove to be poor later. For example, Bryant and Finkel [5] developed an algorithm for point-to-point interconnection networks. The algorithm uses the current load estimate in forming a set of host pairs that differ greatly in load. Once a pair is formed, the more heavily loaded host decides which processes, if any, to send to the other host. This is based on the greatest expected improvement in the response ratio of the migrant process. On the other hand, a preemptive dynamic policy would reassign the process whenever the system state changes and the run-time characteristics of the process indicates that it would be better to execute the process at some other host.

Finally, a cost function is needed to represent the objective function of the load balancing policy. Depending on the formulation, the policy would solve for the minimum or maximum cost function in the system. Algorithms for process scheduling can be grouped into four main general approaches: mathematical programming [9], graph theoretic [4,7,28,31], queuing theory [19,22,25], and heuristics [5,10,18,20].

In this paper, we propose a decentralized dynamic preemptive scheduling model. The model assumes no a priori knowledge about the execution time of processes. Different hosts in the network may have different views of the system state; it is considered a natural extension to the scheduling function in a single host operating system. The nonpreemptive phase of the model has been implemented under the NEST system. Initial results are presented and its implications on the model are discussed.

3. OVERVIEW OF THE MODEL

Our process scheduling model consists of two modules, the *information policy module* and the *control policy module*. These modules are replicated at every host and they cooperate together to provide a network-wide objective function. The information policy module sends the local host's workload state to the network, and receives the corresponding messages from the network. This information is used by the control policy module in assigning processes to hosts in the network. The control policy module is part of the local host's copy of the distributed operating system and is considered a natural extension to the traditional scheduler in the single host case. Since process scheduling is a critical operating system function, any algorithm must be inexpensive. This precludes the use of any sophisticated algorithms including many potential solutions based on mathematical programming. We envision as a part of the distributed operating system that every host will have a scheduling entity called the "Network Scheduler," (see Fig. 1), to perform three functions:

- **Remote execution** — The remote execution function assigns each newly arrived (or created) process using global strategy to the "run queue" of one of the hosts in the network.
- **Local scheduling** — This function schedules the processor among the processes in the local run queue using a local scheduling discipline (e.g., such as Round Robin with interval Δt).
- **Process migration** — The process migration function, at periodic intervals ($N\Delta t$ where N is very large), uses the estimate of the local load and the estimate of the average load in the network to determine whether to migrate one or more processes to the run queue of another host with less load.

Both remote execution and process migration functions use the information gathered by the information policy module about the network state in making assignment decisions. Issues with the process migration function include the criteria on which to select a process for reassignment, how to prevent processor thrashing (i.e., spending most of the time reassigning processes rather than doing actual work), and finally how often to invoke this function. The process migration function is not addressed further in this paper.

Both control and information policy modules use the communication subsystem of the network to perform their functions. The control policy module sends a *request message* to the target host that describes the process to be initiated and the information policy module sends a *status message* that contains information on that host's workload state.

4. REMOTE EXECUTION

In this section we present an algorithm that implements the *remote execution* function of the Network Scheduler as presented in the previous section. Processes arrive at different hosts in an unpredictable manner, and no a priori knowledge about the process description is assumed. The objective of this algorithm is to balance the *processing load* over the entire network in order to improve the response time with a minimum number of processes movement. Given that this function of the Network Scheduler is performed, the same approach (with suitable constraints) can be adapted to handle processes in execution (i.e., the *process migration* function).

State Representation

Because of the rapid fluctuations in the instantaneous value of the processor load and the communication delays, transmitting the instantaneous value of the host load may result in a nonproductive processes movement. To avoid such situation, we suggest that the instantaneous local host state parameters are taken every T_s units of time, and that it is averaged over a period of time nT_s, where n is the number of samples and defines the window size over which we calculate the state distribution parameters. Every T_u time units, the information policy module calculates the average local host state parameters during the most recent window of time. The new calculated local state is sent to the rest of the network if the calculation differs significantly from the last value transmitted. Both n, T_s, and T_u values are affected by factors such as the speed of the communication subsystem and the nature of the applications used by the network.

This scheme contributes to the system stability as sudden changes in the instantaneous value of the host state would not be completely reflected in its representation until it is proven to be a steady trend rather than a temporary one.

Parameters of the Algorithm

Let M be the number of compute servers available to a specific client host. Let Ψ_j be the processing cost of assigning a new process to host j. Let β be the bias used in the algorithm. The bias is defined as the percentage saving of the local cost below which a process is not moved to another host; it is a function of the load unbalance in the system as we shall see later. Let f_1, f_2 be the weighting factors used in the normalized response time

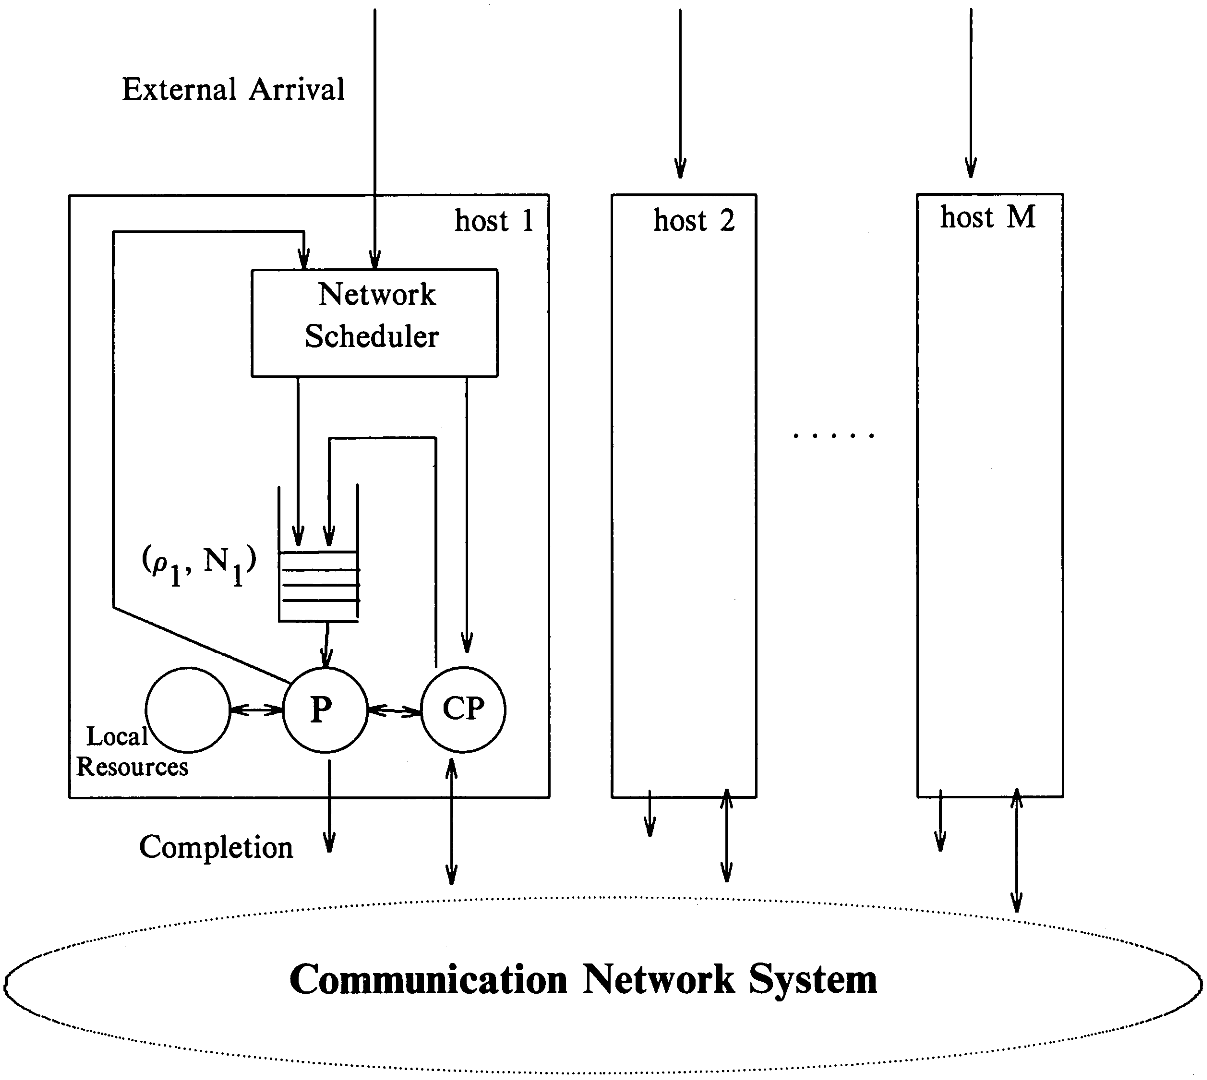

Figure 1. A Distributed Computer Model

formula. The information policy module sends the following state parameters to the rest of the network:

$\bar{N}_j \equiv$ the last updated estimate for the average number of processes at host j.

$\bar{\rho}_j \equiv$ the last updated estimate for the average CPU utilization at host j.

The NRT Algorithm

This algorithm is designed to minimize the *normalized response time* (NRT) for all processes in the network. NRT is defined as the weighted sum of the average number of processes ($\bar{N}$) and the average number of processes during the busy period ($\bar{N}/\bar{\rho}$) over the most recent window in time. The combination of these two parameters is a better description of the load probability density function distribution than just any of the two parameters individually. This is because they represent the average and the peak of the load distribution. Notice that we do not distinguish between user processes, system processes (i.e., swapper, etc.), and network server processes (i.e., network server, file server, or dispatcher server). The cost function Ψ_j to assign a process to host j is defined as the ratio of time needed to complete this process at host j to the time required by the process from host j; ($\Psi_j \geqslant 1$) due to the fact that the process may be sharing the processor with other processes.

Assume that an external process arrives at host i. The following steps are carried out by the Network Scheduler at host i.

Step 1. Calculate the cost function for assigning the process locally, Ψ_i.

$$\overline{NRT_i} = \begin{cases} 0, & \text{if } \overline{\rho}_i = 0. \\ f_1\overline{N}_i + f_2(\frac{\overline{N}_i}{\overline{\rho}_i}), & \textit{otherwise.} \end{cases}$$

$$\Psi_i = \overline{NRT_i}+1$$

Step 2. Calculate the cost function Ψ_j for every host j in the network.

$$\Psi_j = \overline{NRT_j}+1$$
$$\text{for } j = 1, 2, .., i-1, i+1, .. , M$$

Calculate the average cost function in the network, Ψ_a.

$$\Psi_a = \frac{1}{M} \; (\; (\sum_{j=1}^{M} \overline{NRT_j}) + 1 \;)$$

If the local cost is less than or equal to the average cost in the network ($\Psi_i \leqslant \Psi_a$), the process is assigned to the local run queue and the algorithm terminates. This comparison is intended to minimize process movement and contribute to the scheduler stability.

Step 3. Calculate the bias against process movement, δ.

$$\delta = \beta\Psi_i$$

Find the set of hosts in the network having the minimum cost function Ψ_m. If Ψ_m is less than the local cost Ψ_i by at least the bias against process movement ($\Psi_m \leqslant \Psi_i - \delta$), the process is assigned to host m, otherwise it is assigned to the local host. If there is more than one host with minimum cost, one is selected at random.

We conclude this section with a note about incorporating the processor capacity in our algorithm. Let C_j denote the CPU capacity of host j (measured in any commonly units). If $C_j = 2C_i$, and the two hosts have the same load, then the expected response time of host j is half that of host i. Then the normalized cost function formula at host j, $\overline{\Psi}_j$, is defined as $\overline{\Psi}_j = \Psi_j/C_j$. In all results shown in this paper, all processors have the same capacity; therefore $\overline{\Psi} = \Psi$.

5. OVERVIEW OF THE NEST SYSTEM

In NEST, we consider a computing environment that consists of a network of highly autonomous yet cooperative personal computer workstations and shared servers. These computers are interconnected via AT&T 3BNET hardware, which is an Ethernet compatible 10 megabit/second local area network. An important aspect of NEST is to provide processor sharing by creating a pool of compute servers in the network that may be used by the workstations to supplement their computing needs. Some processors are permanently designated to be compute servers. In addition, through an advertisement mechanism [12], any workstation may make itself temporarily available for a specific duration of time to be used as a compute server. Each processor runs the NEST system [1,2,12]. The basic software building block for developing parallel and distributed applications is the "rexec" primitive [1] which provides the execution location independent remote execution capability. At the user level, the remote execution can be initiated as follows,

```
rexec [-s host-name]
      "command string"
```

where host-name specifies the target compute server at which the "command string" to be executed. The "command string" may include a compound operation such as pipe, standard input/output redirection, background execution, etc. It is also possible to initiate the remote execution of a "command string" at the program level by *execing* the *rexec* from a C program [17]. This *rexec* capability allows processes to be offloaded to a compute server and preserves the execution environment of these processes as if they were still executing locally at the originating host. The execution location independent capability is achieved by preserving the process view of the file system (i.e., treating the CPU and the file system as a separate and independent resources), parent-child relationships, process group relationship, and process signaling across machine boundaries in a transparent way.

In NEST, each workstation has its own file tree which is configured from the available network file resources. It is likely that system commands such as *nroff*, *cc*, etc. are replicated at every machine. The SWITCH variable capability gives the user a *system controlled capability* to access absolute pathnames either from the local tree or the compute server tree. This capability is used to alleviate copying system files across the network. Another example of using the SWITH capability is temporary files which would be more efficiently created at the machine on which the process is executing. This is because by default temporary files are deleted at the end of the operation.

To have a feeling for the penalty of remotely executing a process in NEST as well as to demonstrate the use of the SWITCH capability, we measured the response time for both local and remote compilation. Table 1 depicts the penalty of compiling a 26 Kbytes source file remotely using different values for the SWITCH variable. The penalty includes both overheads of remotely invoking the compilation operation and accessing/creating remote files during the compilation. When the SWITCH was set to NULL, all system files (cc, comp, cpp, as, ld, etc.), temporary files (symbol table file, etc.), include files in the source file, and source and output files were accessed or created on the originating machine. The penalty in this case for remotely compiling the source file was 55.6% relative to the local compilation. When the SWITCH was set to "/bin:/lib:/tmp", only input and output files were accessed or created on the originating machine. The penalty in this case dropped to 6% relative to the local compilation. For more details about the remote execution and the SWITCH capability refer to [1].

6. WORKLOAD BENCHMARK

In this section, we present an adapted version of an internal benchmark [15] which is widely used to give a picture of the global UNIX[†] system performance rather than measurements of individual components (e.g., CPU, file system). The benchmark uses a scaling technique which allows measuring the degree to which a time sharing system manages concurrent, competing demands for system resources. The workload is represented by a script of interactive commands. A model was constructed by measuring three days of activity on a UNIX system in a development environment. The script workload was constructed so that resources are consumed in the same proportions as the real workload model. The representative script consists of atomic sequence of commands including compile, load, execute, text format, file edit, spelling check, searching for and copying files, etc. Multiple scripts can be initiated in parallel to increase the level of concurrency. In this case, the ordering of the set of commands in the different scripts are permuted in order to avoid synchronization problem, i.e., all simulated users execute the same command at the same time. This approach allows each instance of the workload to be different, while imposing the same overall amount of work on the system.

In measuring performance for our implemented load balancing algorithm, different loads (i.e., light, moderate, and heavy) are represented by different number of scripts executing concurrently. Performance measures include the average host response time (a script is the unit of load rather than individual commands), average system response time, percentage of commands remotely executed, and the CPU utilization over the life time of the workload.

7. IMPLEMENTATION OF NRT ON NEST

Host's State Measurement

The mechanism used for measuring the local processor load parameters is turned on automatically whenever a processor advertises

	SWITCH= /bin:/lib:/tmp	6%

TABLE 1. Compilation Penalty Measurements

itself as a compute server and is turned off otherwise.

Because parameters needed in our algorithm $(\bar{N}, \bar{p})$ are already computed and available in an accounting data structure in the kernel, we found it convenient to sample this information every second (i.e., select T_s= 1*sec*) in the clock interrupt service routine. In order to tune the other parameters of the information policy module, we have taken measurements of the overhead incurred by the NEST system to move a process and resume its execution at a compute server. For a source program of size 2*Kbytes*, the difference between local and remote compilation is 2.5 seconds. This overhead includes moving the process environment, process view of the file system; it also include copying user source program, system programs (i.e., cc, cpp, ld, etc.), and output module across the network. This would suggest [11] that an update rate of 3 seconds (T_u= 3*sec*), and window size of 6 seconds (n= 6 samples) would help in alleviating the effect of load fluctuations between the time of selecting a compute server and resuming execution at the compute server.

Every T_u= 3*sec*, the clock interrupt service routine wakesup a *state server* kernel process to calculate the local state parameters. If it is different significantly from the last broadcasted value, a state update message is sent to the list of clients previously advertised by this compute server.

On the reception of a state update message by the network server [12] at a client host, the new server's state is updated in the appropriate entry at the server state kernel table. This information is used by the load balancing policy to assign an *rexeced* process to a host in the network.

Bias Selection

The bias β value as expected is very much dependent on the underlying system and the load differences in the network. In a network where the load differences among the different hosts is small, processes movement should be discouraged as the overhead of moving the process may not counterbalance the gain from executing the process remotely. This means a higher bias for fairly balanced networks than that needed for unbalanced loaded networks. Optimal bias values for typical balanced and unbalanced loads were deducted from experiments discussed below and then plugged back into the algorithm as a list. The algorithm indexes the appropriate bias value from the list depending upon the current load differences in the network. This modification does not impose significant overhead as these information are simple to extract.

Policy Implementation

The *rexec* command discussed earlier has been modified as follows,

```
rexec [-s host-name]
      [-g group-name]
      "command string"
```

Using only the "s" option, the system will behave exactly as discussed earlier. If no options are specified, the system applies the NRT algorithm to assign the "command string" request either locally or to any of the available compute servers. If the option "g" is specified, the system applies the NRT algorithm to assign the "command string" request to a host from the group of hosts defined by the alias group-name. Information about the compute servers' load parameters are accessed from the kernel server state table.

This table is maintained by the *state server* process as discused before.

System Resources Considerations

In a case where system resources (e.g., process table entry) are near fully utilized, newly forked processes are forced to rexec remotely if compute servers are available.

Initial Performance Evaluation

In this section, we present results of the remote execution function of our process scheduling model. The load balancing algorithm was tested in a network of three AT&T 3B2 computers interconnected via 3BNET hardware. All computers are functioning as a client and a compute server simultaneously. Different loads in the network (light, moderate, and heavy) are represented by different number of scripts executing concurrently. The selected set of loads have a wide range of load differences among the hosts in the network. The three sets of load parameters are shown in Table 2.

First, we note that in NEST all objects, except processes, are static, i.e., they do not migrate across host boundaries. Examples of such objects are files, devices, etc. These objects however can be shared by some or all hosts in the network. Access to such objects may be originated at any host, but it is performed in the host where the object physically resides using a pool of file servers. In our experiment, we generated enough number of file servers so that they do not contribute degradation to the response time in the system.

The results shown here used the following set of parameters: sampling time $T_s = 1sec$, number of samples $n = 6$, update rate $T_u = 3sec$, and weighting factors for the NRT formula $f_1 = f_2 = 0.5$. In all tests, in order to maintain the same load throughout the tests, the scripts were executed in a loop, i.e., upon completion each script restarts.

We are presenting here three set of tests, e.g., light, moderate, and heavy loads, each including two phases. In the first phase, the load balancing algorithm is enabled and the bias β is varied over a wide range of values. Performance measurements includes the average host response time, average system response time, percentage of processes movement, and the CPU utilization. In the second phase, we run the same set of tests with the load balancing algorithm disabled, i.e., commands in the scripts were executed locally and recorded the same performance measurements. Notice that in the second phase the SWITCH value is irrelevant. The purpose of the second phase is to give an upper bound to our load balancing algorithm. The tests proceeded as follows:

For light balanced load with the SWITCH set to NULL, whose results is shown in Table 3, the algorithm needed high bias 75% to prohibit nonproductive processes movement. The gain achieved at bias 75% is also negligible (less than 1%) as was expected. In general, at low bias, processes movement was nonproductive and degraded the average system response time relative to the nonload balancing case.

For a moderate unbalanced load with the SWITCH set to NULL, whose results is shown in Table 4, the test demonstrates the potential advantage of remote process assignment. In spite of the fact that the load (i.e., scripts) has commands which cost much less than the process movement cost (i.e., local execution of *ls* command costs around 0.8*sec*), the algorithm achieved on the average system-wide gain of 17% at bias value of 50% over the nonload balancing case. Also, we point out that the CPU utilization is almost evenly utilized. The difference in response time between Phase-1 results with 75% bias and Phase-2 results in Table 4 is due to the overhead of the control and information policy modules. When the SWITCH was set to "/bin:/lib:/tmp", the average system response time at bias of 50% was 8 minutes and 25 seconds, i.e., 35% improvement over the nonload balancing case.

For a heavy balanced load with the SWITCH set to NULL, whose results is shown in Table 5, these test results are very similar to the light balanced load case. The algorithm needed high bias of 75% to prohibit nonproductive processes movement. The gain achieved at bias 75% is negligible (less than 1%). At low bias of 25% processes movement was nonproductive and reduced 8.3% degradation in the average system response time.

We conclude this section with a note about selecting the bias value dynamically. The

system rpt	19:58			19:31			18:22			18:26		

TABLE 5. Heavy Balanced Workload Set (response time in minutes:seconds)

NRT algorithm was modified so that if the current ratio of the maximum host estimated load to the minimum one is greater than or equal to 4, the bias is selected to be 50%; otherwise, it is selected to be 75%. Different tests have been conducted using the automatic bias selection and resulted in a consistent response time improvement; however, we feel that more study is needed in this area.

8. RELATED WORK

Our work is related to processor sharing and load balancing in distributed systems. Processor sharing has been an issue of research in many distributed systems like Arachne [14], Accent [24], Cambridge Distributed System [21], DEMOS/MP [23]. However, it is difficult to draw parallels with our work because even though some of these systems support transparent remote process execution, none have reported system wide automatic scheduling. Other systems such as the *Worm* programs [26] have developed the notion of multi-segment worm programs. The warm mechanism is built into each program, necessitating modification in user programs. While the stress in the worm system is on failure recovery and making use of idle workstations, we stress on preserving the user applications without any changes, and load balancing across multi-user machines.

Locus provides preemptable remote execution [6]. The Locus system is geared toward providing a *single virtual machine*, meanwhile in a workstation environment we stress on autonomy. As a consequence, many design and implementations issues are very different.

A network-transparent remote execution facility has also been designed for the V-system [30] that allows a user of a workstations to offload programs onto idle workstations. The emphasis in this work is similar to the Worm programs system in making use of idle workstations rather than load balancing across a multi-user machines. Also, there are no reported results indicating the benefit of automatic scheduling to make a meaningful comparison.

Recently, a decentralized dynamic load balancing policy on the MOS system has been reported [3]. The scheduling policy used the average number of processes during the busy period as the measure of the machine's load. Our algorithm uses more sophisticated measure for representing the machine's load. Using the SWITCH capability in NEST, the average system response time improvement in our scheme without the process migration phase is much higher than those reported in MOS. However, more information is needed about the workload used in testing the load balancing algorithm to make more accurate comparison.

9. CONCLUDING REMARKS

In this paper we described the organization of a load balancing scheme implemented in the NEST distributed system. The scheme consists of two modules, the information policy module and the control policy module. The remote execution phase of the model has been implemented and many of its primitives will be also used for the process migration phase. The remote execution algorithm assigns processes to hosts in order to improve the overall system response time. The algorithm is adaptive in the sense that host's view of the network state is updated to reflect changes in the network workload, and the bias is selected dynamically depending on the current load unbalance in the network.

Some details of the load balancing scheme were described and initial results on its performance were given. The scheme was tested under a realistic environment. The main implication of these results is that, it is possible to reduce the response time by dynamically taking advantage of load differences in the system.

In the conduction of this work we have identified several issues which require further study. One issue is that it may prove to be useful to make assignment decisions for new processes after allowing them to execute locally at least an amount of time equal to the cost of moving the process. This would require studying the tradeoffs between the gain in performance by filtering inexpensive processes from being remotely executed and the extra cost of moving the process after it starts execution.

Checkpointing and Rollback-Recovery for Distributed Systems[*]

Richard Koo[**]
Sam Toueg[†]

Department of Computer Science
Cornell University
Ithaca, New York 14853

ABSTRACT

We consider the problem of bringing a distributed system to a consistent state after transient failures. We address the two components of this problem by describing a distributed algorithm to create consistent checkpoints, as well as a rollback-recovery algorithm to recover the system to a consistent state. In contrast to previous algorithms, they tolerate failures that occur during their executions. Furthermore, when a process takes a checkpoint, a minimal number of additional processes are forced to take checkpoints. Similarly, when a process rolls back and restarts after a failure, a minimal number of additional processes are forced to roll back with it. Our algorithms require each process to store at most two checkpoints in stable storage. This storage requirement is shown to be minimal under general assumptions.

1. Introduction

Checkpointing and rollback-recovery are well-known techniques that allow processes to make progress in spite of failures[12]. The failures under consideration are transient problems such as hardware errors and transaction aborts, i.e., those that are unlikely to recur when a process restarts. With this scheme, a process takes a checkpoint from time to time by saving its state on stable storage[9] When a failure occurs, the process rolls back to its most recent checkpoint, assumes the state saved in that checkpoint, and resumes execution.

We first identify consistency problems that arise in applying this technique to a distributed system. We then propose a checkpoint algorithm and a rollback-recovery algorithm to restart the system from a consistent state when failures occur. Our algorithms prevent the well-known "domino effect" as well as livelock problems associated with rollback-recovery. In contrast to previous algorithms, they are fault-tolerant and involve a minimal number of processes. With our approach, each process stores at most two checkpoints in stable storage. This storage requirement is shown to be minimal under general assumptions.

The paper is organized as follows: We discuss the notion of consistency in a distributed system in section 2, and describe our system model in section 3. In section 4 we identify the problems to be solved. Sections 5 and 6 contain the checkpoint and rollback-recovery algorithms respectively. The algorithms are extended for concurrent executions in section 7. In section 8 we consider optimizations. Sections 9 and 10 contain a discussion and our conclusion.

2. Consistent Global States in Distributed Systems

The notion of a consistent global state is central to reasoning about distributed systems. It was considered by Randell[11], Russell[13], and Presotto[10], and formalized by Chandy and Lamport[2]. In this section, we summarise their ideas.

In a distributed computation, an *event* can be a spontaneous state transition by a process, or the sending or receipt of a message. Event a *directly happens before*[8] event b if and only if

(1) a and b are events in the same process, and a occurs before b; or

(2) a is the sending of a message m by a process and b is the receiving of m by another process.

CH2345-7/86/0000/1150$01.00 © 1986 IEEE

The transitive closure of the *directly happens before* relation is the *happens before* relation. If event a happens before event b, b *happens after* a. (We abbreviate *happens before*, "before" and *happens after*, "after".)

A *local state* of a process p is defined by p's initial state and the sequence of events that occurred at p. A *global state* of a system is a set of local states, one from each process. The *state of the channels* corresponding to a global state s is the set of messages sent but not yet received in s. We can depict the occurrences of events over time with a time diagram, in which horizontal lines are time axes of processes, points are events, and arrows represent messages from the sending process to the receiving process. In this representation, a global state is a cut dividing the time diagram into two halves. The state of the channels comprises those arrows (messages) that cross the cut. Figure 1 is a time diagram for a system of four processes.

Informally, a cut (global state) in the time diagram is *consistent* if no arrow starts on the right hand side and ends on the left hand side of it. This notion of consistency fits the observation that a message cannot be received before it is sent in any temporal frame of reference. For example, the cuts c and c' in Figure 1 are consistent and inconsistent cuts, respectively. The state of the channels corresponding to cut c consists of one message from p to q, and another message from s to r. Readers are referred to the work of Chandy and Lamport[2] for a formal discussion of consistent global states.

3. System Model

The distributed system considered in this paper has the following characteristics:

(1) Processes do not share memory or clocks. They communicate via messages sent through reliable first-in-first-out (FIFO) channels with variable nonzero transmission time.

(2) Processes fail by stopping, and whenever a process fails, all other processes are informed of the failure in finite time. We assume that processes' failures never partition the communication network.

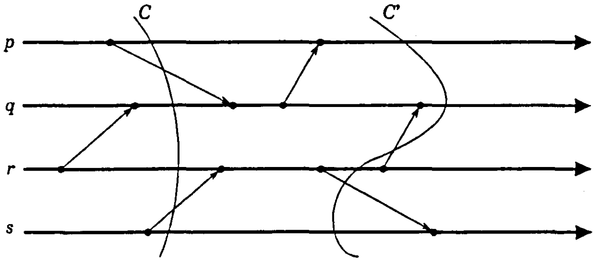

FIG. 1. Consistent and inconsistent cuts in a distributed system

We want to develop our algorithms under a weak set of assumptions. In particular, we do not assume that the underlying system is a database transaction system[4,6]. This special case admits simpler solutions: the mechanisms that ensure atomicity of transactions can hide inconsistencies introduced by the failure of a transaction. Furthermore, we do not assume that processes are deterministic: this simplifying assumption is made in previous results[6,16].

4. Identification of Problems

A checkpoint is a saved local state of a process. A set of checkpoints, one per process in the system, is consistent if the saved states form a consistent global state. For example, consider the system history in Figure 2. Process p takes a checkpoint at time X and then sends a message to q. After receiving this message, q takes a checkpoint at time Y. Subsequently, p fails and restarts from the checkpoint taken at X. The global state at p's restart is inconsistent because p's local state shows that no message has been sent to q, while q's local state shows that a message from p has been received. If p and q are processes supervising a customer's account at different banks, and the message transfers funds from p to q, the customer will have the funds at *both* banks when p restarts. This inconsistency persists even if q is forced to roll back and restart from its checkpoint taken at Y.

The problem of ensuring that the system recovers to a consistent state after transient failures has two components: checkpoint creation and rollback-recovery; we examine each one in turn.

4.1. Checkpoint Creation

There are two approaches to creating checkpoints. With the first approach, processes take checkpoints independently and save all checkpoints on stable storage. Upon a failure, processes must find a consistent set of checkpoints among the saved ones. The system is then rolled back to and restarted from this set of checkpoints[1,5,14,19].

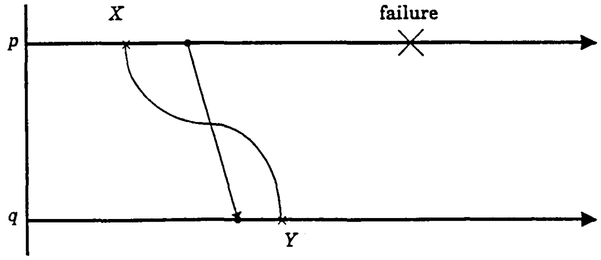

FIG 2. Inconsistent checkpoints.

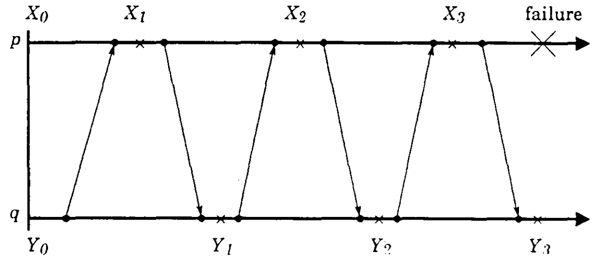

FIG. 3. "Domino effect" following a failure.

With the second approach, processes coordinate their checkpointing actions such that each process saves only its most recent checkpoint, and the set of checkpoints in the system is guaranteed to be consistent. When a failure occurs, the system restarts from these checkpoints[17].

The main disadvantage of the first approach is the "domino effect" as illustrated in Figure 3[10,11]. In this example, processes p and q have independently taken a sequence of checkpoints. The interleaving of messages and checkpoints leaves no consistent set of checkpoints for p and q, except the initial one at $\{X_0, Y_0\}$. Consequently, after p fails, both p and q must roll back to the beginning of the computation. For time-critical applications that require a guaranteed rate of progress, such as real time process control, this behavior results in unacceptable delays. An additional disadvantage of independent checkpoints is the large amount of stable storage required to save all checkpoints.

To avoid these disadvantages, we pursue the second approach. In contrast to Tamir[17], our method ensures that when a process takes a checkpoint, a minimal number of additional processes are forced to take checkpoints.

4.2. Rollback-Recovery

Rollback-recovery from a consistent set of checkpoints appears deceptively simple. The following scheme seems to work: Whenever a process rolls back to its checkpoint, it notifies all other processes to also roll back to their respective checkpoints. It then installs its checkpointed state and resumes execution. Unfortunately, this simple recovery method has a major flaw. In the absence of synchronization, processes cannot all recover (from their respective checkpoints) simultaneously. Recovering processes asynchronously can introduce livelocks as shown below.

Figure 4 illustrates the histories of two processes, p and q, up to p's failure. Process p fails before receiving the message n_1, rolls back to its checkpoint, and notifies q Then p recovers, sends m_2, and receives n_1. After p's recovery, p has no record of sending m_1, while q has a record of its receipt. Therefore the global state is inconsistent. To restore consistency, q must also roll back (to "forget" the receipt of m_1) and notify p. However, after q rolls back, q has no record of sending n_1 while p has a record of its receipt. Hence, the global state is inconsistent again, and upon notification of q's rollback, p must roll back a second time. After q recovers, q sends n_2 and receives m_2. Suppose p rolls back before receiving n_2 as shown in Figure 5. With the second rollback of p, the sending of m_2 is "forgotten". To restore consistency, q must roll back a second time. After p recovers it receives n_2, and upon notification of q's rollback, it must roll back a third time. It is now clear that p and q can be forced to roll back forever, even though no additional failures occur.

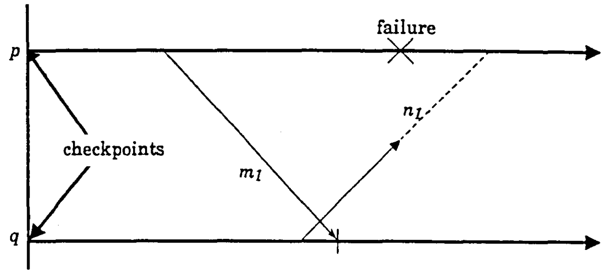

FIG. 4. Histories of p and q up to p's failure.

Our rollback-recovery algorithm solves this livelock problem. It tolerates failures that occur during its execution, and forces a minimal number of processes to roll back after a failure. However, in Tamir[17], a single failure forces the system to roll back as a whole. Furthermore, the system crashes (and does not recover) if a failure occurs while it is rolling back.

5. Checkpoint Creation

5.1. Naive Algorithms

From Figure 2 it is obvious that if every process takes a checkpoint after every sending of a message, and these two actions are done atomically, the set of the most recent checkpoints is always consistent. But creating a checkpoint after every send is expensive. We may naively reduce the cost of the above method with a strategy such

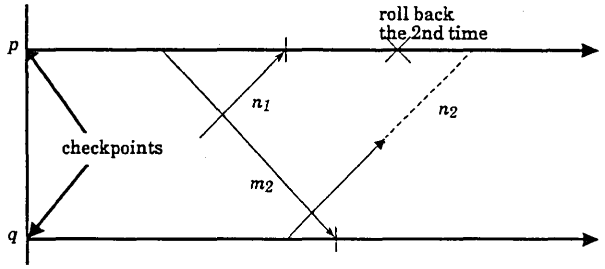

FIG. 5. History of p and q up to p's 2nd rollback.

as "every process takes a checkpoint after every k sends, $k > 1$" or "every process takes a checkpoint on the hour". However, the former can be shown to suffer domino effects by a construction similar to the one in Figure 3, while the latter is meaningless for a system that lacks perfectly synchronized clocks.

5.2. Classes of Checkpoints

Our algorithm saves two kinds of checkpoints on stable storage: permanent and tentative. A permanent checkpoint cannot be undone. It guarantees that the computation needed to reach the checkpointed state will not be repeated. A tentative checkpoint, however, can be undone or changed to be a permanent checkpoint. When the context is clear, we call permanent checkpoints "checkpoints".

Consider a system with a consistent set of permanent checkpoints. A checkpoint algorithm is *resilient* to failures if the set of permanent checkpoints is still consistent after the algorithm terminates, even if some processes fail during its execution. To exclude the impractical "naive" algorithm (in last section) from our consideration, henceforth, we consider only those systems where processes either cannot afford to take a checkpoint after every send, or cannot combine the sending of a message and the taking of a checkpoint into one atomic operation. The following theorem shows that checkpoint algorithms for these systems must store at least two checkpoints in stable storage to be resilient to failures. (The proofs of all lemmas and theorems in this paper can be found in Koo and Toueg[7].)

Theorem 1: No resilient checkpoint algorithms that take only permanent checkpoints exist. □

Theorem 1 shows that in those systems we consider, any resilient checkpoint algorithm must store at least two checkpoints on stable storage.

5.3. Our Checkpoint Algorithm

We assume the algorithm is invoked by a single process that wants to take a permanent checkpoint. We also assume that no failures occur in the system. In section 5.3.4 we extend the algorithm to handle failures, and in section 7 we describe concurrent invocations of this algorithm.

5.3.1. Motivation The algorithm is patterned on two-phase-commit protocols. In the first phase, the initiator q takes a tentative checkpoint and requests all processes to take tentative checkpoints. If q learns that all processes have taken tentative checkpoints, q decides all tentative checkpoints should be made permanent; otherwise, q decides tentative checkpoints should be discarded. In the second phase, q's decision is propagated and carried out by all processes. Since all or none of the processes take permanent checkpoints, the most recent set of checkpoints is always consistent.

However, our goal is to force a minimal number of processes to take checkpoints. The above algorithm is modified as follows: a process p takes a tentative checkpoint after it receives a request from q *only if* q's tentative checkpoint records the receipt of a message from p, and p's latest permanent checkpoint does not record the sending of that message. Process p determines whether this condition is true using the label appended to q's request. This labeling scheme is described below.

Messages that are not sent by the checkpoint or rollback-recovery algorithms are *system* messages. Every system message m contains a label $m.l$. Each process appends outgoing system messages with monotonically increasing labels. We define $\perp$ and $\top$ to be the smallest and largest labels, respectively. For any processes q and p, let m be the last message that q received from p after q took its last permanent or tentative checkpoint. Define:

$$\mathit{last\_rmsg}_q(p) = \begin{cases} m.l & \text{if } m \text{ exists} \\ \perp & \text{otherwise} \end{cases} .$$

Also, let m be the first message that q sent to process p after q took its last permanent or tentative checkpoint. Define:

$$\mathit{first\_smsg}_q(p) = \begin{cases} m.l & \text{if } m \text{ exists} \\ \perp & \text{otherwise} \end{cases} .$$

When q requests p to take a tentative checkpoint, it appends $\mathit{last\_rmsg}_q(p)$ to its request; p takes the checkpoint only if $\mathit{last\_rmsg}_q(p) \geq \mathit{first\_smsg}_p(q) > \perp$.

5.3.2. Informal Description Process p is a *ckpt_cohort* of q if q has taken a tentative checkpoint, and $\mathit{last\_rmsg}_q(p) > \perp$ before the tentative checkpoint is taken. The set of ckpt_cohorts of q is denoted $\mathit{ckpt\_cohort}_q$. Every process p keeps a variable $\mathit{willing\_to\_ckpt}_p$ to denote its willingness to take checkpoints. Whenever p cannot take a checkpoint (for any reason), $\mathit{willing\_to\_ckpt}_p$ is "no". The initiator q starts the checkpoint algorithm by making a tentative checkpoint and sending a request "take a tentative checkpoint and $\mathit{last\_rmsg}_q(p)$" to all $p \in \mathit{ckpt\_cohort}_q$. A process p *inherits* this request if $\mathit{willing\_to\_ckpt}_p$ is "yes" and $\mathit{last\_rmsg}_q(p) \geq \mathit{first\_smsg}_p(q) > \perp$. If p inherits a request, it takes a tentative checkpoint and sends "take a tentative checkpoint and $\mathit{last\_rmsg}_p(r)$" requests to all $r \in \mathit{ckpt\_cohort}_p$. If p receives but does not inherit a request from q, p replies $\mathit{willing\_to\_ckpt}_p$ to q.

After p sends out its requests, it waits for replies that can be either "yes" or "no", indicating a ckpt_cohort's acceptance or rejection of p's request. If any reply is "no", *willing_to_ckpt*$_p$ becomes "no"; otherwise *willing_to_ckpt*$_p$ is unchanged. Process p then sends *willing_to_ckpt*$_p$ to the process whose request p has inherited. From the time p takes a tentative checkpoint to the time it receives the decision from the initiator, p does not send any system messages.

If all the replies from its ckpt_cohorts arrive and are all "yes", the initiator decides to make all tentative checkpoints permanent. Otherwise the decision is to undo all tentative checkpoints. This decision is propagated in the same fashion as the request "take a tentative checkpoint" is delivered. A process discards its previous checkpoints after it takes a new permanent checkpoint.

The algorithm is presented in Figure 6. For simplicity, we create a fictitious process called *daemon* to assume the initiation and decision tasks of the initiator. In practice, daemon is a part of the initiator process.

5.3.3. Proofs of Correctness

We consider a single invocation of the algorithm, and we assume no process fails in the system.

Lemma 1: Every process inherits at most one request to take a tentative checkpoint. □

Lemma 2: Every process terminates its execution of Algorithm C1. □

The next lemma shows that C1 takes a consistent set of checkpoints.

Lemma 3: If the set of checkpoints in the system is consistent before the execution of Algorithm C1, the set of checkpoints in the system is consistent after the termination of C1. □

We now show the number of processes that take new permanent checkpoints during the execution of Algorithm C1 is minimal. Let $P=\{p_0, p_1, \cdots, p_k\}$ be the set of processes that take new permanent checkpoints in C1, where p_0 is the initiator of C1. Let $C(P)=\{c(p_0), c(p_1), \cdots, c(p_k)\}$ be the new permanent checkpoints taken by processes in P. Define an alternate set of checkpoints: $C'(P)=\{c'(p_0), c'(p_1), \cdots, c'(p_k)\}$ where $c'(p_0) = c(p_0)$ and for $1 \leq i \leq k$, $c'(p_i)$ is either $c(p_i)$ or the checkpoint p_i had before executing C1.

Theorem 2: $C'(P)$ is consistent if and only if $C'(P)=C(P)$.

```
Daemon process:

send(initiator, "take a tentative checkpoint and ⊤");
await(initiator, willing_to_ckpt_initiator);**
if willing_to_ckpt_initiator = "yes" then
  send(initiator, "make tentative checkpoint permanent")
else
  send(initiator, "undo tentative checkpoint")
fi.

All processes p:

INITIAL STATE:
  first_smsg_p(daemon) = ⊤;
  willing_to_ckpt_p = { "yes" if p is willing to checkpoint
                      { "no"  otherwise                      ;

UPON RECEIPT OF "take a tentative checkpoint and
  last_rmsg_q(p)" from q DO
  if willing_to_ckpt_p and last_rmsg_q(p) ≥ first_smsg_p(q) > ⊥
    then take a tentative checkpoint;
    for all r ∈ ckpt_cohort_p send(r, "take a tentative
      checkpoint and last_rmsg_p(r)");
    for all r ∈ ckpt_cohort_p await(r, willing_to_ckpt_r);
    if ∃ r ∈ ckpt_cohort_p, willing_to_ckpt_r = "no"
      then willing_to_ckpt_p ← "no" fi;
  fi;
  send(q, willing_to_ckpt_p);
OD.

UPON FIRST RECEIPT OF m = "undo tentative checkpoint" or
  m = "make tentative checkpoint permanent" DO
  if m = "make tentative checkpoint permanent" then
    make tentative checkpoint permanent;
  else
    undo tentative checkpoint;
  fi;
  for all r ∈ ckpt_cohort_p, send(r, m);
OD.
```

FIG. 6. Algorithm C1: the Checkpoint Algorithm

Theorem 2 shows that if p_0 takes a checkpoint, then all processes in P must take a checkpoint to ensure consistency.

*await does not prevent a process from receiving messages

5.3.4. Coping with Failures

We now extend Algorithm C1 to handle processes' failures. We first consider the effects of failures on nonfaulty processes. When failures occur, a nonfaulty process may not receive some of the following messages:

(1) "yes" or "no" from ckpt_cohorts,

(2) "make tentative checkpoint permanent" or "undo tentative checkpoint" from the initiator.

Suppose that process p fails before replying "yes" or "no" to process q's request. By the assumption of section 3, q will know of p's failure. After q knows that p has failed, it sets $willing\_to\_ckpt_q$ to "no" and stops waiting for p's reply. Therefore, to take care of a missing "yes" or "no", it suffices to change the statement in C1 from

```
if $\exists\ r \in ckpt\_cohort_p,\ willing\_to\_ckpt_r$ = "no"
  then $willing\_to\_ckpt_p \leftarrow$ "no" fi
```

to

```
if $\exists\ r \in ckpt\_cohort_p,\ willing\_to\_ckpt_r$ = "no" or $r$ has failed
  then $willing\_to\_ckpt_p \leftarrow$ "no" fi.
```

Suppose that process p does not receive the decision regarding its tentative checkpoint. If p undoes its tentative checkpoint or makes it permanent, it risks contradicting the initiator. The two-phase structure of C1 requires p to block until it discovers the initiator's decision[15]. We will discuss ways to prevent blocking in section 8.

We now consider the recovery of faulty processes. When a process restarts after a failure, its latest checkpoint on stable storage may be tentative or permanent. If this checkpoint is tentative, the restarting process must decide whether to discard it or to make it permanent. The decision is made as follows:

Suppose that the restarting process is the initiator. The initiator knows that every process that has taken a tentative checkpoint is still blocked waiting for its decision. Hence, it is safe for the initiator to decide to undo all tentative checkpoints and send this decision to its ckpt_cohorts. If the restarting process is not the initiator, it must discover the initiator's decision regarding tentative checkpoints. It may contact either the initiator or those processes of which it is a ckpt_cohort; it follows the decision accordingly to terminate C1.

The restarting process is now left with one permanent checkpoint on stable storage. It can recover from this checkpoint by invoking the rollback-recovery algorithm of section 6.

Let C2 be the Algorithm C1 as modified above. C2 terminates if all processes that fail during the execution of C2 recover. At termination, the set of checkpoints in the system is consistent, and the number of processes that took new permanent checkpoints is minimal. The proofs for these properties are similar to those of C1 and they are omitted.

6. Rollback-Recovery

We assume that the algorithm is invoked by a single process that wants to roll back and recover (henceforth denoted *restart*). We also assume that the checkpoint algorithm and the rollback-recovery algorithm are not invoked concurrently. Concurrent invocations of these algorithms are described in section 7.

6.1. Motivation

The rollback-recovery algorithm is patterned on two-phase-commit protocols. In the first phase, the initiator q requests all processes to restart from their checkpoints. Process q decides to restart all the processes if and only if they are all willing to restart. In the second phase, q's decision is propagated and carried out by all processes. We will prove that the two-phase structure of this algorithm prevents livelock as discussed in section 4.2. Since all processes follow the initiator's decision, the global state is consistent when the rollback-recovery algorithm terminates.

However, our goal is to force a minimal number of processes to roll back. If a process p rolls back to a state saved before an event e occurred, we say that e is *undone* by p. The above algorithm is modified as follows: the rollback of a process q forces another process p to roll back *only if* q's rollback undoes the sending of a message to p. Process p determines if it must restart using the label appended to q's "prepare to roll back" request. This label is described below.

For any processes q and p, let m be the last message that q sent to p before q took its latest permanent checkpoint. Define

$$last\_smsg_q(p) = \begin{cases} m.l & \text{if } m \text{ exists} \\ \top & \text{otherwise} \end{cases}.$$

When q requests p to restart, it appends $last\_smsg_q(p)$ to its request. Process p restarts from its permanent checkpoint only if $last\_rmsg_p(q) > last\_smsg_q(p)$.

6.2. Informal Description

Process p is a $roll-cohort$ of q if q can send messages to it. The set of roll-cohorts of q is $roll-cohort_q$. Every process p keeps a variable $willing\_to\_roll_p$ to denote its willingness to roll back. Whenever p cannot roll back (for any reason), $willing\_to\_roll_p$ is "no". The initiator q starts the rollback-recovery algorithm by sending a request "prepare to roll back and $last\_smsg_q(p)$" to all $p \in roll-cohort_q$. A process p *inherits* this request if $willing\_to\_roll_p$ is "yes", $last\_rmsg_p(q) > last\_smsg_q(p)$, and p has not already inherited another request to roll back. After p inherits the request, it sends "prepare to roll back and $last\_smsg_p(r)$" to all $r \in roll-cohort_p$; otherwise, it replies $willing\_to\_roll_p$ to q.

After p sends out its requests, it waits for replies from each process in $roll-cohort_p$. The reply can be an explicit "yes" or "no" message, or an implicit "no" when p discovers that r has failed. If any reply is "no", $willing\_to\_roll_p$ becomes "no", otherwise $willing\_to\_roll_p$ is unchanged. Process p then sends $willing\_to\_roll_p$ to the process whose request p inherits. From the time p inherits the rollback request to the time it receives the decision from the initiator, p does not send any system messages.

If all the replies from its roll-cohorts arrive and are all "yes", the initiator decides the rollbacks will proceed, otherwise it decides no process will roll back. This decision is propagated to all processes in the same fashion as the request "prepare to roll back" is delivered. If failures prevent the decision from reaching a process p, p must block until it discovers the initiator's decision. We discuss nonblocking algorithms in section 8.

The rollback-recovery algorithm is presented in Figure 7. Like the presentation of Algorithm C1, we introduce a fictitious process called *daemon* to perform functions that are unique to the initiator of the algorithm.

6.3. Proofs of Correctness

We consider a single invocation of the rollback-recovery algorithm. The variable $ready\_to\_roll_p$ ensures that a process p inherits at most one request to roll back. As a result, the variable also ensures that a process rolls back at most once. To prove the termination of Algorithm R, it suffices to show that Algorithm R is free of deadlocks.

Lemma 4: Algorithm R is deadlock free. □

We show next that the global state of the system is consistent after the termination of R

```
Daemon process:

send(initiator, "prepare to roll back and $\perp$");
await(initiator, $willing\_to\_roll_{initiator}$);
if $willing\_to\_roll_{initiator}$ = "yes" then
  send(initiator, "roll back")
else
  send(initiator, "do not roll back")
fi.

All processes p:

INITIAL STATE:
  $ready\_to\_roll_p$ = true;
  $last\_rmsg_p(daemon) = \top$;
  $willing\_to\_roll_p = \begin{cases} \text{"yes"} & \text{if } p \text{ is willing to roll back} \\ \text{"no"} & \text{otherwise} \end{cases}$ ;

UPON RECEIPT OF "prepare to roll back and
  $last\_smsg_q(p)$" from q DO
  if $willing\_to\_roll_p$ and $last\_rmsg_p(q) > last\_smsg_q(p)$
    and $ready\_to\_roll_p$ then
    $ready\_to\_roll_p \leftarrow$ false;
    for all $r \in roll-cohort_p$
      send(r, "prepare to roll back and $last\_smsg_p(r)$");
    for all $r \in roll-cohort_p$ await(r, $willing\_to\_roll_r$);
    if $\exists\ r \in roll\_cohort_p$, $willing\_to\_roll_r$ = "no"
      or r has failed then $willing\_to\_roll_p \leftarrow$ "no" fi;
  fi;
  send(q, $willing\_to\_roll_p$);
OD.

UPON RECEIPT OF m ="roll back" or
  m ="do not roll back" and $ready\_to\_roll_p$ = false DO
  if m = "roll back" then
    restart from p's permanent checkpoint;
  else
    resume execution;
  fi;
  for all $r \in roll-cohort_p$, send(r, m);
OD.
```

FIG. 7. Algorithm R: the Rollback Algorithm

Lemma 5: If the system is consistent before the execution of Algorithm R, the system is consistent after the termination of Algorithm R. □

Lemma 5 ensures that a single execution of Algorithm R brings the system to a consistent state after a failure; since processes roll back at most once in any execution of R, the rollback algorithm prevents livelocks. Thus, Algorithm R prevents livelocks.

Many existing rollback algorithms exhibit the following undesirable property. If the initiator rolls back, it forces an additional set of processes P to roll back with it, even though the system will be consistent if some of the processes in P omit to roll back. For instance, all processes are required to roll back every time any process wants to roll back[17]. However, in some cases, the initiator could roll back alone and the system would still be consistent. With our algorithm, the number of processes that are forced to roll back with the initiator is minimal.

Theorem 3: Let E be an execution of R in which the initiator, p_0, and an additional set of processes P roll back. Consider an execution E', identical to E except that a non-empty subset of processes in P omit to roll back upon receipt of the "roll back" decision. The execution E' leaves the system in an inconsistent state. □

7. Interference

In this section, we consider concurrent invocations of the checkpoint and rollback-recovery algorithms. An execution of these algorithms by process p is *interfered* with if any of the following events occur:

(1) Process p receives a rollback request from another process q while executing the checkpoint algorithm.

(2) Process p receives a checkpoint request from q while executing the rollback-recovery algorithm.

(3) Process p, while executing the checkpoint algorithm for initiator i, receives a checkpoint request from q, but q's request originates from a different initiator than i.

(4) Process p, while executing the rollback-recovery algorithm for initiator i, receives a rollback request from q, but q's request originates from a different initiator than i.

One single rule handles the four cases of interference: once p starts the execution of a checkpoint [rollback] algorithm, p is unwilling to take a tentative checkpoint [roll back] for another initiator, or to roll back [take a tentative checkpoint]. As a result, in all four cases, p replies "no" to q. We can show this rule is sufficient to guarantee that all previous lemmas and theorems hold despite concurrent invocations of the algorithms. This rule can, however, be modified to permit more concurrency in the system. The modification is that in case (1), instead of sending "no" to q, p can begin executing the rollback-recovery algorithm after it finishes the checkpoint algorithm. We cannot allow a similar modification in case (2) lest deadlocks may occur.

8. Optimization

When the initiator of the checkpoint or of the rollback-recovery algorithm fails before propagating its decision to its cohorts, it is desirable for processes not to block for its recovery. To prevent processes from blocking, we can modify our algorithms by replacing the underlying two-phase commit protocol with a nonblocking three-phase commit protocol[15]. However, nonblocking protocols are inherently more expensive than blocking ones[3].

We next address the following problem: after a ckpt_cohort q of a process p fails, p cannot take a permanent checkpoint until q restarts (p cannot know if the latest checkpoint of q records the sendings of all messages it received from q). To avoid waiting for q's restart, p can remove q from $ckpt\_cohort_p$ by restarting from its checkpoint (using the rollback-recovery algorithm). After its restart, process p can take new checkpoints.

9. Message Loss

Rollback-recovery can cause message loss as illustrated in Figure 8. When p is rolled back to X following a failure at F, the global state is consistent, but the message m from q is lost. It is lost because the state of the channels corresponding to the global state $\{X, Y\}$ contains m.

One method to circumvent message loss is to have that processes use transmission protocols that transform lossy channels to virtual error-free channels, e.g., sliding window protocols[18]. Another method is to ensure that the state of the channels corresponding to the most recent set

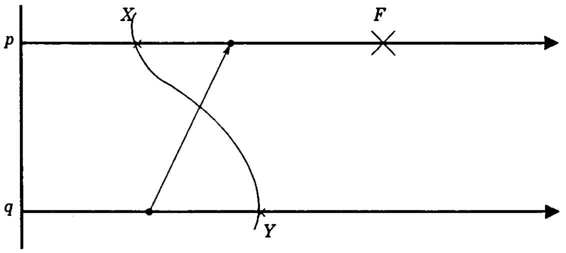

FIG. 8. Message loss following p's rollback to X.

of checkpoints contains no messages. We can modify the checkpoint and rollback-recovery algorithms to implement this latter method, but such modification increases the number of processes that are forced to take checkpoints and roll back.

10. Conclusion

We have presented a checkpoint algorithm and a rollback-recovery algorithm to solve the problem of bringing a distributed system to a consistent state after transient failures. In contrast to previous algorithms, they tolerate failures that occur during their executions. Furthermore, when a process takes a checkpoint, a minimal number of additional processes are forced to take checkpoints. Similarly, a minimal number of additional processes are forced to restart when a process restarts after a failure. We also show that the stable storage requirement of our algorithms is minimal.

The Gutenberg Operating System Kernel [1]

Panayiotis Chrysanthis, Krithi Ramamritham, David Stemple, and Stephen Vinter [2]

Department of Computer and Information Science
University of Massachusetts Amherst MA. 01003

ABSTRACT

The Gutenberg system is a port-based, object-oriented operating system kernel designed to facilitate the design and structuring of distributed systems. This is achieved by providing primitives for controlling process interconnections and thereby controlling access to shared resources. Only shared resources are viewed as protected objects. Processes communicate with each other and access protected objects through the use of ports. Each port is associated with an abstract data type operation and can be created by a process only if the process possesses the privilege to execute that operation. Capabilities to create ports for requesting operations are contained in the *capability directory* which is a kernel object. At any time, each process is associated with a single subdirectory of the capability directory designated as its *active directory*.

This paper describes the design philosophy and the structure of the Gutenberg kernel. First, it discusses the principles and motivations behind the Gutenberg design. Then, it presents the structure, contents and operations of kernel objects and discusses their use in structuring access to protected user-defined objects. Also discussed are the salient aspects of the distributed Gutenberg kernel. A brief comparison with other related systems is given.

1 INTRODUCTION

Modern distributed operating systems must be designed to facilitate structuring distributed computations in an understandable and reliable manner that is suitable for validation. Experience in programming languages and in controlling complexity of large software systems has shown that the strongly typed object paradigm and its associated information hiding can be used to produce manageable and understandable systems. In large distributed systems, lack of a corresponding clean, well-structured interprocess communication paradigm leads to more complexity than is required by the nature of the distribution alone. This points to the need for an efficient mechanism which structures all interprocess communications along the abstract data type lines.

This paper deals with the design of such a mechanism, the distributed Gutenberg kernel [11,12,7,8]. The Gutenberg Operating System Kernel, currently being developed at the University of Massachusetts, takes a unique approach to interprocess communication, provides multiple programming language support, and attempts to minimize overheads. The following three salient features of Gutenberg provide for the controlled establishment of communication connections which serves the goal of understandability and verifiability, and should contribute to its better performance compared to previous communication schemes:

- the adoption of *port-based communication*, whereby interprocess communication is solely by means of ports, queue-like objects which are managed by the kernel.
- the adoption of *non-uniform object-orientation*, whereby only interprocess communication, but not module interconnections within a process, are structured and controlled by means of capabilities; and
- the use of a *capability directory*, which expresses all potential process interconnections in the system and is a distributed persistent object, maintained and manipulated only by the kernel.

Principles underlying the Gutenberg Kernel. The Gutenberg system evolved from the following series of design decisions concerning the nature of communication and protection in the system.

Limit the responsibilities of the kernel. Operating systems that support the definition and protection of arbitrary objects traditionally have had performance problems because of the maintenance of protection domains and the overhead of dynamic access checks, e.g. Hydra [16] and iMAX [4]. We hoped to restrict the overheads of the kernel by taking a *non-uniform object orientation,* in which only resources shared by different processes need to be structured as objects at the operating system level. We believe that conventional mechanisms for protecting unshared data (e.g., local variables) are adequate and desirable, from both a downward compatibility and an efficiency viewpoint. Conventional memory protection mechanisms (e.g. page tables) ensure that the local data of processes are not accessible to other processes. Gutenberg depends on programming languages to provide static type-checking for self-protection. Thus, although local data *are not* necessarily object-oriented (depending on the programming language), shared data *are* required to be object-oriented. An underlying assumption in Gutenberg is that the granularity of objects is medium to large, a size adequate to amortize the cost of the interprocess communication required to access the object.

Programming language independence. There should be no requirement that a specific programming language or that only

object-oriented languages run under the Gutenberg system kernel. In fact, non-object-oriented languages can achieve an object oriented view of other processes through the use of kernel primitives [11]. The system is designed to support applications implemented in any programming language.

Resources are directly manipulated only by their managers. Managers are processes that synchronize the operations on an object (i.e., a shared resource). A process managing an object is the only subject able to directly manipulate the object. The process performs the operations, in part, by invoking kernel primitives for manipulating kernel objects.

Object sharing is via interprocess communication. Processes do not share address spaces. They can interact only through interprocess communication using explicit message passing. An operation can be performed on the object only as a result of a request from another process via interprocess communication. Processes are provided with communication primitives allowing both synchronous and asynchronous communication.

Interprocess communication connections are established using functional addressing [12]. Processes use communication channels called *ports* to request operations on objects. A port can be used to request an operation only if it was created for that purpose. Ports are created by indicating the function of the port (viz., to request an operation), not by identifying a particular process.

The kernel controls access to shared objects by controlling interprocess communication. An operation may be requested only by transmitting the operation request over a port to the object's manager. By limiting the use of ports and constraining their use to request a specific operation on a specific object, access to the object is controlled.

Details of the implementation of the communication mechanism are hidden from the processes using it. Ports are themselves objects with a small set of operations defined on them. They are managed by the kernel. The representation of ports and details of message transmission and reception are hidden from communicating processes.

Privileges persist in a single kernel-managed structure. Gutenberg recognizes that privileges need to persist in the system independent of the execution of processes. Rather than allowing privileges to be placed on secondary storage in user objects (hidden from the view of the kernel), privileges that are not dependent on the existence of a process are stored in a kernel managed structure called the *capability directory.* This directory is shared by the processes in the system. Being physically distributed, it can be designed to ensure availability and reliable access despite communication and node failures. However, since it is logically unified, i.e., appears as a single globally addressable entity, the physical distribution will be transparent to its accessors. Transient capabilities of a process, i.e., capabilities that exist only as long as the process is active, are kept in the process' *c-list.*

The above design principles made it possible to use Gutenberg as the basis for a distributed operating system for the following reasons. The use of resource managers is a common approach to structuring software in distributed systems. Second, the logical separation of process address spaces in Gutenberg corresponds to the physical realization of processes in a distributed system. Third, the close association of communication and protection contributes to decentralized access authorization.

The rest of the paper is structured as follows: Section 2 introduces the structure and the contents of the kernel objects. User-defined objects, type creation, and manager instantiation are the subject of section 3. Issues related to the dynamic control of interprocess communication are also discussed in section 3. The distributed kernel is examined in section 4. Section 5 contains a brief comparison of Gutenberg with related systems. We conclude with a section summarizing our approach and future work.

2 GUTENBERG KERNEL OBJECTS

The Gutenberg kernel itself is structured as a set of cooperative abstract data type managers. Furthermore, the kernel is viewed by the processes as an abstract data type manager of kernel objects with the kernel primitives as the corresponding abstract data type operations. There are four types of kernel objects: *processes*, *ports*, *capability directory* and *transient capabilities.*

2.1 Processes

A process is an independently schedulable unit of computation with the ability to communicate with other processes. Each process is represented by a unique *process control block*, abbreviated *PCB*, which resides within the kernel address space.

Processes can communicate only through explicit message exchanges over communication channels called *ports.* As a result, processes do not *share address spaces*, eliminating the need for synchronization in memory access and generalizing the process interactions in a distributed system.

2.2 Ports

A port is a kernel object that processes manipulate by invoking kernel primitives. It is a communication channel between a pair of processes in one-to-one topology connecting just one pair of processes at a time. Typically, one process has the privilege to place messages on the port, which behaves as a queue of messages awaiting delivery. The other has the privilege to remove messages. This communication can be either synchronous or asynchronous.

The basic interprocess communication of the Gutenberg system is based on the client/server model, in which the creator of a port, called the *client*, communicates with the port server, the manager of some shared object, for the purpose of requesting an operation on the object. A port is established with *functional addressing*: A client creates a port by naming the service it would like to request using the port rather than by identifying the server process. As a result, the server process does not have to be in existence prior to the creation of the port. The advantage of this strategy is that it allows the dynamic creation of server processes. In fact, in Gutenberg, process creation and destruction are byproducts of port operations. There are no primitives for process creation and destruction: *processes are hidden from the programmers, the lowest level of abstraction being the level of operations on the ports.*

Therefore, the only way a process can request an operation on a shared object is to create a port and execute a kernel primitive on that port. The possible kernel primitives on ports that a client is entitled to, include SEND, RECEIVE, and SEND-RECEIVE (to receive the result of an operation based on the parameters sent).

In order to restrict the use of ports to the functionality for which they have been created, a port is typed as either a Send, Receive, or Send-Receive port. This typing specifies the directionality of the port and the kernel primitives used by the client to transmit messages through it. Consequently, it specifies the kernel primitives that the server of the port may use. Figure 1 shows the port primitives used by clients and servers for each port type. Send and Receive ports are unidirectional. Send-Receive ports are bidirectional, allowing the port's client to send a message and receive a response from the port's server.

Port typing also determines the format of messages that may be placed in the port and the *object operation* associated with this, which identifies the operation that will be requested via the port. Each port is represented by a unique *channel control block*, abbreviated *CCB*, which resides within the kernel address space. CCB contains the port type along with information about the

SR	SEND-RECEIVE REVOKE EXAMINE	GETDETAILS SEND REFUSE EXAMINE

Figure 1: Port primitives used by clients and servers for each port type

status of the client and server processes and the owner of the port. Ownership represents the privilege to destroy the port. The creator of a port becomes the initial owner of the port. As part of the sharing mechanism supported by the Gutenberg system, a process may transfer part of its privileges, including port privileges, to another, over ports.

Here is a short summary of the functionality of port primitives.

CREATE-PORT (only a client primitive) creates a port of a specific type. The type is specified via a parameter to the call.

DESTROY-PORT (only a client primitive) destroys a port. The caller must be the owner of the port. The port-id is specified via a parameter to the call.

SEND puts a message on a port. The system has two kinds of SEND primitives: acknowledge-SEND and no-acknowledge-SEND. If the SEND is an acknowledge-SEND, the sending process is informed when its correspondent over the port receives the message. The sender can choose to block until the receipt of the acknowledgement.

RECEIVE requests the next message from the port. The caller elects via a parameter to the call, to either block, if there is no message on the port, or execute concurrently with the servicing of the request.

SEND-RECEIVE (only a client primitive) puts information, termed *request details*, on a port for the server to use in satisfying the request. When the server responds to the request by executing a SEND, the server's reply is returned to the client as in RECEIVE. The caller may block until the server replies, or execute concurrently with the servicing of the request.

ACCEPT-REQUEST (only a server primitive) is used to obtain access to newly created ports and to query a set of existing ports to see if new messages have arrived. The caller may block until the kernel replies, or execute concurrently with the servicing of the request.

GETDETAILS gets request details from a port. The caller (the port's server) may block if there is no pending SEND-RECEIVE, and thus no request details, on the port, or it may execute concurrently with the satisfaction of its request.

EXAMINE examines messages on the port without removing them.

REFUSE rejects a client's request for service as unsatisfiable and notifies the requester by setting a status.

REVOKE revokes privileges sent as part of request details by a SEND-RECEIVE or in a SEND message up to receipt of the message [3].

The choice of these primitives during system design was based on the desire to keep their number and complexity to a minimum while providing users a set of primitives for building systems of communicating processes in arbitrary topologies with reasonable ease. Thus, we have added to the basic SEND and RECEIVE primitives the bidirectional SEND-RECEIVE and its receiving reciprocal GETDETAILS in order to allow such functions as reading a record with a given key (the key being sent as request details) or a remote procedure call (the procedure's parameters being sent as request details) to be implemented by a single primitive. However, it should be noted that the asynchronous mode makes the SEND-RECEIVE operation more robust and flexible than a remote procedure call semantics.

2.3 Capability Directory

Gutenberg controls the creation and use of ports through the use of capabilities. All capabilities for accessing potentially sharable objects are maintained in a logically unified structure called the capability directory. Thus, the capability directory expresses all potential process interconnections in the system. This is similar to the UNIX file directory [10] which provides uniform treatment of files, devices and interprocess communication. The capability directory is a *stable* structure in that its existence does not depend on the existence of any process. It is also *shared* since more than one process may concurrently access the same segment of the directory. It should be noted that no portion of the directory is owned by any process at any time.

2.3.1 Capability Directory Nodes

Capabilities within the capability directory are further organized into groups called the *capability directory nodes*, abbreviated *cd-nodes*. They are identified by both a system-wide unique name created by and visible only to the kernel, and by user-specified names. In general, cd-nodes contain other information along with capabilities. Cd-nodes are linked to other cd-nodes through capabilities. The same cd-node may be linked to several cd-nodes under possibly different user-specified names. All capabilities pointing to a cd-node have equal status. That is, cd-nodes are unique and are *not* contained within other cd-nodes. A cd-node exists independently of any other cd-node and disappears along with the last capability link to it, if it is not explicitly destroyed. In this way the capability directory is structured as a graph in which nodes (each node corresponds to a cd-node) are connected by edges corresponding to capabilities. Figure 2 shows a sample capability directory.

The capability directory may contain two kinds of cd-nodes: *subdirectories* and *manager definitions* (see figure 3). Note that an *asterisk* next to attribute names used in the figures designates that the attribute cannot be modified by the users but is maintained by the kernel.

A subdirectory is a list of capabilities. It is merely an organizational unit of the capability directory, similar to a file directory in a file system. At any time, every process in the system is associated with a single subdirectory in the capability directory designated as its *active directory*. The active directory of a process is the set of capabilities from the capability directory that a process may use or exercise.

Figure 2: Example of Capability Directory Segment
This is a sample capability directory of a basic mail system. The Mail Maintenance Directory which contains the Mail System Manager Definition is created by the creator of the system and stored in the System Maintenance Directory. The two operations defined on the Mail System, namely the Mail and Read, are contained in the login process subdirectory. Each user gets capabilities for these operations during the login procedure. In the default subdirectory of the Mail System, operations on the File Manager exist that permit access to files.

The active directory of a process is one component of a process protection domain. The other component is its current set of transient capabilities; this is discussed later. A process may dynamically switch from one protection domain to another by changing to a new active directory or changing the contents of its current active directory, if it has the privilege to do so.

Manager definitions constitute one of the novel features of the Gutenberg system. All processes in the system are instantiated from manager definitions. Thus, a manager definition provides information necessary for instantiating the manager process, as, for example, a capability for the file containing the executable image (object module) of the process, and the initiation protocol (see section 3.2) for determining the manner in which ports are connected to manager processes. It also includes a capability for a subdirectory containing the privileges that all processes instantiated from the manager definition will initially possess.

One other component of a manager definition node is a set of *port descriptors.* This set corresponds to the set of operations defined within the manager. Each port description contains a *generic operation name* (a name specified by the user at manager creation time), and the type of port through which a user requests this operation.

Capabilities in cd-nodes inherit all the properties of the capability directory in that they are stable and sharable but are not owned by processes. These capabilities are called *stable* capabilities and can only reside in the capability directory.

Capabilities in Gutenberg consist of three parts: a specific kernel primitive, a list of parameters for the primitive, and a list of primitives that can be used to manipulate the capability itself, which are called *capcaps*, for capabilities on a capability.

A capability permits a process which possesses it to invoke the specific kernel primitive it contains. This primitive is also called *primary* kernel primitive in order to distinguish it from

Subdirectory cd-node Contains a set of capabilities, and has the following attributes:

subdirectory id* system-wide unique identifier of the subdirectory.

use count* the number of stable and transient subdirectory capabilities (including those in manager definition cd-nodes) pointing to this cd-node.

active directory count* the number of processes having this cd-node as their active directory.

Manager Definition Node Provides information necessary for instantiating a manager process. The manager definition cd-node has nine attributes.

manager id* system-wide unique identifier of the manager cd-node.

initial active directory a subdirectory capability pointing to the subdirectory cd-node that will become the active directory of the manager process when it is initiated.

initial process image a privilege (represented by a cooperation class capability) for a file containing the object code to be executed when the process is initiated.

manager dependency indicates whether the existence of a manager process is dependent on the existence of ports connected to it.

initiation protocol indicates when a new manager process is created or an existing one is connected to when a port to the manager is created.

port descriptors is the list of (port type, generic operation name) pairs for operation capabilities that may be linked to this manager cd-node. The port type specifies whether it is a Send, Receive or Send-Receive port as well as the format of the arguments that may be passed over the port as part of a message or request-details.

manager use count* the number of manager capabilities pointing to this cd-node.

operation use count* the number of operation capabilities linked to this cd-node.

port use count* the number of ports associated with this cd-node.

Figure 3: Attributes of Capability Directory Node

Operation Capability Provides the privilege to create ports. Operation capabilities have six attributes:

- **operation name** user-specified name of the operation. This name becomes the object operation of created ports. This name also serves to identify the operation capability.
- **generic operation name*** name of the corresponding operation defined in the manager definition cd-node. This name can be the same as or different from the operation name.
- **port type*** specifies the port type for this operation that may be linked to the corresponding manager definition cd-node. The port type can either be Send (S), Receive (R), or Send-Receive (SR).
- **message format*** specifies the arguments that may be passed over the port as part of the message, and the request-details in case of Send-Receive port type.
- **cooperation class(es)** restrict how the port will be connected to a manager process.
- **manager id*** a pointer, global name, to the manager to which this operation capability is linked.

The capcaps of the operation capability are: COPY, TRANSFER, REGISTER, REMOVE, HOLD, MERGE, MODIFY-CAP, MODIFY-CAPCAP, and VIEW-CAP.

Figure 4: Attributes of an Operation Capability

the other kernel primitives that manipulate the capability itself.

The capcaps determine how the capability may be modified and used. Capcaps include the privilege to *transfer* (to another process), *copy*, *register* (make stable), *hold* (make transient), *merge* (with other mergeable capabilities), *view*, and *modify* the capability. Each capcap may be active, in which case the corresponding kernel primitive may be invoked for the capability, or inactive, in which case the corresponding kernel primitive cannot be invoked on the capability. Not every capcap makes sense for each type of capability. When we discuss the specific capabilities next we point out the capcaps that are applicable.

The parameter list may include names of cd-nodes as well as other capabilities (most notably, the cooperation class capability which is discussed later).

2.3.2 Types of Capabilities

There are four different types of capabilities that may be stored in the capability directory: *operation*, *subdirectory*, *manager definition*, and *cooperation class capabilities.*

An operation capability (figure 4) represents the privilege to create a port for use in requesting a particular operation on a given user-defined object type. Thus, the primary kernel primitive of the operation capability is **Create-port**. One parameter of the operation capability is the operation name, which becomes the operation requested via ports created from this capability. This name also serves to identify the operation capability in the subdirectory in which the capability is contained. Another parameter of the capability is the name of a manager definition cd-node in the capability directory that the operation capability is *linked* to. This manager definition is used by the kernel to determine whether a newly created port is to be connected to a new server process instantiated from the manager definition or to an already existing one. It is also used by the kernel in conjunction with a third parameter, the generic operation name, to determine whether the requested operation is currently supported by the manager; this is checked by examining whether the operation generic name is part of the port descriptors in the manager definition.

The primary kernel primitive in the manager definition capability (figure 5) is **Create-operation**, which is used to create operation capabilities, linked to the manager definition named in the capability. Since an operation capability can be used to create a port to access a protected object, a manager definition capability signifies the privilege to provide other processes with specific types of access to their objects. This effectively is the privilege to control access to the object's type.

The primary kernel primitive associated with the subdirectory capability (figure 6) is **Change-directory**. The Change-directory primitive is used by a process to change its active directory to the subdirectory named in the subdirectory capability.

The subdirectory capability also contains a set of *subdirectory rights*. When a subdirectory capability is exercised to make a subdirectory active, the subdirectory rights override the capcaps of each individual capability in the subdirectory, and this further restricts the use of the capabilities registered in the subdirectory. This restriction during the changing of the active directory, referred to as *privilege filtering*, allows a fine granularity of control over the use of capabilities within an active directory. This is vital for supporting an effective mechanism that allows processes to switch from one protection domain to another dynamically. In this situation, when a process wants to switch to a new protection domain, it has to traverse the capability directory and change to a new active directory. While traversing the capability directory, a process may have to visit intermediate subdirectories which contain capabilities that the process need not be authorized to exercise or even view. By deactivating all rights except the CHANGE-DIR along the path between the

Manager Definition Capability Provides the privilege to create operation capabilities. The manager definition capability has the following attributes:

- **manager definition name** user-specified name used to identify the manager definition cd-node to which the created operation capabilities are linked to. This name also serves to identify the manager definition capability.
- **cooperation class(es)** restrict who may create operation capabilities linked to the definition manager. Possession of one of the specified cooperation class capabilities is required when exercising the **Create-operation** primitive.
- **manager id*** a pointer, global name, to the manager definition cd-node corresponding to this capability.

The capcaps of the manager definition capability are: COPY, TRANSFER, HOLD, REGISTER, REMOVE, DESTROY-NODE, MERGE, MODIFY-CAP, MODIFY-NODE, MODIFY-CAPCAP, VIEW-CAP, and VIEW-NODE.

Figure 5: Attributes of a Manager Definition Capability

Subdirectory Capability Provides the privilege to change the process' active directory. The attributes are:

subdirectory name user-specified name of the subdirectory cd-node which becomes the process' active directory when the **change-directory** privilege is exercised. This name also serves to identify the subdirectory capability.

cooperation class(es) used to restrict who may make the subdirectory active. When exercising the **Change-directory** privilege, a process must possess one of specified cooperation class capabilities or else the primitive is illegal.

subdirectory right restricts how cd-nodes and capabilities contained in the subdirectory may be used; each right may be ON (active) or OFF (inactive); the rights are: TRANSFER, COPY, REGISTER, REMOVE, HOLD, MERGE, VIEW-CAP, VIEW-NODE, MODIFY, DESTROY-MANAGER-NODE, DESTROY-DIR-NODE, CHANGE-DIRECTORY, CREATE-PORT, and CREATE-TYPE.

subdirectory id* a pointer, global name, to the subdirectory cd-node corresponding to this capability.

The capcaps of the subdirectory capability are: COPY, TRANSFER, REGISTER, REMOVE, HOLD, DESTROY-NODE, MERGE MODIFY-CAP, MODIFY-CAPCAP, VIEW-NODE and VIEW-CAP.

Figure 6: Attributes of a Subdirectory Capability

Cooperation Class Provides a wild card privilege that may be merged with any other capability type. It has two attributes:

class name user-specified name used to identify the cooperation class in the current protection domain.

class id* system wide unique identification of cooperation class.

The capcaps of the cooperation class capability are: COPY, TRANSFER, HOLD, REGISTER, REMOVE, MERGE, VIEW-CAP, MODIFY-CAP, and MODIFY-CAPCAP

Figure 7: Attributes of Cooperation Class Capability

initial and goal subdirectory, the mechanism for switching to a new domain becomes simple, and the security of the system is not compromised.

The fourth type of capability, the cooperation class capability, represents the privilege of a process to participate in a cooperative activity identified by a unique identifier, the *class id* (figure 7). The cooperation class capability may be associated with any other capability type, thus providing a wild card privilege. Hence, the primitive associated with this capability is ANY denoting its wild card property. When a cooperation class capability is associated with either a subdirectory or a manager definition capability, it restricts the invocation of the corresponding primary primitive to the processes which possess the cooperation class capability. In effect, such processes become members of the cooperative activity represented by the capability. In this way cooperation class capabilities complement the role of capcaps by determining how these capabilities may be exercised. In the case in which a cooperation class capability is associated with an operation capability, it specifies a cooperative activity, for example a communication with a manager of a shared object. Here, the cooperation class capability can be used as a synchronization token or to identify either an instance of a manager or a particular instance of an object. It could also be used to identify a transaction, a file, or a process. It can be used to classify the users in the system into groups and divisions for administrative reasons. New cooperation class capabilities can be created, on request, by the kernel.

2.4 Transient Capabilities

Port capabilities and copies of stable capabilities from the capability directory are the transient capabilities. Two features distinguish the transient capabilities from the stable capabilities: they are owned by a single process, and therefore cannot be shared, and their existence is dependent on the existence of the process that owns them. All the transient capabilities a process owns exist only for the duration of the existence of the process and are destroyed when the process terminates. The transient capabilities possessed by a process, are stored in the process' ***capability list***, or ***c-list***. Capabilities in the c-list, as previously stated, together with the active directory of a process, form the protection domain of the process. Thus, a process, in addition to the capabilities in its active directory, may exercise the capabilities in its c-list.

A transient capability comes into existence when a process moves or copies a capability from its active directory, into its c-list (using a primitive called HOLD), when it receives the capability from another process via a port, when it creates a capability by invoking the proper create primitive, or when it creates a port. In the last instance, two port capabilities are generated to access the created port, one for the client of the port and the other for the server of the port. A process moves a capability in its active directory into its c-list in order not to lose the capability when it changes its active directory to another subdirectory.

The part of the c-list in which the kernel maintains the port capabilities of a process is called the *p-list*. The port capabilities are *exclusive* and as such, port capabilities are inherently transient, cannot be shared or copied. However, either the client or the server process may transfer its port capability to another process. The transferring may be either temporary (the semantics of a lend with the ownership retained) with the SEND-RECEIVE primitive or permanent with the SEND primitive. In the latter case, the ownership of the port is transferred along with the port capability.

The only capcap associated with a port capability is *transfer*. The transfer capcap in the client's port capability is set to the value of the corresponding transfer capcap in the operation capability used. If the used operation capability is stable, then the transfer right of the client's active directory is also taken into consideration. The transfer capcap in the server's port capability is always enabled. A server process may transfer a port that it serves, to another server as long as the port functionality is preserved. This is essential for supporting the implementation of load balancing algorithms and realizing a hierarchy of object managers, features which can improve the performance, flexibility and reliability of a distributed system. A common example of a hierarchy of managers is a manager structured based on the master/slave model, in which a process can only create a port for requesting an operation to the master process. The master process decides which slave process should service the request and passes the port capability to it. A process may reset the transfer capcap of the port capability when it passes the capability to another process, to prevent further transferring.

Transient capabilities contribute to the flexible use of capabilities in Gutenberg without compromising the security of the system because the c-list is saved in the PCB and may only be manipulated through kernel primitives.

The kernel primitives that manipulate the capabilities both within a c-list and an active directory, fall into two classes: *generic* and *special primitives*. Generic primitives are further classified into *constructive* in that they do not affect the participating capabilities, and *destructive*. Constructive primitives are designated by the ending **-C** attached to their names. Recall that a number of capcaps and rights correspond to each primitive, and must be active in the capability on which the primitive is invoked, and must be allowed by the rights of the active directory of the invoking process.

The eleven generic kernel primitives are: *Create, Register, Register-C, Remove, Hold, Hold-C, Drop, View, Modify, Merge* and *Merge-C*. Here is a brief description of their functionality (Details concerning the primitives may be found in [3]).

Create These primitives create a capability. **Create-port**, and **Create-operation** are instances of this generic primitive. A **Create** always creates a transient capability which may then be registered or transferred with all or part of its privileges retained. Creating an operation capability requires a manager capability, and creating a port capability requires an operation capability. Other **Create** primitives require no privilege.

Register and Register-C These primitives make a transient capability, or one derived from transient capabilities, stable. A process may reset part of the capcaps and/or rights of a capability, when it registers the capability. The purpose of these primitives is two-fold: to allow a process to store a capability for future reference in another session; and, to allow a process to share a capability with other processes which are not currently instantiated, but share access to a subdirectory.

Remove These primitives delete a stable capability from the active directory.

Drop These primitives delete a transient capability from the c-list.

Hold and Hold-C These primitives make a stable capability, or one derived from stable capabilities, transient. A process may reset part of the capcaps and/or rights of a capability, when it holds the capability. The purpose of these primitives is to allow a process to retain a capability from its active directory when it changes its active directory to another subdirectory.

View These primitives bring a copy of a transient or stable capability, or a cd-node into the address space of a process. Partial views are also facilitated in the case of a subdirectory; it is possible to bring capabilities of a specified type into the address space of the process. The purpose of these primitives is to allow a process to examine capabilities it possesses, and, if desired, use this information to modify or create new capabilities.

Modify These primitives allow a process to modify an existing transient or stable capability, or a cd-node.

Merge and Merge-C These primitives allow a process to merge two compatible capabilities to obtain another. Two capabilities are compatible if they are of the same type and have identical non-modifiable attributes (attributes whose values cannot be changed with the **Modify** primitive).

As has previously been discussed, the manager definition and subdirectory capabilities are slightly different from other capabilities. These capabilities contain pointers to manager definition and subdirectory cd-nodes, respectively. When one of these capabilities is created with the **Create** primitive, the cd-node is created as well. These cd-nodes exist in the system until either they are explicitly destroyed by using the proper **Destroy** primitives, or all of the capabilities that point to them are deleted using the **Remove** or **Drop** primitives.

The kernel uses the c-list and the active directory of a process to check whether it has a legitimate privilege for executing a primitive it has requested. Therefore, the consistency and availability of the capability directory is fundamental to the correct operation of the protection mechanism. As is commonly done with resources in distributed systems, the capability directory is physically distributed, though still logically unified, across the distributed system as we discuss below.

3 USER-DEFINED OBJECTS

Recall that the Gutenberg kernel is not involved in the protection of objects that are purely local to a process. User-defined objects are those objects managed by one process but accessible by other processes via operations requested using ports. Here, we discuss how user-defined objects are created, shared, and protected.

3.1 Type Creation

User-defined types in Gutenberg are represented by manager definition cd-nodes (figure 3). A manager definition is created by a process invoking the **Create-manager** primitive. Recall that no special privilege is required to invoke this primitive. In invoking the primitive, a process must provide five parameters: A cooperation class capability identifying the file containing the executable image for the process; a subdirectory capability identifying the *default directory,* the subdirectory which becomes the active directory of any process instantiated from this manager definition; the *operation list,* the specification of the operations that are implemented by the manager; the *manager initiation protocol,* indicating how manager processes are instantiated; and, the *manager dependency* indicating whether a manager process will be destroyed when all ports connected to it are destroyed.

Upon successful execution of the **Create-manager** primitive, the kernel places a manager definition capability, pointing at the new manager definition and containing its name, in the process's c-list. After the manager definition and the corresponding manager definition capability are created, the process may use the manager capability to invoke the **Create-operation** primitive to create the operation capabilities for the type. These operation capabilities can then be stored in the capability directory or distributed over ports to processes wishing to use the type.

3.2 Manager Initiation Protocols

The manager initiation protocol specified when creating a manager definition determines the manner in which ports are connected to the manager processes instantiated from the definition. It specifies whether all the object instances of a type are managed by one process or each object is managed by different processes. There are three initiation protocols in Gutenberg: *conservative, creative* and *class conservative.* In the conservative manager initiation protocol, a manager process is instantiated from the manager definition only if there is no other manager process executing in the system which was instantiated using this manager definition. If such a process already exists, the port being created is attached to this process. This protocol provides the means to produce a manager process that manages all the objects of a type, and to automatically connect port-creating processes to this manager. Using this protocol, the manager can be informed of the object being accessed at port-creation time using a cooperation class capability. Instantiating more than one conservative manager requires creating more than one manager definition.

The creative protocol creates a new manager process from the creative manager definition cd-node for each new port created. This protocol allows a process to create a port to a new process under all situations. This protocol allows a process to isolate the newly created manager in order to ensure that the manager cannot leak information. However, it cannot support multi-port interconnections between a specific client and a specific server.

The third protocol is the class conservative manager initiation protocol. It allows new managers to be instantiated selectively based on the cooperation class capability supplied at port creation time. The class conservative manager is typically designed to manage one object of the type, and may serve multiple ports from any number of processes.

In the class conservative protocol, when a port is created using an operation capability, the kernel checks to see if a process associated with the specified class id has been instantiated from the manager definition pointed to by the operation capability. If so, the port is connected to this manager. If not, a new manager is instantiated and associated with the specified class id.

Both conservative protocols allow any two processes to communicate indirectly through a conservative process, although they cannot establish direct, full duplex interconnections. However, using these protocols and by allowing processes to pass port use privileges via ports, the one-to-one process intercommunication topology adopted by Gutenberg can be expanded to arbitrary topologies. For a more detailed description of manager initiation protocols, see [12].

3.3 Object Protection and Sharing

Once a type is created, distributing privileges to allow other processes to use the object type corresponds, in Gutenberg, to distributing operation capabilities linked to the manager definition. As has previously been discussed, for a process to access a shared resource, a port is needed between itself and the process managing the object. Establishing a port involves checking for an operation capability in the active directory or c-list of the requesting process. Thereafter the kernel performs access authorization for a user-defined operation simply by checking that the requesting process has the privilege to access the port associated with the operation. Thus, creating and accessing user-defined objects involves using kernel-defined capabilities to authorize access to kernel-defined objects, and does not involve checking user-defined capabilities as in other capability-based systems.

In Gutenberg, process interconnections can change dynamically through the transfer of capabilities on ports. There are three ways in which one process can transfer some of its capabilities to another; The transferred capabilities are always placed on the receiving's process c-list. Since the kernel is the manager of the capabilities and ports, it monitors the transfer of capabilities between processes.

The first method of capability transfer is the transfer of a port capability. The sending process loses the port capability, and therefore the privilege to execute the object operation associated with the transferred port; the receiving process obtains this privilege.

The second method of capability transfer is the transfer of an operation capability (which can be associated with a cooperation class) that can be used to create any number of ports to access an object (identified by the cooperation class).

The third method of capability transfer is by registering the capability to be transferred in a subdirectory and transferring the subdirectory capability that points to it. Using this method a process may transfer a number of capabilities at once with the minimum communication overhead.

In all three methods, capabilities are transferred either by SEND as part of the message or by SEND-RECEIVE as part of the request details. These two mechanisms of capability transfer are distinguished by the semantics of the transferring. The transfer by SEND is permanent, whereas the transfer by SEND-RECEIVE is temporary and the transferred capabilities can be held only while the recipient is processing the request to which it pertains. When the recipient executes the SEND that satisfies the request, the kernel automatically returns the *outstanding* capabilities to the process which executed the SEND-RECEIVE. For more detailed discussion of the privilege transferring mechanisms as well as their implications see [8].

4 DISTRIBUTED GUTENBERG KERNEL

An instance of the Gutenberg kernel is running on each site in the system. From the objects that the kernel maintains only the capability directory needs to be distributed. The other three objects, namely processes, ports and transient capabilities, are naturally distributed since processes always execute on a single site, and ports and transient capabilities can only be used by the process which possesses them.

The capability directory is partitioned and replicated to ensure availability and reliability. Manager definitions are replicated only at the sites in which manager processes from these can possibly be instantiated. Subdirectories are replicated in locations where they are expected to be used and in a number of other locations in a manner that meet the resiliency requirement and balance the distribution of local directory storage space. The site where a cd-node is created has a copy of that cd-node and also keeps track of which sites have copies of that cd-node.

The set of capabilities and cd-nodes from the capability directory that resides on a site forms that site's *local directory*. The site's local directory dynamically expands and contracts to accommodate the needs of any process executing on the site. *Dynamic adjustments* pertain only to the migration of subdirectories; modifications to manager definitions are expected to be relatively rare to justify their migration. A subdiretcory is migrated only when processes make repetitive use of the capabilties located there, justifying the move. Even then, only (lockable) portions of the subdirectory are copied in a *lazy copy* fashion.

Synchronization of access to components of the capability directory is achieved with the use of two locking-based concurrency control schemes with the granularity of locks being on portions of cd-nodes. For example, a subdirectory is associated with three locks; one is used for the set of operation and cooperation class capabilities; the second for subdirectory capabilities; and the third for manager definition capabilities.

Two concurrency control schemes used are the *primary two-phase locking scheme* [2] where a single copy is designated as the site to gain all locks, and the *basic two-phase locking scheme* [2] where to lock a cd-node for reading it is necessary to lock only the local copy whereas a write requires obtaining the write lock on all replicates of the cd-node. Which scheme is used for a specific cd-node depends on the likelihood of its predominant access by processes on one site or on multiple sites. A *dynamic recategorization* allows the kernel to adapt to the system behaviour by changing the concurrency control mechanism for a cd-node in response to the nature of its use.

A two-phase commit protocol is used to achieve a reliable distributed commitment and ensure atomicity. For a more detailed discussion of issues involved in the distribution and the approach adopted see [7].

5 A COMPARISON WITH RELATED SYSTEMS

A large part of the improvement in programming languages has come from the promotion of data and procedural abstraction as a major tool for structuring modules. This led to the adoption of abstraction and encapsulation mechanisms in Gutenberg, as in many other systems, e.g. Argus [6], NIL [13]. While in these two systems, the mechanism for dynamic module interconnection control is built within a programming language, the approach taken in Gutenberg separates process interconnection control from programming languages. Gutenberg supports the dynamic control of process interconnections through the use of capabilities. However, it is different from the other protection-oriented operating systems such as Hydra [16] and iMAX [4], in that it adopts a non-uniform object-orientation.

A few systems provide port-based communication facilities using functional addressing [12], but none ties protection so closely to communication as Gutenberg does. The Accent system is port-based and supports asynchronous communication with process transparency [9]. Communication in Gutenberg is also similar to the mechanisms used in Intel iAPX-432 [4], DEMOS [1] and NIL [13]. In all these systems, apart from NIL, even though a communication link could be typed, thus restricting its use, they do not support the concept of restricting access to shared objects by restricting the creation of communication channels is not supported directly, as in Gutenberg.

As mentioned earlier, a unique feature of Gutenberg is the capability directory, which contains stable capabilities in a unified structure controlled by the kernel. Other systems, such as Hydra, iAPX 432, and CAL [5] allow capabilities to be stored in inactive objects (i.e., data structures, as opposed to processes) that are not kernel objects. The problem of how to allow such objects to be permanently stored in secondary memory is noted in [5]. Having a unified structure for stable capabilities that is separate from user-managed data facilitates their management by the kernel and their use by application processes.

6 CONCLUSION

The Gutenberg system is a novel attempt to facilitate the design and structuring of distributed computations in an understandable and reliable manner that is suitable for validation. The crux of the Gutenberg approach is the use of port-based communication, non-uniform object-orientation and decentralized access authorization using ports and the capability directory. This nonprocedural directory provides an abstract view of the functional building blocks of a large system of distributed cooperating modules and should serve the goal of understandability and verifiability.

In this paper we discussed the design of the Gutenberg kernel. In particular, we presented the kernel primitives, i.e., kernel-implemented operations for manipulating the capability directory and ports. Since process creation and destruction are byproducts of port operations, there are no explicit primitives to deal with processes in Gutenberg. Gutenberg does allow users to construct managers for user defined objects. Such manager definitions are registered in the capability directory.

A Privilege in Gutenberg is represented by capabilities which can have two levels of persistence, transient for those capabilities which persist only as long as an owning process exists, and stable for those capabilities in the capability directory, whose existence is independent of processes. Gutenberg has mechanisms for achieving transfer of privileges represented by both transient and stable capabilities. Some of the highlights of these mechanisms include:

- Using both unidirectional and bidirectional communication primitives and associating them with permanent (unidirectional) and temporary (bidirectional) granting of privileges in order to provide flexibility in privilege granting while keeping the kernel simple.
- Typing ports with respect to the ability to transfer privileges on them in order to expedite communication in cases where no privilege transfer can be made.
- Restricting ports to connecting one client process with one server process in order to simplify interprocess communication in general and the transfer of privileges in particular.

Design and implementation of a Gutenberg kernel (built on top of UNIX) is currently nearing completion. Experimentation with this kernel should provide qualitative evaluation of the advantages of the Gutenberg approach.

CARAT: a Testbed for the Performance Evaluation of Distributed Database Systems[1]

Walt Kohler and Bao-Chyuan Jenq[2]

Department of Electrical and Computer Engineering
University of Massachusetts
Amherst, MA 01003

Abstract

This paper describes the goals, design, and current implementation of CARAT, an operational distributed software testbed. CARAT is a simplified but complete transaction processing environment. It was designed to be a flexible tool for the testing and performance evaluation of distributed concurrency control, deadlock detection and avoidance, and recovery mechanisms used in distributed database systems. CARAT contains all the major functional components of a distributed transaction processing system (transaction management, data management, log management, communication management, and catalog management) in enough detail so that the performance results will be realistic. Some of the protocols currently implemented in CARAT and discussed in this paper are: a two-phase locking protocol with distributed deadlock detection, a distributed version of optimistic concurrency control, before-image and after-image journaling mechanisms for transaction recovery, and a two-phase commit protocol for global consistency of distributed transactions.

1 Introduction

During the past decade, concurrency control and recovery in transaction-oriented database systems has been the subject of intensive research [GRAY79, BERN81, KOHL81, HAER83]. Even though a wide variety of concurrency control and recovery algorithms have been proposed, there is currently little quantitative knowledge on how the choice of algorithms impacts the performance of the overall transaction processing system [STON83].

There are three major approaches to system performance evaluation: simulation, analytical modeling, and measurement. Simulation studies are most widely used primarily because system parameters and configurations are relatively easy to change and any desired level of detail can be captured. However, it often requires a tremendous amount of computation to gather convincing simulation results for complex systems. Furthermore, the results can be misleading if some significant factors are ignored by the simulation model.

Analytical modeling is relatively inexpensive to perform and often provides good insight into system behavior, if an appropriate model can be found. But analytic models for complicated systems are difficult to construct and solve without introducing simplifying assumptions that may be inappropriate.

Both analytical and simulation models require estimates of the system resource requirements of the primitive elements of the algorithm as implemented in the system under study. Usually they can only be obtained by extensive measurement of a prototype implementation. Performance measurement of a real system is more conclusive than either simulation or analytical analysis. However, performance data is time comsuming to collect and reduce and it is not feasible to generalize the results of performance measurement to different system configurations and designs without using some type of model.

One way to obtain the model parameters needed for analytical and simulation studies is through the implementation and measurement of a *testbed* system. A testbed system is an operational prototype system that is simple and flexible enough to permit the designer to "plug in" various algorithms or strategies and then measure and study their impact on system performance. As discussed in a special issue of *Computer* (Vol. 15, No. 10, 1983), testbeds are becoming recognized as an important research tool because "We expect experimentation with distributed systems to provide

1. an improved understanding of the functional requirements and operational behavior of distributed systems,
2. measurements from which quantitative results about distributed systems can be derived,
3. an integrated environment in which interrelations of solutions to individual problems can be evaluated, and
4. a design environment in which design decisions can be based on both theoretical and empirical studies." [BERG82, page 9]

We believe that an evaluation approach based on a combination of performance measurement and modeling studies is necessary in order to characterize and understand the impact

of different concurrency control and recovery algorithms on the performance of a distributed database system. The testbed system we have implemented for the performance measurement of concurrency control and recovery algorithms is called **CARAT** (**C**oncurrency **A**nd **R**ecovery **A**lgorithm **T**estbed). Some of the protocols currently implemented in CARAT and used in performance measurement experiments are:

- a two-phase locking protocol with distributed deadlock detection based on probes
- a distributed version of optimistic concurrency control
- before-image and after-image journaling mechanisms for transaction recovery
- a two-phase commit protocol for global consistency of distributed transactions.

Performance comparisons of concurrency control algorithms have been carried out by a large number of researchers using simulation and analytical models, for example, by Irani and Lin [IRAN79], Ries and Stonebraker [RIES79], Lin [LIN81], Thomasian [THOM82], Galler [GALL82], Menasce and Nakanishi [MENA82], and Carey and Stonebraker [CARE84]. But there are important issues that have received little consideration in previous studies:

- There has been little empirical comparison of different concurrency control and recovery algorithms in distributed database systems, as pointed out by Stonebraker et al.[STON83]. Moreover, even though system resource requirements for the basic components of concurrency control and recovery algorithms are necessary for realistic performance modeling studies, few results have been reported.
- The validity of the various assumptions made in the models have not been carefully examined. In fact, the previously reported results have been contradictory. Refer to the recent modeling work of Agrawal, Carey, and Livny [AGRA85a] for an examination of the discrepancies.
- Most of the previous modeling studies considered only the performance of concurrency control algorithms in a centralized database system. Few studies have addressed the distributed database environment [GARC79, LIN81, NAKA82].
- Although concurrency control and recovery mechanisms are intimately related, except for the recent modeling work of Agrawal and DeWitt [AGRA85b] they have been treated as two separate problems when studying their impact on database system performance.

In this paper we describe the design and implementation of the CARAT testbed. Our goal is to show how we constructed the testbed and to identify our major design decisions. Since our initial performance studies have concentrated on transaction management issues, i.e., concurrency control and recovery protocols, we have separated transaction management from data management as much as possible. A discussion of our performance measurement methodology and experimental results can be found in [KOHL86]. We have also developed and validated an analytical queueing network model for the CARAT distributed transaction processing system [JENQ86b]. The current paper serves as an introduction to the testbed used in those studies. The next section begins with an overview of the physical design of CARAT.

2 Overview of the CARAT Architecture

The *process* and *communication* structure are the two major architectural issues in developing a testbed for the efficient execution of distributed transactions. In determining the process structure, there are three primary considerations. First, it is important to minimize communication overhead and context switching. Second, it should support a high degree of concurrency among multiple transactions, called inter-transaction concurrency. Finally, to exploit the processing parallelism available in a distributed system, it should be possible for requests from a single transaction to be executed sequentially or in parallel at multiple nodes, this is called intra-transaction concurrency.

CARAT is implemented as a set of cooperating server processes which communicate via a uniform and efficient message passing mechanism. After experimenting with an early prototype [GARC83], we decided to implement CARAT using two levels of servers at each node. Figure 1 illustrates the process and message structure of CARAT for two nodes, but the architecture generalizes to any number of nodes. The top level server process, called the TM server, is the Transaction Manager. At the next lower level there is a pool of Data Managers, designated the DM servers. This structure cleanly divides most of the functions of transaction management and data management between the two server categories. (See the book by Ceri and Pelagatti [CERI84] for a discussion of distributed transaction management issues and architectures.) The TM and DM servers work cooperatively to service transaction requests from user application processes. Each user process, labeled TR, submits transaction requests sequentially. In our experiments each node runs on a single processor.

One function of the TM server is to act as the inter-process communication agent for user processes. Inter-node communication links are established at system start-up time among the TM servers and are maintained forever. There is no communication link between a TM server and a remote DM server. Since all inter-process connections are maintained, there is no connect or disconnect overhead for individual transactions. Each request to a remote DM server is routed through a remote TM server. This also reduces the required number of inter-node links, which would otherwise become overwhelming for an environment with many users at each node.

A user application process issues transaction requests only to its local TM server. The local TM server is called the Coordinator TM. A local transaction request is routed by the Coordinator TM to a local DM server while a remote request is sent to a remote (slave) TM server. The DM servers execute the transaction requests and send response messages to their local TM server. For responses to local requests, the TM server then routes the messages to the initiating user processes, while responses to remote requests are routed to the user processes

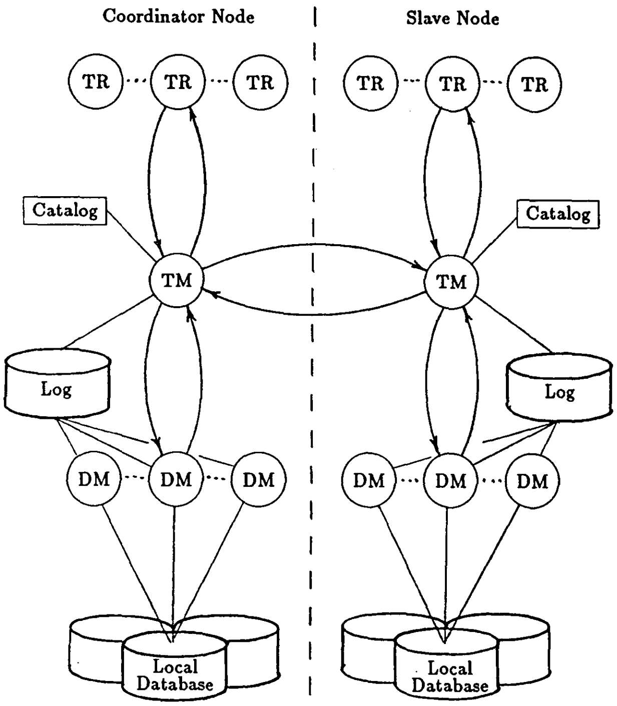

Figure 1: CARAT process and message structure.

through the initiating TM server.

A DM server for a particular transaction is dynamically allocated by the TM server from the DM server pool. The association of a DM server with a transaction is maintained throughout the lifetime of the transaction. For a distributed transaction, there is a DM server agent at each of the participating nodes.

Inter-transaction concurrency can be achieved by having multiple DM's active concurrently at one or more nodes on behalf of different transactions. The degree of inter-transaction concurrency at a node is thus bounded by the number of DM servers at the node. Intra-transaction concurrency can be achieved if a user transaction issues multiple requests in parallel for different DM server nodes.

We believe that the two-level server structure is well-suited for the distributed workstation and database server environment. The TM server may become a bottleneck when the message arrival rate is high. However, our experience so far has shown that the serialization delay due to the TM server is not a significant factor for a wide range of message request rates. Besides, our testbed architecture allows the TM server to control the effective multiprogramming level by simply queueing the message requests from transactions. By controlling the multiprogramming level, TM is able to control the level of conflict among transactions. This process structure also maps well into an environment where each node is a multiprocessor or tightly-coupled cluster. Each TM or DM process could run in a separate processor.

CARAT contains the functional components: *transaction management*, *data management*, *log management*, *communication management*, and *catalog management*. Transaction management, inter-node communication and catalog management are the responsibilities of the TM server processes. The data management function is handled by the DM server processes, which also hold the primary responsibility for log management if recovery based on logging is used. The CARAT system has been implemented for a high-speed network of DEC VAX/VMS[3] systems with DECnet/Ethernet connections . In the next section we will describe the communication management component. This will be followed by a section that sketches the execution of a transaction and then sections that describe the implementation of each of the other functional components.

3 Communication Management

To reduce programming effort and increase flexibility, a port interface is implemented by the communication management module. A uniform call interface is provided by the port interface for both intra-node and inter-node process-to-process communication. There is at least one port associated with each of the CARAT system processes (TM's and DM's) and the user transaction processes (TR's). The coupling of ports and processes enables us to categorize the port types by the associated process types. Thus, there are three basic port types in CARAT: TM, DM and TR. Each of the ports is named by port type, port number, and node number.

In essence, a port is an abstraction of a first-in-first-out queue containing messages destined for the associated process. Messages received either through inter-node or intra-node communication are all appended to the tail of the port queue. A process is transparently interrupted when a message arrives and it is then automatically resumed after the message has been placed on the queue. Both synchronous and asynchronous primitives for sending and receiving messages are provided by the communication module. Our experience has shown that asynchronous send and receive are essential for the operation of the TM server process due to its multi-threaded nature. Each of the server processes defines its port at system start-up time. By defining a port, the process has essentially set up an incoming channel from the port. Outgoing communication channels are established by connecting to the ports owned by the other communicating processes.

Intra-node process-to-process communication is implemented using the mailbox facility provided by the VAX/VMS operating system. Mailboxes support synchronous and asynchronous communication between processes by buffering messages in system dynamic memory. When using synchronous mailbox communication, the process that issues the receive blocks and waits, if it finds no message in the mailbox. It remains blocked until a message is sent to the mailbox by some other process. Likewise, a process sending synchronously is blocked until the message it sent is received by another process connected to the mailbox. Asynchronous communication, on the other hand, allows a sending process to continue before the message is read by a receiver and a receiving process to continue even if there is no message in the input queue.

For inter-node process-to-process communication, the underlying communication mechanism is based on DECnet virtual circuits. This shields undesirable conditions such as lost messages,

[3] DEC, VAX, VMS, and DECnet are trademarks of Digital Equipment Corporation.

message duplication, and out-of-order message delivery from the servers. Communication link failures and node crashes can be observed by DECnet and the involved communicating parties can be notified of the failures. DECnet supplied failure information can be used to supplement the TM server's timeout based failure detection mechanism. The only inter-node communication in the current CARAT architecture is between TM servers.

4 Model of CARAT Transaction Execution

A transaction is basically a sequence of host language statements, including terminal input/output statements, and database DML statements bounded by the transaction delimiters TBEGIN and TEND. In a distributed database system based on message-passing, each of these DML commands may be carried by a message to a DM server which will interpret and then execute the command. This approach requires one request/response message per DML command in addition to the processing overhead associated with the run-time interpretation of the command. To reduce message overhead, several DML commands with parameters can be grouped into a *request* and carried by a single message. To reduce the run-time interpretation overhead, the requests can be compiled.

In CARAT a request is compiled into a small object module and stored with the DM server. Requests are invoked at run time by a message that carries the request number and the actual parameters used by the request. Requests are the basic units of execution and distribution among participating nodes.

There are five basic message types issued by a CARAT transaction: TBEGIN, DBOPEN, TDO, T_ABORT, and TEND. A user process initiates a transaction by sending a TBEGIN message to its local TM server. This TM becomes the Coordinator TM for the transaction. A TBEGIN message is followed by a DBOPEN message and a sequence of TDO messages, each of which contains a transaction request. A DBOPEN message carries the description of the data objects (e.g., name of the area or file) upon which the subsequent TDO messages will operate. Upon receiving a DBOPEN message, the TM server determines the location of the data object by consulting its local catalog. The catalog is replicated at each site. If the data object resides locally, it will allocate a local DM server to serve the transaction if one is not already allocated and then forward the DBOPEN request to the DM server. For remote data objects, the TM forwards the DBOPEN message to the TM server where the data object resides. The remote TM server is called the Slave TM. Transactions initiated at another node are called foreign transactions for the Slave TM server. When a Slave TM receives a request from a foreign transaction, it assigns it a DM server, if it does not have one already, and then forwards the request. After processing the request, a DBOPEN_K acknowledgment is returned to the transaction. One of the parameters included in the DBOPEN_K message is the location of the data object for use in subsequent TDO requests.[4] Note that there is exactly one DM server which acts as an agent for a transaction at every node the transaction visits. The use of a catalog by the TM coordinator provides *location transparency* to transactions. This allows transparent file migration and simplifies application programming.

The TDO message carries a request number, a location indicator, and the actual parameters for the request. Each TDO message is routed by the coordinating TM server to either a local DM server, using a DOSTEP message, or a remote TM server, using a REMDO message. For TDO messages which expect data to be returned to the requesting transaction, an acknowledgment message, TDO_K, will carry the response data. Our current implementation assumes that the entire response set can fit into the message buffer.

The user process issues a TEND message to commit a transaction. To coordinate execution of distributed transactions, the cooperating TM and DM servers execute a commit protocol.

An example of the flow of messages that might occur during the execution of a simple CARAT transaction is shown in Figure 2. The sequence of events are time ordered from the top of the figure to the bottom. Each column represents the user process or a system process and the interchange of a message is shown by an arrow.

Figure 2: Flow of messages for a simple CARAT transaction.

[4] The "_K" on a message name is used to indicate an acknowledgment message.

5 Transaction Management

The basic function of transaction management is to coordinate distributed transaction execution to guarantee that all the participating nodes reach the same decision about the outcome of each distributed transaction, despite node, communication or transaction failures. This is achieved by implementing a commit protocol. Another responsibility of this module is to provide an interface to user transactions and to route requests and responses between the transaction, TR, and the local DM or remote TM processes based upon the transaction state information it maintains and the message type. In the following subsections we will discuss transaction state management, the two-phase commit protocol, and the failure handling mechanisms implemented in CARAT.

5.1 Transaction state management

Upon receiving a TBEGIN message, the transaction management component of the TM process registers the transaction by assigning it a globally unique transaction identification, TS. TS is a timestamp [LAMP78] formed by concatenating three numbers: a local counter, a node number, and a retry number. The local counter represents *logical time* and is incremented by each local transaction registration. TS is returned to the transaction in the TBEGIN_K acknowledgment message. All future messages sent by the transaction contain TS as identification. To maintain the correct partial ordering of transactions in the distributed system, the local counter is brought up-to-date every time it receives a message from another node.

The transaction management module keeps track of the transaction state of every active transaction. Each TM server process maintains two tables for transaction state information. The **Coordinator Table** contains *global* state information on each active transaction that was initiated locally. The **Slave Table** contains *local* state information on each active foreign transaction that has opened a database file and executed requests at that node.

The *global state* of a transaction is either: *inactive*, *active*, *collecting*, *committing*, or *aborting*. A TBEGIN message received by the Coordinator TM marks the beginning of the transaction's *active* state. The transaction normally remains in the active state until a TEND message is received by the TM coordinator from the transaction. While in the active state, the TM coordinator accepts and forwards DBOPEN and TDO messages for processing by local or remote DM managers. A TEND message triggers the TM coordinator into the transaction commit protocol.

The Slave Table maintains the *local state* of foreign transactions. There are six local states: *inactive*, *active*, *preparing*, *prepared*, *committing*, or *aborting*. An entry is maintained for each foreign transaction that is not inactive at the node. The local state becomes *active* when a REM_DBOPEN message is received and a DM server is assigned to the foreign transaction. Under normal operation the state remains active until a PREPARE message is received from the Coordinator TM process. This marks the beginning of the *preparing* state and a PREPARE message is sent to the assigned DM process. The *prepared* state is entered when the DM process returns a PREPARED_K message. This tells the Slave TM that the DM has safely stored the information to undo (or redo, depending on the recovery method used) the transaction in stable storage. A transaction in the *prepared* state means that the slave has given up its right to unilaterally abort the transaction. It must wait for the Coordinator TM server's commit or abort decision.

The transaction management component is also responsible for coordinating failure recovery. The three basic types of failures that are usually considered as recoverable are [GRAY79, HAER83]: *transaction failure*, *system failure*, and *media failure*. We assume that *transaction* failures do not corrupt the volatile or non-volatile database or the log, that *system* failures do not corrupt the non-volatile database or log, and that *media* failures do not corrupt the log or the database checkpoint. Transaction failures occur with the highest frequency and they are typically caused by user abort and deadlock abort. Before failures can be handled they must be detected. User abort failures can be detected by the underlying operating system and message system. Deadlock failures are detected by the deadlock detection component of lock based concurrency control schemes.

Since our performance experiments have only been concerned with transaction deadlock abort, we have not yet implemented a sophisticated user and node failure detection mechanism. The basic mechanism employed for user abort and node crash detection in the current implementation is message timeout. For example, if the Coordinator TM does not receive a message from an active TR within a predefined timeout interval, the TM coordinator assumes the transaction has failed and initiates an abort procedure. Similarly, a remote node crash or communication network failure is detected by the inability to send a message to the node or by timeout waiting for the next message or acknowledgment from the node.

The logic of the transaction manager (TM) is specified using a finite state machine representation. Depending on a transaction's current state and the type of input message received on behalf of the transaction, it may make a transition to another state or stay in the same state, and it may send messages to a DM server, other TM servers, or the user transaction. The implementation of the TM module is based on this finite state machine representation. This approach proved to be of great value in the debugging and modification of the system. A complete description of the state transition tables can be found in [JENQ86a].

5.2 Commit Protocol

The conventional centralized two-phase commit protocol [GRAY79] has been implemented in CARAT. For each transaction, the Coordinator TM is the the controller. The coordinator communicates with the participating slave TM's to reach unanimous agreement on the outcome (commit, or abort and rollback) of the transaction. During execution of the commit protocol, log records with recovery information are written to the stable storage so that the effects of the transactions can be correctly recovered from system failures in which the volatile memory is lost.

Performance improvements to the basic two-phase commit protocol can be achieved by reducing the number of inter-node messages and the number of log writes in the distributed environment. In addition, since read-only transactions are likely to be dominant in most application environments, it is desirable to optimize the protocol for read-only transactions. Two more efficient commit protocols, called Presumed Abort 2PC and Presumed Commit 2PC, have been proposed and implemented in IBM system R* [MOHA83]. Two-phase commit protocols are vulnerable to coordinator failures and to network partitions that isolate the coordinator. We plan to study additional protocols in the future.

5.3 Failure Handling

Following the work of Skeen and Stonebraker [SKEE81], we classify the failure handling mechanisms into two protocols: the *termination protocol* and the *recovery protocol.* The *termination protocol* is invoked at failure detection time to guarantee transaction atomicity. It attempts to terminate consistently (commit or abort, depending on the transaction's current state) all affected transactions at all the participating nodes.

If a failure is detected before the commit decision is made, i.e., while the transaction is in the *active* or *collecting* state, the TM coordinator sends an ABORT messages to the local DM server process and all the participating Slave TM servers. The slave TM server then forwards an ABORT message to the participating DM server to roll back the transaction.

However, if a node crash is detected by the Coordinator TM while a transaction is in the *committing* state, which corresponds to the second phase of the two-phase commit protocol, then the transaction will be left in the *committing* state until the slave node recovers and informs the coordinator it is functioning again. Then the commit message will be forwarded to the slave.

For communication failures, the underlying DECnet virtual circuit communication layer will first try to send messages through an alternate communication path. If one exists, the communicating processes will be allowed to continue; otherwise, the Coordinator TM follows the protocol for a failed slave.

If a Slave TM server detects that the Coordinator TM server for one of its transactions has failed, it will either abort the transaction or wait for the coordinator to recover. The decision depends on the local state of the transaction stored in the slave table. If the local state is *prepared*, then it must remain in the *prepared* state until the coordinator node recovers and sends a COMMIT or ABORT message. However, if the slave is not *prepared*, the transaction is immediately aborted.

A node which has failed must execute a *recovery protocol* before it resumes communication with other nodes. The major functions of the recovery protocol are to restart the system processes, the TM and DM's in the case of CARAT, and to re-establish consistent transaction states for all transactions affected by the failure. The information in the system log is sufficient to re-establish a consistent state and it is assumed to survive the failure.

We have taken a simple approach in the current implementation of CARAT. All transactions that were active at the time of the node crash but not in the second phase of the two-phase commit, i.e., not in the *committing* state in the coordinator table or the *prepared* state in the slave table, are rolled back.

6 Data Management and Concurrency Control

The DM servers manipulate the database on behalf of user application processes. The implementation of the DM servers can be partitioned into five major modules: **Request Processor**, **DML Processor**, **Buffer Manager**, **Concurrency Control**, and **File IO**.

The **Request Processor** module is the front-end for the DM server. It processes the transaction requests received in DOSTEP messages from the Transaction Manager. It contains a set of request-handling routines that map the request number and input parameters into a sequence of DML statements to be executed by the DML Manager. Each request from the TM server is dispatched to a corresponding request-handling routine. In our current implementation, the request handlers are statically defined and linked into the Request Processor module.

The **DML Processor** module supports database DML routines. We are currently using a simple CODASYL database processor because we have access to the source code and it is easy to modify those parts that impact our transaction processing experiments. Other data models could be supported, but we believe that the concurrency control and recovery issues can be studied independently of the data model. The DML Processor routines are called to execute CODASYL DML statements using currency, set information and data definitions specified in the database schemas. A simple database protection mechanism is provided by checking passwords contained in the DBOPEN statements before opening the database files for access. Currently, our distributed database is just a collection of independent database fragments, one at each node. But other structures, including replication, can be supported by our architecture.

The DML Processor calls routines in the **Buffer Manager** module to fetch the database pages it requires. To reduce disk IO, the Buffer Manager manages a private buffer, i.e., private to each DM server, for high traffic data pages. A least-recently-used (LRU) strategy is employed for buffer page replacement. The size and management of the buffer can be adjusted to accommodate different concurrency control and journaling strategies. For the lock based concurrency control scheme, a fixed size private buffer is managed by each DM server. Modified pages are written back to the on-disk database when the buffer slots are re-assigned to other data pages. The Buffer. Manager is also called to flush the modified data pages during the first phase of the two-phase commit execution. For the optimistic concurrency control approach, the size of the private buffers are extended to accommodate all modified pages, since no updates to the on-disk database is allowed before a transaction is committed. A global buffer mechanism, in which one or more shared buffers are used to further reduce the disk IO traffic for concurrent transactions will be considered for future implementation.

Low level IO routines for file operations are contained in the **File-IO** module. This module supports both synchronous and asynchronous write to non-volatile disk storage. Asynchronous write is used for database read/write operations while synchronous write, also called force-write, is primarily used for journaling operations to ensure that the log records are safely stored on disks before a process can continue executing other operations.

The **Concurrency Control** module contains most of the routines for local and distributed concurrency control and deadlock detection. Several mechanisms have been implemented and tested. A two-phase locking protocol with distributed deadlock detection [ESWA76, CHAND83] and a distributed version of Kung's and Robinson's optimistic concurrency control [KUNG81] are described in the next two subsections.

6.1 Two-Phase Locking with Distributed Deadlock Detection

Two-phase locking (2PL) in CARAT is supported by a **Lock Manager** that uses a hashing technique to manage a lock table containing Lock-Grant queues and Resource-Wait queues. There is one lock table at each node. It is used to record the locks on resources at the node. Five lock modes are supported [GRAY79]: Concurrent Read (CR), Concurrent Write (CW), Protected Read (PR), Protected Write (PW), and Exclusive (EX). A lock request is queued for a resource if the requested lock mode is not compatible with the locks held by other transactions or with other queued lock requests for the resource. The Buffer Manager issues a read or write lock request before reading a page into its buffer. All locks are held until a transaction has committed or rolled back.

Both local deadlocks and global deadlocks are resolved by detection. Local deadlocks are detected by searching cycles in the Transaction-Wait-For-Graph that is encoded in a two dimensional array. One approach to distributed deadlock detection that is implemented in CARAT is based on the *probe algorithm* proposed by Chandy and Misra [CHND82]. In this case, the TM server at each node acts as a controller for distributed deadlock detection. A PROBE message is an ordered pair (initiator, receiver), where the initiator denotes the transaction that initiates the probe computation and the receiver denotes the transaction which is in the dependent set of the initiator.

Our implementation of distributed deadlock detection using probes will be described using the following notation:

- TM(n) denotes the TM server and DM(Ti,n) the DM server for transaction Ti at node n.
- A transaction Ti is said to be in the Remote-Wait state, i.e., communication wait state, at node n if the DM(Ti,n) server for Ti is waiting for a request or response from a remote node. The remote node will be denoted by RWN(Ti,n).
- At each node the dependencies of transactions, e.g., Ti on Tj, are registered in an array DEPENDENT(Ti,Tj) in order to filter out redundant PROBE messages.

DM(Ti,n) executes the following protocol:

```
If DM(Ti,n) is blocked on a lock request then
    If Ti is locally dependent on itself then
        Declare Ti as the deadlock victim
    else
        If (Ti is dependent on Tj) and (Tj at node n is in
            Remote-Wait state) then
            Send an INIT-PROBE(Ti,Tj) message to TM(n)
        endif
        Idle, i.e., wait for lock release
    endif
endif
```

On receiving an INIT-PROBE(Ti,Tj) message from DM(Ti,n), TM(n) sends a PROBE(Ti,Tj) message to TM(m), where m is the remote node from which Tj at node n is waiting for a request or response to an request, i.e., RWN(Tj,n).

TM(m), on receiving a PROBE(Ti,Tj) message from TM(n) executes the following protocol:

```
If (Tj is idle) and (DEPENDENT(Ti,Tj) = FALSE) then
    DEPENDENT(Ti,Tj) := TRUE
    If (Ti = Tj) or (Tj is locally dependent on Ti) then
        Declare Ti as the deadlock victim
    else
        If Tj is in Remote-Wait state at node m then
            Send PROBE(Ti,Tj) to RWN(Tj,m)
        else
            For each Tk that blocks Tj and Tk is in
                Remote-Wait state at node m
                Send PROBE(Ti,Tk) message to TM at node
                RWN(Tk,m)
            endfor
        endif
    endif
else
    Ignore probe message
endif
```

To illustrate the implementation of distributed deadlock detection in CARAT, a deadlock that was detected in one of the performance experiments is shown in Figure 3. In the figure, each transaction Ti is identified by its associated timestamps q.n, where q is the local counter and n is the node number. The sequence of the events is listed below.

1. DM(7.1,1) for transaction 7.1 at node 1 is in Remote-Wait state waiting for DM(7.1,2) at node 2;
2. DM(7.1,2) for transaction 7.1 at node 2 is blocked on a lock request by DM(2.2,2) for transaction 2.2;
3. DM(6.2,2) for transaction 6.2 at node 2 is in Remote-Wait state waiting for DM(6.2,1) at node 1;
4. DM(7.2,2) for transaction 7.2 at node 2 is blocked on a lock request by DM(6.2,2) for transaction 6.2;
5. DM(6.2,1) for transaction 6.2 at node 1 is blocked on a lock request by DM(7.1,1) for transaction 7.1;
6. DM(2.2,2) for transaction 2.2 at node 2 is blocked by on a lock request by DM(7.2,2) for transaction 7.2. Since transaction 2.2 is dependent on transaction 6.2 and 6.2 is in Remote-Wait state, an INIT-PROBE(2.2,6.2) message is sent to TM(2); A
7. On receiving INIT-PROBE(2.2,6.2) from DM(2.2,2), TM(2) sends PROBE(2.2,6.2) to TM(1);
8. On receiving PROBE(2.2,6.2), TM(1) executes the probe protocol and sends PROBE(2.2,7.1) to TM(2);
9. On receiving PROBE(2.2,7.1), TM(2) executes the probe protocol. Since 7.1 is locally dependent on 2.2, transaction 2.2 is declared the deadlock victim.

6.2 Optimistic Concurrency Control

In the optimistic approach (OPT)[KUNG81], a transaction consists of *three phases*: a *read phase*, a *validation phase*, and possibly, a *write phase*. Our implementation of the optimistic approach is based on the use of two counters at each node: 1) NVN, the node validation number, and 2) NWN, the node write number. At the beginning of the read phase at each node transaction Tj visits, Tj reads the value of NWN into START-WN(Tj). START-WN(Tj) is the highest assigned transaction write number, NWN, when the transaction starts. During the read phase, each transaction performs read and write operations by managing data in the private buffers of the DM servers and its read-set and write-set are maintained in arrays of resource names.

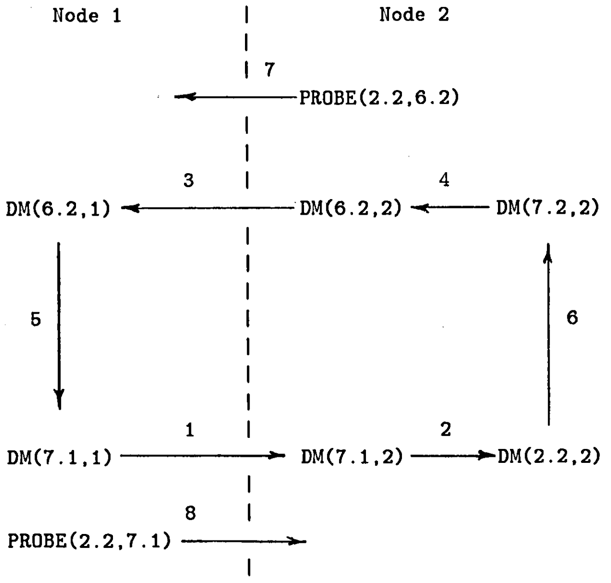

Figure 3: An Example of distributed deadlock detection in CARAT.

At the end of the read phase, the transaction is validated within a critical section. For distributed transactions, validation proceeds independently and in parallel at each node within separate critical sections. The DM(Tj,n) server at node n becomes ready to enter the validation phase for transaction Tj when it receives a PREPARE message from its TM server. If transaction Tj is validated successfully at node n, the node validation number, NVN, is incremented by one. The write-sets of validated transactions are kept in a VALIDATED-WRITE-TABLE (VWT), since they may be needed for the validation of some concurrent transactions.

Transaction Tj is validated within a critical section at node n as follows: First, the current value of NVN is assigned to VAL-VN(Tj). Then the read-set of Tj is checked against the write-set of each transaction Ti that completed writing after Tj started its read phase. Tj will fail validation if its read-set intersects with the write-set of at least one of the Ti's. As discussed in [CERI84, page 236], Tj must also be validated against other *active* transactions that have successfully validated but have not yet completed writing to the database.[5] Therefore, for each Ti such that VAL-VN(Ti) < VAL-VN(Tj) and Ti has not yet completed writing, we compare the union of the read-set and write-set of Tj with the write-set of Ti. If the sets intersect, Tj fails validation and the transaction is aborted. If Tj does not fail validation, the node validation counter NVN is incremented by one before leaving the critical section.

A transaction Tj enters the write phase only if it is an update transaction and it has been validated successfully at each node where it was active. The two-phase commit protocol is employed to ensure global consistency as described in [BHAR82]. The parts of the transaction at each node, called subtransactions, are validated separately. In the PREPARE phase, each subtransaction that succeeded in validation locally returns a positive acknowledgment, i.e., a "Yes" vote, via a PREPARE_K/OK message to its TM server. The Coordinator TM server commits the transaction only if each subtransaction of the transaction validates successfully. In order to guarantee global consistency in the face of failures, the after-image log records of successfully validated transactions are force-written to the log file before a PREPARE_K/OK message is returned by the DM server. The effects of a committing transaction can be recovered by rolling forward the database using the after-image log records. At the end of the write phase, the value of NWN is incremented by one and assigned to FINISH-WN(Tj). Note that the value of NWN is incremented and assigned to Tj only after all writes are completed. Therefore, a transaction Ti that has START-WN(Ti) ≥ FINISH-WN(Tj) is able to see all the updates produced by Tj.

7 Log Management

When a transaction is aborted, for example, because of concurrency control conflict or node failure, the effects of the transaction have to be removed by a recovery mechanism provided by the database system. One approach is to update-in-place the data objects altered by the transactions. In this case, each data object has a fixed location in non-volatile storage and each site maintains, perhaps on a storage device with different failure modes, a sequence of log records containing a before-image, an after-image, or both, of the data objects modified by the transactions to undo and redo the transactions [GRAY79, HAER83]. The log is manipulated as an append-only file on a per node basis. The log record for a data object has to be written to non-volatile storage before the data object is modified at its home location, which is the reason the mechanism is often called a write-ahead-log (WAL).

The journaling facility currently implemented in CARAT is based on this write-ahead-logging mechanism. The TM and DM servers at each node share a single system log file for before-image (BI) or after-image (AI) log records and data objects and two-phase commit protocol records. journaling can be done at various levels of data object granularity, however, only page level journaling is currently implemented.

When two-phase locking is used with before-image journaling, designated as 2PL/BI, before-image data pages are force-written to the logging disk by the DM servers before the data pages are modified in the buffers and, therefore, before the data buffers are written back to the database. The resulting before-image log can

[5] We discovered that the approach described in [CERI84, page 235-236] is not adequate to handle all cases. We introduced the node validation number, NVN, and modified the validation procedure as described here to correct the problem.

be used to roll back the database if the transaction aborts.

For the optimistic concurrency control approach with after-image journaling, designated as OPT/AI, log records of modified pages are force-written to the logging disk during the prepare phase of the two-phase commit execution, i.e., before the DM server returns a PREPARE_K message to the TM server. Note that, for the optimistic approach, all the modified data pages are buffered in a virtual memory buffer and are flushed out to the database only when the COMMIT message is received by the DM server.If the transaction does not commit, the buffer is just discarded.

To safely record the transaction state against system failures, the Coordinator TM server, as the coordinator for a distributed transaction, force-writes a COMMIT or ABORT log record to the system log at the end of the first phase of the two-phase commit, after the fate of the transaction is determined. Also, a PREPARED log record is force-written to the system log when a DM server reaches the prepared state. A PREPARED log record contains the coordinator node number to resolve the fate of the transaction at system recovery time.

The TM server at a recovering node executes a *recovery protocol* before it resumes transaction processing. First, the system log file is examined for the states of the transactions at node crash time. Active transactions are rolled back, for example, by using the before-images in the system log. For committing transactions a COMMIT message is sent to the Slave TM servers and, for each Prepared transaction, an inquiry message is sent to its Coordinator TM server for the final outcome of the transaction.

8 Catalog Management

Catalog management is introduced to support location transparency and replication transparency [LIND80]. CARAT uses a distributed catalog mechanism consisting of local catalogs managed by each of the TM server processes to provide location transparency to user transactions. In the current implementation, the mapping of file names and locations in the catalog is static, since no file migration or file deletion is allowed and each node has the complete global knowledge of the mapping. However, catalog management schemes such as those described by Lindsay [LIND80] can be implemented in the future.

A DBOPEN message carries the name of the data objects (i.e., file names) to be accessed. Upon receiving a DBOPEN message, the TM server determines the location of the data object by consulting its local catalog. If the data object resides locally and no DM server was allocated for the transaction, it allocates a DM server as the local agent for the transaction. The DM server then checks the protection and opens the file for access. For remote data objects it forwards the DBOPEN message to the remote TM server which allocates a DM server at that node for the transaction or, if a DM server has been already allocated, forward the DBOPEN message to the DM server to open the file. Note that there is at most one DM server for a transaction at each node.

9 Summary

We have described the design and implementation of CARAT, a distributed testbed for use in the performance evaluation of integrated concurrency control and recovery algorithms. The testbed approach has enabled us to "plug in" various algorithms and protocols, verify their correctness, and measure their impact on system performance. Some of the protocols that we have implemented and used in performance tests are: two-phase locking with distributed deadlock detection based on probes, a distributed version of optimistic concurrency control, before-image and after-image journaling mechanisms for transaction recovery, and a two-phase commit protocol for global consistency of distributed transactions. Other companion papers [KOHL86, JENQ86b] describe the use of CARAT in performance measurement and modeling studies. Our experience has shown that the empirical and analytical studies are synergistic. We are now in the process of gathering additional measurements for different hardware configurations (more disks and more nodes), other combinations of concurrency control and recovery algorithms, and other buffering schemes. We are also extending our modeling efforts in these areas.

Acknowledgments. A prototype version of the CARAT testbed was implemented in the Corporate Research Group at Digital Equipment Corporation by Hector Garcia-Molina, Frank Germano, Walt Kohler, and others between 1980 and 1982 . CARAT has been redesigned and reimplemented at the University of Massachusetts under the direction of Walt Kohler, Jack Stankovic, and Don Towsley with support from National Science Foundation, grants ECS-8120931, ECS8340029, and SDB-8418216.

REQUEST II - A DISTRIBUTED DATABASE SYSTEM FOR LOCAL AREA NETWORKS

Marek Rusinkiewicz and Dimitrios Georgakopoulos

Department of Computer Science
University of Houston - University Park

ABSTRACT

The design and implementation of a distributed database management system, organized as a collection of a central database and several member databases is described. The central database contains copies of all data items that reside in member databases, and (possibly) some additional data that are not replicated. All updates are applied first to the master copy of the data item at a member database, and then propagated to the central site. Distributed concurrency control uses the Two-Phase Locking with primary copies. Protection from the loss of data consistency, due to site or network failures, is provided by a spooling mechanism which is used to keep logs of all incomplete update operations. The controlled data replication scheme used in the system simplifies the implementation of transaction processing, concurrency control and fault recovery facilities.

INTRODUCTION

For many database applications distributed systems constitute an attractive alternative by offering improved availability of data, increased reliability, and response times better than those possible in functionally equivalent centralized systems. Recent developments in the Local Area Networks (LAN) lead to a significant reduction in the communication overhead, which used to constitute a major bottleneck in computer networks. Thus the development of practical and reliable distributed database systems (DDBMS) became feasible [1]. REQUEST II is an example of a DDBMS such system designed to manage databases whose data is distributed over the multiple sites of a local area network.

The distributed configuration of the system fits naturally into hierarchical organizational structures of many modern corporations. These tree-like structures usually consist of functionally or operationally separate units with varying level of autonomy (divisions, branches, departments, etc.). The units are frequently allowed to create and maintain their own operational data. In such environments access to a single pool of information is required, while the data sources are distributed in a close geographic area. At any level of the corporation hierarchy, an efficient mechanism should be provided allowing to access not only the local data, but also the data belonging to the subordinate units.

REQUEST II provides a logically integrated view of data with distribution transparency and controlled data replication to meet the above requirements. Distribution transparency is a feature expected from modern distributed database system and allows users to interact with REQUEST II exactly as if it were not distributed. Replication of data is controlled by a static scheme which reflects the hierarchical structure of data and allows to improve response time, fault tolerance and data availability. Under the proposed replication scheme all members of a hierarchy, are provided with a local copy of data owned by their direct subordinates. This hierarchical organization applies to the data distribution and replication scheme but not to the underlying data model. In fact a REQUEST II database is a collection of (possibly replicated) relations.

Many general solutions to the problems of failure and recovery in distributed systems [2] are not directly applicable to the design of (efficient) distributed databases. The main reason for this is the number of data items involved in a transaction and the fact that the relevant data items may be determined dynamically during the transaction processing. Majority of solutions proposed for distributed database systems [3] are tuned towards long haul, low bandwidth communication networks. Since the design trade-offs are different in LANs, the solutions suitable for this type of environments would have to be developed.

In a Local Area Network such as Ethernet or ring network, many of "classical" reliability issues such as network partitioning need not to be considered. Instead, the achievement of a high level of performance becomes more important. Furthermore, it is possible to impose some data architecture constraints to allow the use of efficient transaction processing algorithms that improve the response time and simplify fault error recovery. REQUEST II constitutes an attempt to provide an efficient solution for a LAN-based DDBMS with a reasonable set of restricting assumptions.

The remaining part of the paper is organized as follows. The next section describes the data architecture and outlines the nodal database system used by REQUEST II. The following sections introduce the techniques used by REQUEST II to solve the most difficult problems in distributed data management, namely transaction processing, concurrency control and fault tolerance. The last section describes the system implementation. The discussion concludes with some comments on further system development.

DATA ARCHITECTURE

Data distribution and replication

A distributed database under REQUEST II can be viewed as a collection of a central database and several member databases. A copy of each data item can be stored in at most two locations: the central database and one of the member databases. The central database contains copies of all data items that reside in member databases, and (possibly) some additional data that is not replicated. Each member database contains copies of its local data items, which are used as master copies for concurrency control and recovery purposes. The member databases are considered to be the owners of that data. The central database owns only the data that is not stored in any member database. No data item resides in more than one member database (Figure 1).

The configuration of the central database (CDB) and the member databases (MDBs) can be described using the concept of data objects - collections of data items constituting the contents of databases. The master copy of a data object D, will be denoted by Di. If only one copy of a data object exists, it is considered to be a master copy. Based on the previous discussion of the data distribution and replication, we may say that the objects (Di, i=1..n) are stored in the corresponding member databases (MBDi,i=1..n). The central database (CDB) contains the duplicate copies of data objects (Di', i=1,2,...n) and the non-replicated data object (D0) which is stored only in the central database.

Thus, the data distribution and replication scheme of REQUEST II satisfies the following conditions:

central database:
$CDB = \{D0, D1', D2', \ldots, Dn'\}$

member databases:
$MDBi = \{Di\},\ i = 1, \ldots, n$

replication rules:
$Di' = Di,\ i = 1, \ldots, n$
$Di \wedge Dj = \{\},\ i <> j,\ i,j = 1, \ldots, n$

where $\wedge$ stands for intersection and $\{\}$ represents the empty set.

Extension of this scheme to a clustered distributed database environment is straightforward. Each member database can be thought of as a central database of an underlying (lower) level in a hierarchy, thus allowing to implement a hierarchically structured database collection. A REQUEST II cluster can be defined as a collection of database network sites (nodes) whose data items follow the above model of data distribution and replication (Figure 2).

A database network node is allowed to participate in at most two clusters, i.e. a node that is a member database in one cluster can constitute a central database in another cluster. In a clustered environment a copy of an object located in the lowest-level member database is considered to be the master copy of this object.

Distributed dictionary structure

The meta-information about data objects is stored in a hierarchical system of database dictionaries (catalogs). REQUEST II uses a simple general rule for dictionary replication: copies of table dictionaries reside where a copy of the corresponding data table is located.

A node dictionary resides at each site and contains information about all active nodes in the clusters of the distributed system, in which the site participates as a member and/or a central node. The entry for each node contains the information necessary to access the

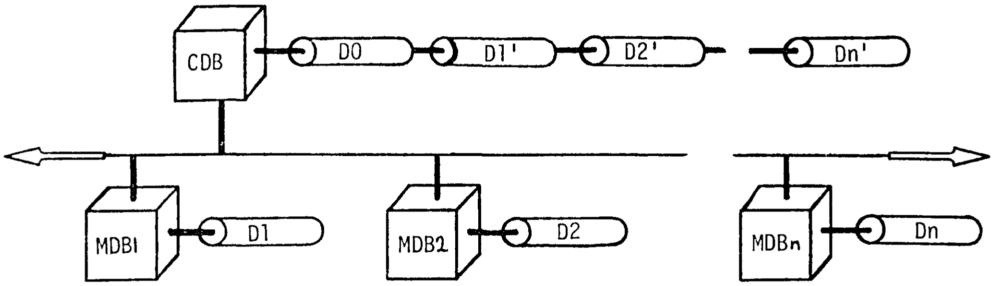

Figure 1. Data Architecture for a Two-level Hierarchy

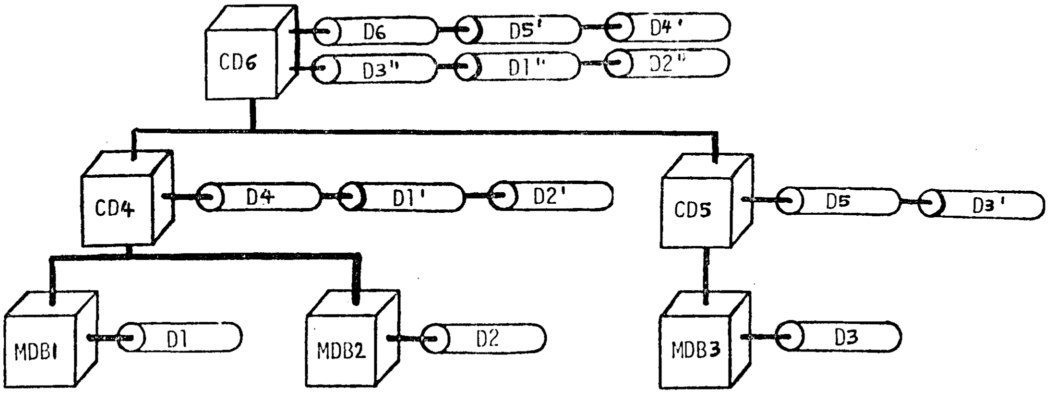

Figure 2. Multi-level Data Distribution and Replication Scheme

data stored at this node, including the logical node ID and the access information used by REQUEST II to perform remote operations.

The database dictionary lists all the databases defined in the distributed system, and provides access information (addresses) for their dictionary, security and data files. The database dictionary is fully replicated, i.e. a copy of it exists at each node. Table dictionaries describe the structure of every relation in the system. In each cluster, there are at most two copies of each table dictionary located together with the corresponding data files. REQUEST II dictionaries can be manipulated only by special routines which clearly distinguish dictionary relations from data relations.

The nodal Database Management System

REQUEST [4, 5] is a relational multi-user DBMS used as a "nodal" Database Management System for both central and member databases. REQUEST supports a wide variety of user interfaces, including several non-procedural query languages such as SQL, QUEL and Query-By-Example, a report generator, a screen-oriented application development tool, a host language interface, an integrated data dictionary and an on-line HELP facility. Most user interfaces are menu driven.

A database under REQUEST stores three kinds of relations: dictionary, data and security tables. The integrated dictionary system is hierarchically structured and consists of a database dictionary and a number of table dictionaries. For each database the information is kept describing all existing tables, including the owner, the table logical record length, table cardinality, table type (i.e. the information whether the relation is a view or a base table) and the physical organization of data files. A table dictionary file contains description of all fields defined in that table including field name and length, field type (i.e. integer, real, string, money or date), maximum and minimum values, default value (if applicable), default display format, and key information. A table security file contains the list of users authorized to access the table together with the allowed operations. Security file can be modified only through a GRANT-REVOKE authorization mechanism. Data files can be internally stored and accessed either as hash files or an indexed sequential files. REQUEST access method uses multi-key extendible hashing [6] and sequential organizations with secondary (dense) indexing for data files.

The local concurrency control under REQUEST uses the Two-Phase Locking [7] with intent locks [8]. REQUEST uses only a restricted form of transactions in which locks can be imposed on linearly ordered database object classes. This restricted form of transaction allows efficient implementation of a deadlock-prevention strategy.

When the user enters and executes a query, the query language interface (UFI) calls the language processor to parse, optimize and interpret the query. Before a parse tree is created, all relation and attribute variables are validated, and the domains of all constants used in the query are checked. At this stage it is determined whether the query is local or remote.

A nodal REQUEST can be viewed as a two level abstraction consisting of user interfaces (upper level) and the run-time unit (lower level). The run-time unit is capable of serving requests independently of the request source (local user or another site in the distributed system). User interfaces generate requests to be satisfied either at the local or at a remote site. The "centralized" REQUEST has been converted to a "nodal" database management system by modifying the interface between the run-time unit and the user access requests, so it became flexible enough to support both the calls from local users interfaces and the calls from the distributed system software.

Currently the distributed environment of REQUEST II, allows basic DDL, DML and SQL data retrieval functions to be performed interactively from any site in a network-transparent manner.

TRANSACTION PROCESSING

A single execution of a Data Definition, Data Manipulation or Query command constitutes a transaction. Transactions can be classified as queries (read-only) or updates (read-write) and apply either to the dictionary tables or to both dictionary and data tables. In order to support a multi-user, multi-site environment it is necessary to schedule conflicting transactions using some concurrency control mechanism. The concept of serializability [9] is employed to assure that conflicting read and write operations are scheduled according to some serialization order. Serializability requires that whenever transactions execute concurrently, their effect must be identical to some serial execution of these transactions.

Nodal DBMSs use the "Two-Phase Locking" to resolve local conflicts, while the distributed system extends this basic locking scheme to satisfy the distributed environment requirements. Two different locking methods are employed in REQUEST II. The "Basic Method" is used for the database dictionary copies and the "Primary Copy" method is used for table dictionaries and data items. [9]

Under the "Basic method", a read-lock is set at the local copy, if it is available. Otherwise, an arbitrary copy of the data item is read-locked. For update operations, write-locks are requested from all copies of the data item and the transaction is allowed to proceed only after all of them are granted. This reader-preference solution was adopted since, the changes to the data definition scheme do not occur frequently. To eliminate the possibility of a deadlock priorities are assigned to all database dictionary copies. Deadlocks are prevented by requiring all transactions to request their locks on copies of the database dictionary, in the a priori assigned order. Under the "Primary Copy" method both the read-locks and write-locks are imposed only at a designated master (primary) copy.

REQUEST II requires all transactions to lock distributed database objects in the following order:
- database,
- table (optional),
- data record (optional),
- table header (optional).

This linear ordering defines a hierarchy of all classes of lockable database objects. During the transaction execution a tree of locked objects of different granularity is produced. Deadlock avoidance techniques have been used, to carefully analyze the lock/unlock sequences in all transactions types and assure that deadlocks can not occur. Deadlock prevention in REQUEST II relays on two assumptions: the linear ordering of all classes of lockable objects in the restricted REQUEST II transactions and intent locking of these objects. Intention mode is used to lock all the ancestors of a node which is to be locked in shared or exclusive mode.

Transaction processing algorithms depend on the availability of data (data replication). For each transaction a transaction processing plan is determined by a Transaction Manager. Transaction Managers locate the remote and local copies of database items and manipulate them by calling the corresponding (local or remote) Data Managers. The distributed system obtains the information about data location from its dictionary system and executes the transaction as follows.

1. Updates: All updates are performed first at the site that stores the primary copy of a data item. Then, if there are other copies to be updated, the the primary copy site assumes the responsibility for propagating updates to the other sites involved. The primary copy of the updated object remains locked until all copies are updated.

2. Dictionary Queries: If the dictionary is available at the local site it is read locally. Otherwise read requests are forwarded to the site that holds the primary copy of the dictionary. Database dictionary queries need to lock only the local copy of the database dictionary, while for table queries the primary copy of the table dictionary must be locked.

3. Data Queries: If all data tables (and therefore dictionaries) required to evaluate a query are available locally then the query is processed. Otherwise, the query is submited to the central site, evaluated there and the response table is sent back to the originating site. Data queries lock the primary copies of the data tables.

Processing of data queries is facilitated by the data replication scheme used in REQUEST II, under which no decomposition of compound queries is required. This approach may have one drawback, namely little use is made of potential for parallel processing within a single transaction (although different transactions can be processed in parallel). Parallel processing requires the decomposition of a query into sub-queries, to be evaluated in parallel at different sites. The query evaluation cost consists of the I/O cost, the CPU cost and the communication cost. Studies of local area networks have shown that communication overhead is reasonably low and therefore the communication time does not necessarily dominate the cost of a query evaluation. This observation is not true in packet switching networks where the communication overhead is a dominant factor [10, 11].

As an example illustrating the use of our locking protocols, let us consider the processing of an interactive transaction performing a data record update. In the discussion below, S stands for shared lock, X means exclusive lock and IX means intent exclusive lock.

Data record update:

```
Get database and table names;
LOCK(IX) the local copy of the database;
Search local database dictionary for
database and table names;
If database or table name are not found
then error;
If the local site is not the primary copy
site of the data then
   SUBMIT update request to the primary
   copy site;
   UNLOCK(IX) the local database copy;
   Wait for a response;
else {primary copy site}
   LOCK(IX) the primary (local) copy of
   the table;
   Get the new data value(s);
   LOCK(X) the primary (local) copy of the
   data record to be updated;
   Perform the update on the primary
   (local) copy and propagate the update
   to the other (remote) copy;
   UNLOCK(X) the primary copy of the
   updated data record;
   UNLOCK(IX) the primary copy of table;
   UNLOCK(IX) the local database copy;
```

Other classes of transactions, i.e. data queries, dictionary queries, table field updates, table updates, database updates and authorization checks are performed in a similar way.

FAULT TOLERANCE

One of the frequently mentioned benefits of distributed database systems is the improved reliability and data availability. However, in order to achieve this benefit, the system must be able to operate correctly (preserve database consistency) even in the presence of failures. There are several types of failures that could occur in a distributed system. Two main categories are communication network failures and site failures. Undetected failures may severely damage the integrity of the system. Thus a failure detection mechanism must be provided to notify the system when a failure occurs. Failure detection and notification mechanisms usually reside in the communication subsystem. Distributed Database Systems logically belong to the (ISO) application layer of communication subsystems [12] and they rely on the network error detection mechanisms [13].

If a site fails during an update, the distributed system may be left in an inconsistent state. To protect distributed databases from this type of inconsistencies, a log of an operation must be recorded in a stable storage, before the execution of any update operation. In REQUEST II a spooling mechanism is used to maintain logs. A spooler is a process with access to the secondary storage, that serves as a first-in, first-out message queue. Any message sent to a node is first delivered to a spooler. The spooler secondary storage is managed using conventional DBMS reliability techniques (i.e. locking and message invalidation) to guarantee the integrity of these messages. Log entries are uniquely identified within the site by (local) timestamps. Other sites can refer to a specific log entry by providing its timestamp to the spooler where the log is kept, e.g. to commit an operation. Log files can be inspected by the recovery procedures to Undo/Redo any update that left the database inconsistent.

A Two-Phase Commitment Protocol

The commit protocol employed by REQUEST II to help maintain the consistency of the distributed database is a modification of the "presumed abort" two-phase commit protocol [14]. The protocol ensures that an update is either committed at all sites or not committed at all, even if a failure occurs during its execution. A transaction is aborted and the the user is informed if during an update operation the site holding the primary copy of a data object fails, before the commit message of the transaction is accepted for processing at that site. This assumption implies that sites holding primary copies of database objects must be operational at least up to the point where the transaction is accepted (marked as committed) but they can fail anytime before, during or after the effects of the update operation are actually installed in their local databases.

The REQUEST II two-phase commit protocol uses one process called the coordinator, which is connected to the user application and a set of subordinate processes running in cohort sites. The coordinator is responsible for preparing and committing an update in the site where the primary copy of the data item is stored (primary cohort site). When this task is completed the coordinator "forgets" the operation and informs the user that a transaction has been committed, even though the actual database updates are not yet installed in all copies. Thus, the response time as perceived by the user is significantly reduced. The primary cohort site becomes responsible for performing the update on the primary copy and propagating the update to the remaining copies of the data item.

Algorithm: Two-phase Commit

Step 1: When a transaction at some site of the system requests an update operation that involves remote sites, it automatically becomes a coordinator for this transaction. The coordinator constructs a message composed of the site ID and the remote DM operations to be performed. Then a PREWRITE(site ID, DM operations) message is sent by the coordinator to the spooler of the cohort site which stores the primary copy of the data item (primary cohort site). If the primary copy of the data item is stored in the local site then the primary cohort site is the coordinator's site.

Step 2: When a PREWRITE message arrives at the primary cohort site, the spooler receives the message and constructs a Log_uid based on its local clock value. This Log_uid uniquely identifies the log at the primary cohort site. Then, the spooler creates a log entry consisting of the Log_uid, the DM operations, the number of non updated copies of the data item to be updated (target count), and the set of nodes that store the yet to be updated copies of that item (target set). The target count is initially equal to the total number of copies for the data item. Its purpose is to serve as a commit flag. If its value is less than the total number of copies of the data item to be updated, then the transaction is considered committed else it is uncommitted. The target set initially contains all nodes that store copies of that item. It is used as a checkpoint for the transaction progress at the various nodes involved in its execution. Finally, the primary cohort site locks properly the spooler storage and inserts the log entry. At this point a PREWRITE_ACK(Log_uid) message is sent back to the coordinator.

Step 3: If the coordinator does not receive the PREWRITE_ACK message from the primary cohort site (the site is down), then it aborts the transaction and informs the user. Otherwise it sends a COMMIT(Log_uid) message to the primary cohort site.

Step 4: When the COMMIT(Log_uid) message, is received by the primary cohort site, its spooler locates the log entry using the Log_uid as an index, and extracts the DM operations to be performed from the log. The target count is decremented by one and simultaneously a COMMIT_ACCEPTED_ACK message is sent back to the coordinator (i.e. transaction is accepted for completion). The above two actions are performed in a single indivisible step (i.e. similar to the "test and set" instruction found in all types of computers). Finally, the DM operations are forwarded to the local DM for execution, and the target set is modified by removing the local site ID. The purpose of the COMMIT_ACCEPTED_ACK message is to inform the user site that the transaction will be eventually completed under the control of the primary cohort site.

Step 5: When the coordinator receives the COMMIT_ACCEPTED_ACK message it assumes that the update has been completed and "forgets" about it. The primary cohort site assumes the responsibility for propagating the updates to the remaining copies of the data item. This task is accomplished by determining the IDs of the cohort sites which keep non updated copies of the data item (i.e. target set). For every such site, the target count is decremented, and an update message is sent to the corresponding remote DM. When an acknowledgement is received the target set is modified by removing the remote site ID. These updates are performed in accordance with a one-phase commit protocol. When the target set becomes empty, the INVALIDATE(Log_uid) operation is performed to remove the log entry from the spooler storage.

The above process can be simplified taking into account data replication and the location of the primary copy in relation to the user's site, resulting in reduction of the processing and communication overhead.

Crash recovery

When a site resumes running and prior to the execution of any transaction, the recovery routine accesses the spooler storage (local and remote) and if possible, finishes all incomplete updates violating the consistency of the database in the recovering node. Crash Recovery routine is essentially a ReDo procedure that examines the log files and and performs all the necessary updates. The requirement for designing a REDO recovery process is to implement most recovery operations in such a way that may be repeated without producing any additional inconsistency. This can be achieved by keeping additional information in the logs and/or allowing the recovery process to perform read-only DM operations on the distributed database. The latter implies the use of monolithic recovery locks which are necessary to preserve consistency and will not be discussed here.

In the first phase the recovery process examines its local spooler storage and all uncommitted log entries (i.e. entries where the target count of a data item is equal to the total number of copies of that item) are discarded.

In the second phase, the recovery process completes the committed transactions by executing the DM operations which are recorded in the log entries (i.e. entries where the target set is not empty). The effects of those DM operations are directed only to the nodes which are found in the target set of each log. Before the remote execution of a DM operation the target count for that data item is decremented. After the DM operation is executed, the target set is modified by removing the ID of the node where the effects of the DM operations were installed. Installing the effects of an incomplete transaction is performed in a pre-defined order, on a node by node basis. At each node, the recovery DM operations are executed in a sequential order for each log entry. This sequential order is reflected in the structure of the logs, where log entries are associated with timestamps. Therefore, later events follow the earlier ones when the log is examined sequentially.

If a log is stored locally (i.e. the recovering node is a primary node) its effects are installed in all nodes found in the target set of that log entry. For every log entry its target set contains only the sites where the recorded DM operations are not yet installed. Thus, all copies of data items whose primary site is recovering will be eventually updated and all related inconsistencies will be resolved. Since we assumed that no updates to a data item are allowed if its primary node is not available, the log at the primary node must contain all unfinished DM operations related to this data item.

Whenever the recovering node is found in the target set of a log entry at a remote spooler, the DM operation(s) of this log entry are applied only to the recovering node. The purpose of this type of recovery is to remove inconsistencies by "informing" the recovering node about changes that occurred to database objects having their primary copies at different sites while the recovering site was not accessible. In addition, inconsistencies in the distributed database dictionary are resolved this way (e.g. if a table whose primary node is different than the recovering node has been deleted, the database dictionary copy at the recovering node must be modified to reflect this change).

In the final phase all invalid logs (i.e. entries for which the target set empty) are removed.

If a node failure occurs during a crash recovery, the recovery process need to be repeated. Most recovery operations are repeatable (e.g. if the current log that is examined by the recovery process indicates an "update data record" DM operation, the recovery process is designed to verify the existence of a valid version of the record to be updated before it actually attempts the update). Therefore, a failure of the recovery process cannot cause any additional inconsistency.

The proposed spooler structure scheme requires that the log files entries that reside at different nodes correspond to independent database objects, namely, primary copies which by definition reside in at most one site. Thus, in the case of a multiple site failure, the processing of the log files located at different member sites by different recovery processes could be performed in any order.

The proposed protocol provides complete protection against single site failures and many multi-site failures. This is achieved at the expense of limiting somewhat data availability.

SYSTEM IMPLEMENTATION

Inter-site process communication alternatives

When a user requests an operation on remote data, the request is passed to and executed at the site where the data is stored. Several alternative organizations can be considered for implementing the execution of remote operation requests.

1. One solution is to provide a single service process (server) that accepts and services requests from remote processes (i.e instances of REQUEST II on remote machines). A server of this type must multiplex itself among multiple client requests and maintain transaction state information from one transaction to another. The problem with such organization of a server is the throughput degradation due to delays associated with page faults and database I/O operations.

2. Another solution is to create a separate process to service each incoming request. However, creating and initializing a process is a time consuming operation which adds overhead to the execution of a request. A more serious drawback is that such organization does not preserve the notion of a transaction, thus all requests belonging to a transaction must be associated by some mechanism that ties them together. Data access authentication is a problem too. Each request must be individually authenticated, which is a potentially expensive operation [15].

3. Another solution is to create a process for each user on his first request and retain that process for subsequent use for the duration of the session. This reduces the process set-up cost necessary to service multiple requests for data. Since a process belongs to a single remote user and since all requests that are part of a transaction originate from the same user, there is no need to transmit the user ID and perform user authentication every time.

4. Another possibility is to initialize the server as a single process. The server process handles all incoming transaction requests until its performance degrades. At this point a new instance of the server is spawned to share the load with the "old" instance of the server. The spawning of new instances of server can be controlled statically, by setting an upper limit to the number of transactions that can be serviced concurrently by a single server instance, or dynamically, by monitoring the server load [16].

In our implementation the system sites communicate using the DECNET transparent communication facility. The client process (Transaction Manager) and the server process (Data Manager or Spooler) are connected by a virtual circuit (logical channel). When a process requests an activity at another site for the first time, a virtual circuit between the sites is established. This is accomplished by remotely executing a command procedure which activates the REQUEST II programs. The virtual circuit and the server processes are retained for the duration of the user session. The processes can now communicate with each other by performing remote procedure calls. A process constructs and sends a message describing the function to be performed and its parameters, and then waits for replay. Remote procedure calls are used to perform most of the inter-site operations except for transferring large amounts of data which is done by explicitly invoking the DECNET file transfer facilities.

In detecting network or node failures REQUEST II relies upon this send/receive interface to report if a process or a processor at the other end has failed. Communication failures are reported to the processes on both ends of the virtual circuit. The DECNET provides the necessary failure detection and reporting capabilities.

A pilot implementation of the system runs on five VAX-11 computers using the DECNET facilities and the VMS mailbox mechanism for inter-nodal communication [17]. In our further work, we plan to compare the efficiency and the overhead of the four outlined organizations of the inter-site process communication, and evaluate their suitability to implement a distributed database systems using the testbed approach. Another direction of our work, is to adapt the database management system to an environment in which several Local Area Network clusters are connected through gateways. In particular, we are investigating a distributed database system which can operate in a heterogeneous network and OS environment consisting of DECNET/VMS and UNIX/3BNET.

A PROTOCOL FOR FAILURE AND RECOVERY DETECTION TO SUPPORT PARTITIONED OPERATION IN DISTRIBUTED DATABASE SYSTEMS

Jung K. Kim and Geneva G. Belford
Department of Computer Science
University of Illinois at Urbana-Champaign

ABSTRACT

Data replication in distributed database systems is designed to achieve high reliability and availability. In case of network partitioning, the mutual consistency of data may become doubtful unless the transaction processing mechanism puts appropriate limits on its operation. To achieve high availability, transactions must be processed despite failures. An optimistic approach allows transactions to be executed in each partition and the database is reconciled when the partitions are merged. To coordinate the partition merge process correctly, the system must know the partitioning and merging points. This paper presents a new protocol for failure and recovery detection, which correctly supports partitioned operation and subsequent merging.

1. Introduction

To achieve high reliability in a distributed database system, component failures must be tolerated. Since unexpected failures may occur at any time, the transaction processing mechanism must be robust against them. In a distributed database system, concurrent accesses to a data object must be synchronized and recovery from failure has to preserve the consistency and integrity of the database. If data is replicated, an update to a data object must be *atomic*; i.e., it should be performed on all copies or none. Also, transactions should not be delayed indefinitely in the face of failure. It is therefore important that failures and recoveries are detected accurately and efficiently.

When failure occurs it is possible that one group of sites cannot communicate with another group. This type of failure is called *network partitioning*. If network partitioning occurs, the mutual consistency of data items may become doubtful unless the transaction processing mechanism appropriately limits its operation. When data redundancy is used in order to increase the availability of data, transactions must be processed despite failure. Several approaches to operation in the face of network partitioning have been proposed. One approach allows all transactions to be processed, and later, when partitions are merged, any data inconsistency is resolved. (See [1], [12], [9], etc.) This approach is called *optimistic*, since it is efficient only when there are few inconsistencies to be resolved after the partitions are merged.

In order to support partitioned operation, a mechanism to detect changes in the status of the network is necessary. Recently, a number of protocols for failure and recovery detection have been proposed (e.g., [5], [10], [11], [4], [6]). Most of these protocols are based upon periodic checking of the system status, which requires considerable overhead. Even when the system is lightly loaded or idle, the status of the network is periodically checked. This paper presents a new failure and recovery detection algorithm, which may be used to support optimistic partitioned operation. In this algorithm, each site monitors other sites only when necessary. Specifically, if a transaction includes operations to be carried out at remote sites, its home site then checks the status of the other sites. A *Status Monitor* (SM) resides in each site to detect status changes (failure or recovery) of other sites and to coordinate the construction of a consistent view of the membership of a partition. In addition, our protocol handles the problem of synchronizing multiple failure/recovery detection in a particularly robust way. This protocol consists of two subprotocols – the Failure and Recovery Detection Protocol (FRDP) and the Status Change Protocol (SCP).

In section 2, background material, basic assumptions about communication facilities, and the system model are presented. The transaction management mechanism is briefly described in section 3. Section 4 presents the detailed description of the FRDP and the SCP. Section 5 discusses the feasibility of our protocols and gives arguments that they work correctly. Finally, our conclusions are in section 6.

2. Background

A *transaction* is defined here as a process that manages a sequence of read and write actions to be executed atomically for one application. A maximal subset of sites which can communicate with each other forms a *partition group* (or *partition*, for short). In the optimistic approach, while the network is partitioned, the system processes all transactions, but commitment becomes temporary until partitions are merged, even though actual copies of data items are updated. This means that some transactions may have to be rolled back after partitions are merged. Logical merging of the transactions processed in different partitions must be done in such a way that the resulting transaction schedule is serializable. Serializability means that concurrent transactions are executed in a manner equivalent to a serial execution [8]. To enforce serializability, a transaction that reads a copy of a data item in one partition must logically precede a transaction that updates the same data item in another partition. A *serializability conflict* is defined as a situation that occurs when a transaction reads or updates the copy of a data item in one partition and

CH2345-7/86/0000/1189$01.00 © 1986 IEEE

another transaction updates the copy in another partition. Thus, if an update to the same data item occurs in more than one partition, there is a serializability conflict.

In Davidson's protocol [1] for recovery after partitions are merged, possible inconsistencies among data item values are detected by using a precedence graph, which checks for the serializability of the executions of transactions across partitions. A concurrency control mechanism is assumed to guarantee the serializability of the execution of transactions in each partition. A transaction is assumed to read a data item before updating it. This assumption facilitates serializability conflict detection in the precedence graph, since the graph can be reduced considerably. It is also assumed that each partition has a unique coordinator. When partitions are merged, the coordinator in each partition is notified and local transaction executions in each partition are stopped. The coordinator then derives the total ordering of the transaction execution history in its partition. Then a global precedence graph is generated from these histories. Conflicting transactions are detected as a cycle in the precedence graph. If there is such a cycle, conflicting transactions are rolled back until the cycle is eliminated. Then the remaining transactions are executed at sites that have not yet executed them yielding a consistent database. A new coordinator of the merged partition is then elected.

To coordinate such a partition merge process, the system must know when the partitioning occurred and when the merge process is initiated. (By "when" we mean not clock time, but the point within the execution schedule of transactions.) Thus, some surveillance mechanism which sees the status changes is necessary. The only way to detect a status change is to send messages and use timeouts, because a global snapshot of the network status is not possible. A site may periodically send messages to check for network status changes or the status may be checked only when necessary. If a surveillance mechanism which operates only as needed is adequate to support partitioned operation, then we can save on overhead. Essentially, we only need to know about status changes that can affect the consistency of the database. If the system is partitioned but the transactions can be processed without any problem (i.e., there is no conflict), we do not need to know that partitioning has occurred. Our protocol provides only those network status change points that are needed to restore the database to a consistent state after the partitions are merged.

Site failures and communication link failures are considered in our protocol. A site failure occurs when a site in the network goes down, and a communication link failure occurs due to a transmission medium fault. Generally, it is not possible to distinguish between a site crash and a partitioning. Therefore, when it is not possible to communicate with a site, network partitioning is assumed. When a site failure occurs, it is assumed to be *pure*, meaning that the processor simply stops running and no garbage messages are produced.

Since our protocol does not detect all network status changes, it is necessary to define a *view* of a partition. A *logical partition* view (or just *view*) at a site is defined as being the subset of sites with which communication is thought to be possible [7]. A site may think that it cannot communicate with certain other sites even if they are available. Similarly, a site may be unavailable when it is thought to be available. But, if communication is needed with such a site, our protocol will detect the status change. Thus, a site's view of the network may be updated only when knowing the status of the network is necessary. A site S_i is considered to be UP at site S_j if S_i and S_j are in the same logical partition in S_j's view. Otherwise, it is considered to be DOWN. A site status table is maintained by each site to maintain its current view.

In order to detect conflicts and to resolve them after partitions are merged, each partition is assumed to have a unique coordinator. Garcia-Molina discussed elections of a coordinator in a distributed system [3]. To avoid the question of electing a coordinator in a partition, an ordering of the sites is assumed. For example, the sites may be numbered 1,...n, and we assume $S_1 < S_2 <...< S_n$. The site which is lowest in order becomes the coordinator when a new partition is created. This ordering need not be related to the physical topology of the network.

Data items are assumed to be partially replicated, so that some sites may have copies of a data item while other sites may not. It is assumed that transactions follow the 2–*Phase locking* protocol [2]; also that a write operation requires that all copies be locked and a read operation requires that the copy read be locked. This guarantees that serializability within a partition is not violated. Furthermore, the following are assumed.

- All messages are delivered to their destinations in the order in which they are sent.
- Message delivery is not guaranteed. The sender only knows of the delivery of its message by an explicit acknowledgement.
- The maximum and minimum network message transmission delay, T_{MAX} and T_{MIN}, can be defined.
- The relation 'can communicate with' is symmetric and transitive.

3. Transaction Management while the Network is Partitioned

The system is assumed to be running an optimistic algorithm such as Davidson's protocol [1]. When a transaction reads or updates data items and all copies of those items are not in the same partition, then its commitment is temporary until the sites that have the other copies join the partition. After temporary commitment, the transaction sends its execution history to the coordinator of the partition. And the coordinator sends an acknowledgement to the transaction. (This allows the transaction to recognize when the coordinator has failed or a partitioning has cut it off from the coordinator. See section 5.) The coordinator uses these transaction execution histories to produce a totally ordered transaction execution history within the partition, so that conflicting updates can be resolved when partitions are merged.

Even a *read—only* transaction may be involved in a serializability conflict, if it is processed in a partition which does not have all copies of the data items read by it. Therefore a site executing any transaction involving data items with copies in other partitions has to monitor the status of other sites that have copies of the data items used until commitment of the transaction becomes permanent.

Whenever the transaction performs an action (read or write), it references a data dictionary to get the identifiers of the sites which have copies of the data items used. Then:
– For all of those sites marked UP in the current view, the transaction sends a *watch* request to the SM. The SM then begins monitoring the sites for failure. The transaction sends a *watch–release* to the SM when it completes (temporary commitment).
– If not all of those sites are marked UP, then the transaction requests a watch for recovery of the sites marked DOWN and does not release those watch requests until its commitment becomes permanent. In this way, recovery of the sites in the other partitions is detected.

If a status change is detected by the SM, transaction processing is stopped and updating of the network view is carried out.

4. The Protocol Description

In this section, a detailed description of the proposed protocol is presented. Our protocol consists of two subprotocols – the Failure and Recovery Detection Protocol (FRDP), and the Status Change Protocol (SCP). Before presenting the FRDP and the SCP, we describe the messages and data structures needed.

4.1 Messages and Data Structures

To facilitate the operation of the FRDP and the SCP, the following messages are used.
- The site status checking message (CHECK) – This message is used to check the status of a site during normal FRDP operation.
- The status response message (RESPONSE) – This message is used to respond to the CHECK.
- The network status checking message (NETCHECK) – This message is used to determine the status of the network after a site status change is detected.
- The network status response message (NETRESPONSE) – This message is used to respond to the NETCHECK.
- The status inconsistency report message (ALERT) – This message is used to alert sites to the problem that inconsistent view vectors might be generated in the partition during SCP execution.
- The message to acknowledge the ALERT (ACK)
- The message carrying the view vector, V_vector_i, which contains the partition view at site i – Component k of V_vector_i, $V\_vector_i(k)$, represents the status of site k, UP or DOWN, as viewed by site i.

- The message to acknowledge that the view vector was received (VIEWACK)

In order to handle arriving messages, the following queues are maintained by the SM:
- The C–queue – This queue is used to receive the CHECKs and the NETCHECKs.
- The R–queue – This queue is used to receive the RESPONSEs, the ALERTs, and the NETRESPONSEs.
- The T–queue – This queue is used to receive requests from local transactions.

To maintain a current, consistent view of a partition and to support the exchange of status messages, each site maintains a Site Status Table (SST). The SST is shared with local transactions but is updated only by the SM. Each entry in the SST represents a site (S_i) in the network and has four fields:

1) Request_Set : The set of local transactions requesting message exchange with site S_i

2) Sent_Flag : Set when a CHECK is sent to site S_i

3) Received_Flag : Set when a RESPONSE is received from site S_i

4) Status : UP if S_i is available, DOWN if not

In order to detect failures, two timers are used:
- BROADCAST – This timer is used by the FRDP and the SCP.
- VCHECK – This timer is used by the SCP for robustness.

In order that a consistent timeout period be used throughout the network, it is assumed that each site owns a physical clock and that all clocks run at close enough to the same rate so that there is no discernible difference between timeout periods.

The following variables are used by the SCP protocol at each site.
- L_{ID} – is used to synchronize multiple detections of a status change.
- D_{VAL} – is used to store the values carried by ALERTs and NETRESPONSEs.
- *D_Record* – is used to keep track of possible problem sites.
- ST (State variable) – is used to keep track of the state of the protocol execution: The state can be "Normal", "Init_Collection", "Part_Collection", or "View_Sent". When the SM is executing the FRDP protocol, ST is set to "Normal". When the SM initiates the SCP to collect the current status information for partition reconfiguration, ST is set to "Init_Collection". ST = "Part_Collection" means that the SM is participating in a collection. When a new view vector is sent by the SM, ST is set to "View_Sent".

4.2 Description of the Failure and Recovery Detection Protocol

When a transaction sends a request (*Read* or *Write* request) to remote sites, it sends a request for a *watch* on the sites involved to the SM. When the SM receives a watch request from a local transaction, it puts the transaction identifier (TR_j) into the Request_Sets of the sites from which that transaction is requesting service:
SST.Request_Set$[S_i]$ = SST.Request_Set$[S_i] \cup TR_j$.

While a local transaction is waiting for service from remote sites, its SM periodically sends CHECKs to the sites involved and receives RESPONSEs from those sites. After the transaction receives its service from all remote sites that are UP, it sends a *watch release* to the SM to indicate that it does not need to check the status of those sites any more. The SM then deletes this transaction identifier (TR_j) from the Request_Sets of the sites:
SST.Request_Set[S_i] = SST.Request_Set[S_i] - TR_j.

When the SM sends out a CHECK, the timer BROADCAST is restarted. The Received_Flags of all sites in the SST are reset and the Sent_Flags for those sites to which the CHECK is sent are set. When a RESPONSE is received, the SM sets the Received_Flag of the source site entry in the SST. The SM responds with a RESPONSE as rapidly as possible upon receiving a CHECK. When BROADCAST expires, the SM checks whether the sites with set Sent_Flags responded. If all sites marked UP responded and none marked DOWN responded, then the SM generates the next CHECK and sends it to the sites. If any site marked DOWN responded or any site marked UP did not respond, then a status change is detected and the SCP is executed. While the SM is waiting for BROADCAST to expire, it may receive CHECKs as well as RESPONSEs from remote sites. These are handled as described above.

If a CHECK is received after BROADCAST expires but before the next CHECK is generated, the SM cannot respond with a RESPONSE immediately, but must wait until after the next CHECK is generated. Then, in order for the SM to respond quickly, before it sends out the CHECK it processes the C-queue. Let T_{check} and T_{msg} denote the times needed to check the site responses and to generate the next CHECK, respectively. And let T_{cq} be the maximum time to process the C-queue. (Note that the actual time is proportional to the length of the C-queue.) Let $T_{GEN} = T_{check} + T_{msg} + T_{cq}$. Thus, the timeout period of BROADCAST must be set to at least $2T_{MAX} + T_{GEN}$ in order to ensure that responses from normally operating sites will be received before BROADCAST times out.

The actions of the SM during normal FRDP operation may be then summarized as follows.

- **Event:** timer BROADCAST expires.

1. The SM checks the SST to see whether all sites to which CHECKs were sent have responded. If all sites marked UP responded and all sites marked DOWN did not, go to step 2. (Otherwise, a status change is suspected and normal FRDP operation stops. The SCP is then executed.)
2. The next CHECK is generated if there is a site in the SST with a non-empty Request_Set.
3. The C-queue is processed. At this time, the SM responds with RESPONSEs to all CHECKs received after BROADCAST expired.
4. If a CHECK has been generated, the SM sends this message to all sites with non-empty Request_Set and restarts BROADCAST.

- **Event:** Receipt of a watch request

The SM puts the transaction identifier into the Request_Set of each of the sites for which a watch was requested. If the SM is not currently sending CHECKs to any sites, then CHECKs are sent to the sites with non-empty Request_Set and BROADCAST is restarted.

- **Event:** Receipt of a watch release

The SM deletes the transaction identifier from the Request_Sets of the sites.

- **Event:** Receipt of a CHECK

The SM responds with a RESPONSE to the source site.

- **Event:** Receipt of a RESPONSE

The SM sets the Received_Flag of the source site entry in the SST.

- **Event:** Receipt of a NETCHECK

FRDP operation stops. See SCP discussion for details.

4.3 Description of the Status Change Protocol

In summary, the SCP works as follows. When the SM detects failure or recovery, it suspends the locally executing transactions and broadcasts a NETCHECK to collect up-to-date status information from all sites. After collecting the responses (NETRESPONSEs) from the sites, it creates a new view vector and sends it to all sites in the new partition.

An SM which detects failure or recovery becomes a system reconfiguration initiator (SRI) for the SCP, and the SM's of other sites become cohorts. (Notice that the SRI is not the database merge coordinator, but only an initiator for system reconfiguration. The site with the lowest rank in the logical partition which is formed after system reconfiguration is automatically assigned as the coordinator.) Many sites can simultaneously be SRI's, because status changes may be detected nearly simultaneously by different sites and each site that detects a status change executes the SCP. Therefore, multiple executions of the SCP must be synchronized. To accomplish this, the SM of each site tries to be a cohort of the SCP execution that was initiated by the SRI at the site of the lowest rank among the SRI's in the partition.

Unless some messages can be lost during the execution of the SCP, SRI's with higher site rank will abort their executions upon receiving the NETCHECK from the SRI of lower site rank. But it is quite possible that inconsistent view vectors can be delivered to different sites if some messages are lost.

[Example 4.1] Let us suppose the following situation. Two sites, i and j, become SRI's nearly simultaneously and the rank of i is lower than that of j. Site j broadcasts a NETCHECK and then site i broadcasts a NETCHECK. All cohorts except site i receive the NETCHECK from site j, but the NETCHECK sent to site i from site j is lost. Before the NETCHECK from site i reaches the cohorts, all cohorts respond to site j. They all accept site j as the proper SRI. The NETCHECK from site i then arrives at all cohorts except site j, while the NETCHECK sent to site j from site i has been lost. All cohorts realize that the rank of site i is lower than that of site j and they now accept site i as the proper SRI. Site j generates a new view vector which has site i marked DOWN and sends it to the cohorts. Site i generates a new view vector which has site j marked DOWN and sends it to the cohorts. Now two inconsistent view vectors have been sent by two different SRI's. All sites except site j accept the new view vector from site i, but site j's view vector is different from that of the others. This is an undesirable situation since two different views which are not disjoint make partition management difficult and the error will soon be detected and need to be rectified. □

Therefore, the SCP protocol must satisfy the following condition to guarantee consistency of views.

[Condition 4.1] For any two sites S_i and S_j with ST = "Normal", if S_j is marked UP in *V_vector*$_i$, then S_i must be marked UP in *V_vector*$_j$ and vice versa. □

Condition 4.1 guarantees that a site is marked UP in only one partition view at any one time; that is, the sets of sites marked UP in any two views are either identical or disjoint. In order to enforce this condition, when a cohort receives NETCHECKs from the SRI's as in example 4.1, it sends ALERTs to the SRI's that may initiate different views informing them of the problem, so that the SRI with higher rank aborts its SCP execution; that is, if the SRI with higher rank did not receive a NETCHECK from the SRI with lower rank, then it aborts its SCP execution upon receiving an ALERT. When the SRI sends out a new view vector it waits for acknowledgements from cohorts. If all cohorts acknowledge, then the SRI sets its state to "Normal". While the SRI is waiting for acknowledgements, if it receives a NETCHECK, then it assumes that the network status has changed or inconsistency has been detected. It then participates in the execution of SCP by the site that sent the NETCHECK. This mechanism enforces condition 4.1. (See Chapter 5 for proof.)

Since the SRI can fail during the execution of the SCP, the protocol must be robust against this possibility. That is, the protocol must guarantee that its execution will finish successfully despite SRI failure. The timer VCHECK is used to detect SRI failure and to support the resolution of inconsistent views.

The actions of the SM during SCP execution are described as follows.

- **Event:** A status change is detected by site i running the FRDP.

1) The SM stops FRDP execution, sets ST to "Init_Collection", and stores its site rank in L_{ID}.
2) The SM initializes each component of *V_vector*$_i$ to DOWN.
3) The SM then broadcasts a NETCHECK to all sites in the network and starts the timer BROADCAST to $2T_{MAX} + T_{GEN}$. (It is assumed that T_{GEN}, although derived from FRDP event timings, is more than adequate time for the generation of a NETRESPONSE.) Normal FRDP operation is resumed after the successful execution of the the SCP.

- **Event:** Receipt of a NETCHECK at site i from site k.

For simplicity, let k be the rank of site k. Upon receiving a NETCHECK, the SM performs different operations depending on its state:

○ *Case* 1: ST = "Init_Collection" - The SM has initialized the collection of status information.

1) The SM compares k with L_{ID}, its site rank, and takes appropriate action:

○ *Case* 1.1: $k < L_{ID}$

The SM stores k in L_{ID}, and aborts its SRI activity by setting ST to "Part_Collection". Now it considers itself participating in the collection initiated by the site k.

The SM starts the timer VCHECK. The timeout period of VCHECK is $3T_{MAX} + 2T_{GEN} - T_{MIN}$. (See chapter 5 for the justification of this timeout period.)

○ *Case* 1.2: $k > L_{ID}$

The SM sets *V_vector*$_i(k)$ = UP.

2) The SM then sends site k a NETRESPONSE with parameter D_{VAL} set to L_{ID}. The inclusion of parameter D_{VAL} causes site k to abort its SCP execution in case 1.2.

○ *Case* 2: ST = "Part_Collection" - The SM is participating in the collection initiated by another SRI.

The SM compares k with L_{ID}, the lowest SRI site rank seen thus far.

○ *Case* 2.1: $k < L_{ID}$

In this case, inconsistency may occur as described in Example 4.1.

The SM sends an ALERT to site k with parameter D_{VAL} set to L_{ID}, and an ALERT to the site whose rank is equal to L_{ID} with parameter D_{VAL} set to k. The ALERT causes the site with higher rank to abort its SCP execution if it had not received a NETCHECK from site k, and causes site k to mark the site with higher rank UP in case site k did not receive a NETCHECK from that site.

The SM stores L_{ID} in *D_Record*. The entry for the site with rank equal to L_{ID} in *D_Record* will be removed if the SM receives an ACK from that site.

The SM stores k in L_{ID}.

The SM starts the timer VCHECK.

○ *Case* 2.2: $k > L_{ID}$

The SM sends site k a NETRESPONSE with parameter D_{VAL} set to L_{ID}. Receipt of the parameter D_{VAL} causes site k to abort its SCP execution.

○ *Case* 3: ST = "Normal" - The SM is not executing the SCP.

1) The SM stops its normal FRDP operation.
2) The SM stores k in L_{ID}
3) ST is set to "Part_Collection".
4) The SM sends site k a NETRESPONSE with parameter D_{VAL} set to L_{ID}.
5) The SM starts VCHECK.

○ *Case* 4: ST = "View_Sent" - The SM sent a new view vector to cohorts and is waiting for their acknowledgements.

In this case, receipt of a NETCHECK means that the network status has changed or inconsistency has been detected by a cohort.

1) The SM stores k in L_{ID}.
2) ST is set to "Part_Collection".
3) The SM sends site k a NETRESPONSE with parameter D_{VAL} set to L_{ID}.
4) The SM starts VCHECK.

- **Event:** Receipt of a NETRESPONSE at site i from site k.

○ *Case* 1: ST = "Init_Collection"
1) The SM compares D_{VAL} with L_{ID}
○ *Case* 1.1: $D_{VAL} = L_{ID}$
The SM sets $V\_vector_i(k) =$ UP.
○ *Case* 1.2: $D_{VAL} < L_{ID}$ - Another SRI with a lower site rank is executing the SCP.
The SM aborts its SCP execution by setting ST to "Part_Collection".
The SM stores D_{VAL} in L_{ID}.
The SM starts the timer VCHECK.
○ *Case* 2: ST = "Part_Collection"
The SM just discards the NETRESPONSE.

- **Event:** Receipt of an ALERT from site k.

○ *Case* 1: ST = "Init_Collection"
The SM compares D_{VAL} with L_{ID}.
○ *Case* 1.1: $D_{VAL} < L_{ID}$ - The SM did not receive a
The SM aborts its SCP execution by setting ST to "Part_Collection".
The SM stores D_{VAL} in L_{iD}
The SM starts the timer VCHECK.
The SM sends an ACK to site k.
○ *Case* 1.2: $D_{VAL} > L_{ID}$ - The SM did not receive a NETCHECK from the SRI with higher rank.
The SM sets the view vector entries for site D_{VAL} and site k to UP.
○ *Case* 2: ST = "Part_Collection" - The SM already received a NETCHECK from the SRI with lower rank.
1) The SM just discards the ALERT.
2) The SM sends an ACK to site k.

- **Event:** BROADCAST expires.

○ *Case* 1. ST = "Init_Collection" - Normal case
1) The SM generates a new view vector according to the responses from the cohorts.
2) The SM sends V_vector_i to all sites UP in its view.
3) The SM sets ST = "View_Sent".
4) The SM starts BROADCAST.
○ *Case* 2. ST = "Part_Collection" - The SM has aborted the execution of the SCP.
The SM ignores the signal from BROADCAST and waits for a new view vector.
○ *Case* 3. ST = "View_Sent" - The SM has sent a new view vector to cohorts.
If the SM did not receive VIEWACKs from all sites marked UP in its view, it assumes that there has been a problem and initiates the SCP again.
If the SM received VIEWACKs from all sites marked UP in its view, it sets ST = "Normal" and returns to FRDP operation.

- **Event:** Receipt of a new view vector from site k.

○ *Case* 1: ST = "Part_Collection"
○ *Case* 1.1: $k \neq L_{ID}$ - The SM realizes there is an inconsistency.
The SM resets all necessary data structures and initiates the SCP.
○ *Case* 1.2: $k = L_{ID}$
The SM checks *D_Record* to see if there is a possibility of inconsistency. If *D_Record* is empty then the SM updates its Site Status Table (SST) with the new view vector, sets ST = "Normal", sends a VIEWACK to site k, and resumes FRDP execution. Otherwise, it assumes that there has been a inconsistency problem and initiates the SCP.
○ *Case* 2: ST = "Normal" or "Init_Collection"
The SM discards the new view vector received.
○ *Case* 3: ST = "View_Sent" - This can only happen if an ALERT to this SM notifying it of a lower ranked SRI was lost.
The SM accepts the new view vector, sends a VIEWACK to the sender, sets ST = "Normal", and resumes FRDP execution.

- **Event:** VCHECK expires. - The SM has been waiting for a new view vector.

○ *Case* 1: ST = "Part_Collection"
The SM assumes that the SRI has failed, resets all necessary data structures, and executes the SCP as when a status change is detected.
○ *Case* 2: ST = "Normal"
The SM just discards the signal from VCHECK.

- **Event:** Receipt of an ACK from site k.

○ *Case* 1: ST = "Part_Collection"
The SM deletes site k's entry from *D_Record*.
○ *Case* 2: ST = "Normal" or "Init_Collection"
The SM just discards the ACK.

- **Event:** Receipt of a VIEWACK.

The SM records the acknowledgement from the sender.

- **Event:** Receipt of a CHECK or RESPONSE used by the FRDP.

The SM just discards them.

4.4 Starting or Restarting sites

Since both recovery from a crash and partition merging are treated as partition merging, a site just coming on line or recovering after a crash executes the SCP, informing all sites with which it can communicate of its recovery. When a site rejoins the network, it must execute the network merge process since it does not know whether it becomes a member of the same partition which it was in before the failure.

5. Discussion

We believe that implementation of our protocol is quite feasible for support of the optimistic approach to partitioned operation. Since our protocol provides the necessary network status change points, a partition merge process to restore the database to a consistent state can be done correctly.

Before we prove properties of our protocol, a justification of the timeout period of the timer VCHECK, which is used by the SCP to detect failure of the SRI, is presented. The timeout period of VCHECK must safely allow enough time for the proper operation of the protocol, so that false failure detection is avoided.

[Assertion 5.1] The timeout period of VCHECK is safe.

[Proof] The timer VCHECK is used in four cases.

Case 1. (VCHECK is started after sending a NETRESPONSE to the SRI.)

Suppose that site i becomes a cohort of the SCP initiated by site j when i receives a NETCHECK. Site i responds with a NETRESPONSE to the NETCHECK and starts VCHECK. Site i expects to receive a new view vector from site j before VCHECK expires. Suppose that site j sends out the NETCHECK to sites and starts the timer BROADCAST at time t_1. Site i receives the NETCHECK at time t_2. The minimum time period between t_1 and t_2 is T_{MIN}. Thus, the NETCHECK is received at site i no earlier than $t_1 + T_{MIN}$. Therefore, $t_1 + T_{MIN} \leq t_2 \leq t_1 + T_{MAX}$. Site j's timer BROADCAST expires at $t_1 + 2T_{MAX} + T_{GEN} = t_3$. Therefore, the maximum time between t_2 and t_3 is $2T_{MAX} + T_{GEN} - T_{MIN}$. After BROADCAST expires, site j takes at most T_{GEN} to generate the view vector and the view vector is delivered within T_{MAX} to site i. Therefore, under normal operation the new view vector must be received at site i before $t_2 + 3T_{MAX} + 2T_{GEN} - T_{MIN}$.

Case 2. (VCHECK is started after sending an ALERT to the sites which may be involved in the generation of inconsistent view vectors.)

Suppose that ALERTs are sent to site i and j from site k at time t_1, and $i < j$. Site j is expected to take at most T_{GEN} to generate an ACK and the ACK takes at most T_{MAX} to be delivered to site k before time $t_1 + 2T_{MAX} + T_{GEN} = t_2$. The new view vector from site i will be delivered at site k before $t_1 + 3T_{MAX} + 2T_{GEN} - T_{MIN} = t_3$ as in *Case* 1. Since $T_{MAX} + T_{GEN} - T_{MIN} > 0$, $t_3 > t_2$. Thus, the new view vector and ACK must be received at site k before $t_1 + 3T_{MAX} + 2T_{GEN} - T_{MIN}$.

Case 3. (VCHECK is started when a site j receives a NETRESPONSE which indicates that another SRI with a lower site rank is executing the SCP.)

Suppose site i is the SRI with the lower site rank and a NETRESPONSE arrives at site j from site k at t_2. If site i sent out a NETCHECK at t_1, then it must arrive at all cohorts before $t_1 + T_{MAX}$. By assuming that NETCHECK from i to k took T_{MIN} and the NETRESPONSE from k took T_{MIN}, the new view vector from site i must be received at site j by $t_2 + 2T_{MAX} + T_{GEN} - 2T_{MIN} + T_{GEN} + T_{MAX} = 3T_{MAX} + 2T_{GEN} - 2T_{MIN}$.

Case 4. (VCHECK is started when an ALERT is received.)

Suppose that site i sent a NETCHECK at time t_1 and site k sent an ALERT at time t_2. If the NETCHECK took T_{MIN} and the ALERT took T_{MIN} to be delivered, then site i's BROADCAST will expire at some time before $t_2 + 2T_{MAX} + T_{GEN} - 2T_{MIN}$. Site i will take at most T_{GEN} to generate the new view vector and the new view vector will take at most T_{MAX} to be delivered. Therefore, the new view vector must arrive before $t_2 + 3T_{MAX} + 2T_{GEN} - 2T_{MIN}$.

Therefore, the timeout period of VCHECK is safe for all four cases. □

Next, we demonstrate the property of our protocol that all sites in a newly formed partition have a consistent view.

[Assertion 5.2] The Status Change Protocol satisfies condition 4.1

[Proof] Suppose condition 4.1 is violated. Since views are only created by SRI's, there must be two different SRI's, S_1 and S_2, $S_1 < S_2$, each of which assumed the other was DOWN. Furthermore, they both received acknowledgements successfully from all of their cohorts after they sent out the new view vectors. In this case, (a) there must be a site S_k which responded to both SRI's with NETRESPONSEs, or (b) ALERTs that were sent to the SRI's were lost so that the SRI's were not aware of the problem. From the SCP specification, if the SM of S_k receives a NETCHECK from S_2 when it had already received a NETCHECK from S_1, then it sends an ALERT to both S_1 and S_2. Therefore, case (a) is impossible. Assuming case (b), the SM which sent ALERTs initiates the SCP upon receiving a view vector from S_2 before it receives a new view vector from S_1, and S_1 will receive a NETCHECK from the SM before its BROADCAST expires. If the NETCHECK was lost, S_1 would execute the SCP again since it did not receive acknowledgements from all of its cohorts. If the SM which sent ALERTs receives a new vector from S_1 before it receives a new vector from S_2, then it checks whether an ACK from S_2 is received already and if not it initiates the SCP. Also, S_2 will not set its ST = "Normal" unless it receives acknowledgements from all of its cohorts. Therefore, the assumption contradicts the specification of the SCP. □

Let us elaborate on our comment that our protocol provides the necessary status change points. The problem is that when partitions are merged, the merge algorithm must know when partitioning occurred in terms of transaction history.

For simplicity, let partitioning be ***pairwise***, meaning partitioning subdivides one old partition P_k into two subpartitions – P_i which contains the coordinator of P_k, and P_j.

Definition 5.1 A *partitioning point* for the site S_j, $LT_k(S_j)$, $S_j \in P_k$, is the last transaction processed at site S_j in P_k before P_k is partitioned.

Definition 5.2 A *partitioning point* I_i^k of partition P_i, which was formed when P_k was partitioned, is the set of $LT_k(S_j)$, for all S_j in P_i.

When P_i and P_j are merged to re-form P_k, the coordinator of P_j sends I_j^k to the coordinator of P_i (i.e. of P_k) so that conflicting transactions may be serialized beginning at that point.

[Assertion 5.3] If partition P_k is subdivided into subpartitions P_i and P_j as defined above, then the FRDP and the SCP correctly determine I_i^k and I_j^k.

[Informal Proof] We must show that when partitioning occurs and there is a possibility of a serializability conflict, the partitioning is detected by our protocol and the coordinator obtains the necessary partitioning point information. To see this, there are four possible cases to consider, depending upon whether or not possibly conflicting transactions are processed in the partitions while P_k is partitioned:

Case 1. Transactions are processed in both P_i and P_j.

When a transaction in either partition executes an action on a data item having a copy at a remote site (in the other partition), it sends a watch to the SM. If a site fails, the FRDP then detects it, transactions are halted, and the SCP updates the network view. The coordinators of both partitions are elected and they collect the partitioning points, I_j^k and I_i^k from the sites.

Case 2. Transactions are processed in P_i but not in P_j.

P_i notices the partitioning, and the coordinator of P_i is elected and it collects I_i^k from the sites in P_i as above. When P_i and P_j are merged, the coordinator of P_i requests the execution history from P_j and no conflicts need to be resolved.

Case 3. Transactions are processed in P_j but not in P_i.

P_j notices the partitioning and its coordinator collects I_j^k. The coordinator of P_k, which is the same as the coordinator of P_i, does not know about the partitioning since no transactions involving sites in P_j are processed. When P_i and P_j are merged, the coordinator of P_j sends I_j^k to the coordinator of P_i. The coordinator of P_i gets the partitioning point by checking the history of the transactions processed in P_k against I_j^k. It finds that there has been no possibility of a serialization conflict.

Case 4. No transactions are processed in P_i and P_j.

The coordinator of the merged partition will recognize that there was no possibility of serialization conflict.□

6. Conclusion

We have presented a new protocol which supports optimistic partitioned operation by detecting failures and recoveries. We believe that our protocol is adequate to support optimistic partitioned operation.

Protocols based on periodic status checking require considerable overhead. Even when the system is lightly loaded or idle, the status of the network is periodically checked. Therefore, the system may unnecessarily work to detect failures and to reconfigure the system.

With our protocol, a status change may not be detected right after a site crashes or the network partitions, but it is detected later and system reconfiguration is initiated when the cooperation of that site is needed by a transaction. However, the whole system does not have to pay the cost of periodic checking.

In addition, our protocol handles the problem of synchronizing multiple failure/recovery detection in a particularly robust way.

Replication in Distributed Systems: The Eden Experience

Jerre D. Noe, Andrew B. Proudfoot, and Calton Pu

Department of Computer Science

Abstract

Two different methods for replicating objects were implemented on the Eden local area network. One was at the object level, and it provided easier implementation and maintenance at some cost in performance. The other, at the kernel level, gave better transparency and performance from the client's view but was more difficult to implement. Both approaches maintained object availability in spite of crashes. Their implementation gave insight into the conflict between performance and transparency, the cost of naming replicated resources, and some inescapable effects on system users who do not want replication.

1. Introduction

In a distributed system that supports applications using multiple machines, the probability of failure-free execution is the product of the probabilities of success for the related sub-tasks running on the individual machines. Two approaches may be taken to increase the chance of success for a distributed application; either increase the reliability of the nodes or provide replicas of crucial resources. This paper is concerned with the latter approach, for which the following are the design goals:

1. The loss of copies of replicated resources should not prevent operation.
2. The use of replicas should not alter the client interface.
3. There should be minimum performance penalty for users of replication and none for non-users.

1.1. Background

Hardware replication has been an accepted design approach for a long time, but software replication is more recent. A non-exhaustive list of early efforts on software replication in distributed systems includes one that led to a commercial product, Tandem[1], which added replication of processes to its replicated hardware structure. Bernstein and colleagues[2], in an early design paper on the SDD-1 System, made use of distributed atomic transactions for updating replicas, using methods that depended upon a global clock. Lampson and Sturgis[3] introduced the concept of stable storage, using replicas of unreliable disk files in a careful manner to provide reliable storage, which was used to support atomic transactions. These ideas were incorporated in XDFS, the Xerox Distributed File System[4], where replicas were cached for performance reasons. The Cambridge File System[5] used backup replicas on disk, with transactions for atomic update, but the design was so conservative in its attempts to cause no penalty for non-users of replication that it was restricted to single-site transaction, a limitation later removed. An interesting comparison of CFS and XDFS is given by Mitchell and Dion[6].

Distributed INGRES provided replicas for databases as an add-on feature. The design is described by Stonebraker[7]. LOCUS[8], another commercially available system, supported replication of Unix™ files with a primary-copy update transaction

mechanism. Walker, et al., reported that concurrency control in their transactions was made more complicated by replication because the primary storage site no longer knew about all the activity for a given file.

Since the early experiments, many proposals and analyses of schemes for concurrency control and crash recovery have appeared in the literature, including some survey articles[2, 9]. One of the trends developing for such work has been the adaptation of distributed database tools for atomic transactions and their availability as part of the operating system. Several new designs and prototype implementations are being explored in which the resources for control of distributed transactions, replication and crash recovery are, to varying degrees, being built into the underlying systems[10, 11, 12, 13], but at this point few observed results have been reported. It is in this context that our experience with replication in the Eden system is of interest.

1.2. The Experiments and Summary of Observations

The Eden distributed system, which began operating in April 1983, has provided a means to implement and test various schemes for the control and use of replication. This paper reports on the observations from two such experiments. One approach, described previously[14], implemented replication at the object level. Another[15] was done at the level of the kernel which creates and supports Eden's object environment. These experiments arose through curiosity about the two approaches and were not initially conceived as a comparison, hence they differ in detail. Nonetheless they do provide an opportunity in retrospect to contrast some of their features.

With either approach, two features must be added to the non-replicated system: First, where formerly one object was dealt with, now a set of names of the copies of an object must be recognized and handled. Secondly, a mapping must exist between this set of names and a *single* name used by the client; without this level of indirection any change in the number or identity of replicas would require notifying all clients of the change. When these two functions, mapping and the use of multiple names, are implemented at object-level we mean that they are accomplished by objects without changing the underlying kernel or its interface. Alternatively, both functions may be embedded within the kernel, hence the term kernel-level implementation. These approaches differ in the degree of transparency to the user of replication, in the cost of programming the replication system and the execution cost for users and nonusers of the facilities.

We shall first state the main observations that result from the experiments. More complete discussions appear in the following sections of the paper.

- Both approaches succeeded: objects were made available in spite of crashes.
- The kernel-level implementation was more difficult and required more programming effort.
- The object-level implementation was easier due to modularization, location-independent invocations and high-level language support, but it requires some degree of kernel support beyond the initial Eden design.
- The kernel-level replication gave more transparency from the client's view.
- Kernel size was increased about 20% by including replication control.
- In a test case requiring writing to two disk copies, both implementations allowed replicated data to be read and written in less than twice the time required for ordinary non-replicated objects, due to concurrency in the updates.

Our experience led us to believe:

- There is an inescapable cost to the nonuser of replication, although careful design can keep it small.
- Transparency and performance are in conflict.
- If the underlying network operating system cannot deal with network partitions, it is difficult but not impossible to do so in replication systems that are added.
- Naming of replicated resources has a cost: Either the clients must hold names of multiple access routes, or some form of

dynamic binding, such as broadcast, must be used.

- One need not implement transaction management especially for the purpose of replication; specialized use of a general transaction tool can handle it.**

1.3. Structure of the paper

Having declared our principal findings above, we shall describe the evidence that led us to these conclusions. Some understanding of the Eden system is needed in order to proceed; this information is provided in Section 2. Section 3 describes the kernel-level approach, and section 4 summarizes the object-level approach. Section 5 provides detailed reasoning behind our observations. Section 6 seeks to relate our findings to what we understand about the "new-wave" of systems that are incorporating replication or transaction-control mechanisms. Section 7 summarizes the paper.

2. The Eden System

Eden is a distributed system used as a test-bed for experimental research on implementation of distributed computer systems and the construction of distributed applications. Many of its technical features have been described[16], and recently assessed[17]. The implementation on which the experiments were run consisted of sixteen Sun workstations, of which four are disk servers that provide virtual disk to the other twelve.

2.1. Logical features of Eden

Eden objects encapsulate data, the procedures that operate upon them, and active processes. Objects are defined by the user rather than being restricted to a few system defined types. All objects are named by system-wide unique identifiers called capabilities. All communication between objects is through invocation, a form of remote procedure call, with the same syntax used for local and remote invocations.

A high level Eden Programming Language (EPL) [18] is used for defining Eden objects. EPL is based on Concurrent Euclid[19] with extensions to handle capabilities and to deal with sending and receiving invocations. It provides "light-weight" processes and monitors that the application programmer may use to control concurrency.

Invocations are location independent and objects are mobile. Objects may move from one node to another or they may be fixed to specific locations, under the control of kernel calls. Eden objects always appear active from the viewpoint of the invoking object. To achieve this, Eden objects have two forms: the active form and the passive representation. The former is in volatile memory with a virtual processor assigned to it; the latter is the long term state of the object, recorded on disk. Creation of a new object establishes an active form which, at the discretion of the designer of the object, can *checkpoint* itself (i.e., record its passive representation on disk). This checkpoint to disk is the only atomic action that is built into the Eden kernel. It is implemented so that it either succeeds or has no effect. The object designer may also make checkpoint available as an invocation so that other objects may request the active form to checkpoint itself. The active form may vanish due either to a crash or to deliberate deactivation. A subsequent invocation of the object will cause the kernel to fail to find the active form and therefore to search for the passive representation and create a new active form which then responds to the invocation. Thus an object always appears active from the viewpoint of the invoker, but the response time may vary depending upon whether or not reactivation had to take place. As originally designed, each object instance could have at most one active form and one passive representation. This is the feature that becomes changed by replication, as subsequent sections will show. Replects, in the kernel-level implementation, provide a single active form and multiple passive representations; R2D2 replicates both the active forms and passive representations.

**Note that this says nothing about the use of general transaction mechanisms for *all* applications, as opposed to taking advantage of application semantics. That distinction requires further research.

2.2. Implementation features of Eden

The kernel of the Eden distributed operating system is composed of two sets of cooperating processes. Running on each node is a process called the Host that is responsible for creating objects, protecting capabilities from forgery, locating objects, and passing invocation messages among objects. The second type of process is the *permanent object database* (POD), a copy of which may run on any node, although it makes most sense to run them on the nodes attached to physical disks. The normal Eden POD stores the passive representations, ensures that at most one active form and passive representation exists, and cooperates with the Hosts to create an active form for an invoked object if none exists.

Eden objects may be thought of as values of abstract types. They will perform certain actions in response to invocations, as well as internal actions. The code implementing these abstract types, i.e., the concrete types, is encapsulated in TypeStore objects and this code may be "replugged" (e.g. to provide a faster implementation) as long as the externally available invocations are preserved. TypeStore objects have all the features of ordinary Eden objects but in addition, their data consists of executable code. Every object includes a capability for the TypeStore that contains its code. In principle, all objects of the same type share the TypeStore object; in practice, for implementation reasons, one copy of the code in a TypeStore is cached on each node that contains one or more objects of that type. Obviously, if instances of Eden objects are replicated, the TypeStore must also be replicated in order to protect against crashes, and updates should be automatically handled by the same mechanism.

3. Kernel-Level Replication: Replects

The Replect approach, the kernel-level implementation of replication in Eden, seeks to overcome the loss of passive representations stored in unavailable PODs. This is done by creating multiple passive representations on separate machines, thus increasing the probability that a passive representation will be available for activation if an object is invoked. From the viewpoint of the client there is no visible change between invoking a Replect or an ordinary Eden object; at most one active form exists and it is invoked using one capability. The difference is visible, of course, to the client that creates the Replect; the number of copies is under its control. TypeStore replication is straightforward; a TypeStore object is just another Replect.

3.1. Replect implementation

The Replect approach required changes to the kernel; a few to the Host and an almost complete rewrite of the POD.

When a Replect is to be altered, the update must be treated as a distributed transaction in order to allow competing actions (activations, checkpoints, typestore reads) to take place without mutual interference and in order to protect against crashes that might leave inconsistent copies. Similarly, transactions are required during activation to ensure that only one active form is produced. In both cases, one POD is selected to act as the transaction manager. During update the transaction manager locks the other participating POD's passive representations, writes a commit record, causes participating PODs to write shadow copies and/or writes in-place entries in the headers for the copies (with an "undo" log for crash recovery). It then uses a two-phase commit protocol to complete the transaction. If the transaction manager crashes when the slaves are in the ready-to-commit state, the slaves are blocked until the transaction manager recovers.

Gifford's voting scheme[20] is used both for activation and for updating. Given a number of copies of an object, Gifford's voting method makes use of a read-quorum and a write-quorum chosen so that their sum exceeds the total number of copies. This overlap ensures that when a read-quorum is read, at least one copy of the latest version is found. There are minor differences between the scheme actually used and the approach described by Gifford, but no major change in the concepts.

Gifford assumed an underlying general transaction mechanism. The Replect implementation did not have one to draw upon and provision of it accounted for a fairly large part of the implementation effort. However, by not exporting a general transaction tool to Eden users, shortcuts in the Replect implementation were possible. The transaction manager code is in a POD with no interface to objects and the transaction deals only with single objects that are replicated. In contrast, a generally usable transaction tool would have to deal with a list of objects involved in the transaction. Instead, the kernel code within the POD deals only with a list of all the PODS that have copies for a given Replect.

Very few changes were made in the Host kernel code, involving only about a one or two percent increase in the total amount of Host code. POD code, however, had to be extensively rewritten and its size increased by about 20%. The Replect approach took a graduate student the better part of a year elapsed time in order to become acquainted with the problem, and define the implementation, followed by about six months of coding, debugging, and testing.

3.2. Replect system performance

To assess performance of Replects, measurements were made under three different conditions:

1. The Eden object case: With the standard Eden system, not modified for Replects.
2. The 1-copy Replect case: With the Replect system, using single-copy Replects. This assessed the penalty for using Replect kernel code for accessing non-replicated objects, rather than branching to standard code.
3. The multi-copy case: With the Replect system, using three copies of the passive representation, with read quorum and write quorum equal to two. ($n = 3$; $n_r = n_w = 2$). TypeStore used $n = 3$, $n_r = 1$ and $n_w = 3$.

Multiple measurements were made, to provide data at a confidence level of 98% with the confidence interval varying for the different cases, but in the neighborhood of plus or minus 10%. The measures of interest were the elapsed times for activation, read invocation and write invocation involving checkpoint of the modified objects. ByteStore objects containing 1000 bytes of data were used.

Activation of Replects required 10% to 13% more than activation of a standard Eden object. This was for the most favorable activation case in which current copies of the passive representation and TypeStore were located at the host where the ByteStore was to be activated. The standard Eden object required a mean time of 1.94 seconds; the single-copy Replect took 2.13 seconds; the multi-copy case required 2.20 seconds.

In the very unfavorable activation case, in which neither the passive representation nor the TypeStore were on the host where activation was to occur, activation time was much longer; 32.5 seconds for the Eden object case and 34.4 seconds for the multi-copy Replect. This involved locating the TypeStore, having a copy sent over the network, running the activation protocol, finding and copying the remote passive representation.

Remote read invocation of an active object should be, and was, no greater for the Replect case than for the single Eden object. A "do-nothing" invocation requires 0.084 seconds. The test invocation read 1000 bytes. The Eden object mean invocation time for reading was 0.237 seconds at 98% confidence level with, in this case, a confidence interval of plus or minus 2%. The mean times for the single and multiple Replect invocations fell within this range.

A write invocation to active objects required 13% more time for a single-copy Replect and 27% more for the multi-copy case compared to the standard Eden object. The Eden object required 1.81 seconds; the single-copy Replect took 2.05 seconds and the multi-copy Replect used 2.30 seconds. Concurrent writing of the two copies of the passive representation kept the elapsed time well below double the single object figure.

4. Object-Level Replication

A previous paper[21] describes an Eden object level implementation of replication. The emphasis in that report is on the Regeneration method of increasing availability, and its advantages and disadvantages relative to other data replication methods. For example, Regeneration differs from Voting in the number of replicas necessary for each access. To read or update a resource replicated with Regeneration, one copy is sufficient. If copies are inaccessible, new and up-to-date copies are created elsewhere to substitute the inaccessible ones.

At the heart of the object level replication is a replicated directory, described in section 4.1. In the replicated directory, the user may specify the number of copies for each resource; the copies are placed on machines with independent failure modes, with user over-ride. Replication of general objects is described in section 4.2. Implementation effort and performance are summarized in section 4.3.

4.1. The Replicated Directory

As we have mentioned in section 1.2, a mapping must exist between a single resource name used by the client and the set of copies. In the Replect implementation (section 3.1), the mapping is stored in each POD containing a copy, and a broadcast mechanism is used to find them. Since there is no such broadcast mechanism at the object level, a mapping must be constructed. Furthermore, the mapping must be itself replicated for availability; otherwise a replicated resource would be as available as a non-replicated mapping. For object-level replication, the Eden Replicated Resource Distributed Database (R2D2) was designed and implemented to serve as the replicated mapping.

R2D2 maps pathnames (character strings similar to Unix pathnames) into sets of capabilities. Each level in the path corresponds to a directory, which may be replicated with several copies. Each copy of a replicated directory is unaware of its siblings; a specialized transaction manager maintains the consistency of replicas despite concurrent access and crashes. Since pathnames are organized in a hierarchy, R2D2 has a tree structure with replicated nodes.

R2D2 supports typical operations on a mapping such as Lookup, Add, Replace, and Delete. Each request is handed on to the R2D2 transaction manager, which traverses the tree and finds the appropriate directory on which the operation must be performed. For example, *Lookup("users/alice/testfile")* is a read operation serviced by one copy of the directory named *"users/alice"*. In contrast, a write operation like Add is sent to all copies. If any of the set is unavailable, it is replaced by Regeneration, which creates new copies on operable machines to replace the missing ones. This ensures that the transaction never fails due to crashes, as long as sufficient machine resources remain to handle the required number of copies.

If a missing copy of the lowest directory is replaced this requires altering the next higher directory, to eliminate the capability of the missing copy and replace it with the newly created one. This approach proceeds recursively up to the root of the addressing structure. Note, however, that protection against a crash of the root must be handled in some other way. The manner in which "hardening" the root against crashes is done depends upon other requirements that one might wish to meet, such as performance or transparency at the client interface. One might give clients a fixed set of capabilities, with enough copies of the root to give a satisfactory level of availability without regeneration, but that requires all clients to include code to deal with the set of capabilities. Alternatively, one might arrange to broadcast for access to a copy of the root, or to use the Replect scheme. These alternatives were not explored in the R2D2 implementation, and a Replect was used for the root.

The root directory receives all R2D2 requests and forwards them to R2D2 transaction managers for processing. A centralized lock manager in the root synchronizes concurrent updates. At the time R2D2 transaction manager receives an update request, it is given an implicit lock on the name being updated. To avoid deadlocks, conflicting updates are returned to clients for later resubmission.

4.2. Eden Resource Management System

Although R2D2 provides transparent access to replicated directories, other invocations to client-defined objects are not directly supported by R2D2 transaction manager. The Eden Resource Management System (ERMS)[14], has been designed and implemented to provide atomic object access within nested transactions. Here, we delineate ERMS transaction features concentrating on its client access to replicated resources.

From within transactions, ERMS clients access their resources, which are controlled by a transaction manager. The ERMS transaction manager is more general than the R2D2 transaction manager, since ERMS handles groups of objects of any type. ERMS has adopted locking concurrency control, and a lock manager (separate from the R2D2 lock manager which handles single replicated objects) synchronizes resource access.

For update atomicity, ERMS uses R2D2 as the authoritative mapping; only committed versions of resources are stored in R2D2. At the beginning of a resource update, the ERMS transaction manager creates a new version, which is a single object directly invoked by the client. At commit time, the ERMS transaction manager creates the necessary number of copies, co-located with the old version if possible, and installs the new copies in R2D2, substituting the old versions.

4.3. Discussion

The design of R2D2 took about the same time as for Replects. The coding and debugging took approximately three man months. Additional design and implementation effort was dedicated to ERMS. Significant code sharing between R2D2 and ERMS, such as the locking concurrency control, brought ERMS online in another three months.

ERMS provides other functions beyond handling client access to replicated resources. For example, ERMS nested transactions are implemented with nested concurrency control and crash recovery, both independent of replication. Also, ERMS uses one transaction manager per transaction to simplify implementation, introducing some additional communication cost. Consequently, ERMS resource access time is dominated by features unrelated to replication.

In this paper, we use R2D2 as an example of object level replication, and compare R2D2 performance measurements with those of a non-replicated directory with the same tree structure. Multiple measurements were made to provide data at a confidence level of 98%, with the confidence interval at plus or minus 4%. For the read case, a mean value of 0.23 seconds was obtained for the non-replicated directory and 0.42 seconds for the replicated resource. The increase is due to the extra invocations to the R2D2 root and its transaction manager. This could be decreased by combining these two objects into one, but it would be done at the cost of decreased modularity and probably more difficulty in debugging and maintaining R2D2.

For updates in which no regeneration of missing copies was necessary, the two-copy resource required more time than for the non-replicated directory by a factor of 1.5. The single directory required 1.43 seconds and R2D2 needed 2.18 seconds to update two copies.

5. Observations Based on the Implementations

Availability, transparency, and performance were affected by the level at which replication was implemented, by the concurrency control and crash recovery methods used, and by features of the underlying Eden systems. Implementation problems also were affected by these factors. The following sections comment on these facets.

5.1. Availability

Both implementations succeeded in making objects available in spite of crashes of nodes in the network. In the object-level case, the disappearance of one of the file-servers in the Sun network for several days had no noticeable effect on the objects replicated through use of R2D2; the resources were automatically regenerated on surviving file-servers. In the Replect case, PODs were deliberately switched on and off without decreasing availability of the replicated resources. (An advantage of the Eden system is that logically separate experimental versions of the kernels can be run simultaneously with the "official" version, interacting only through competition for memory, Ethernet time, and CPU cycles.)

To measure the change in availability due to replication would require either long-term observations with natural system loads, or use of synthetic loads chosen to represent particular classes of system use. Such studies are important for an understanding of *policies* for use of replication, to answer questions such as the number of copies to use, how they should be distributed and which objects should be replicated. We restricted our concerns to the *mechanisms* for replication, and made no attempt to make quantitative measurements of availability. A separate simulation study to examine availability and policy questions have been conducted and recently reported[22].

5.2. Transparency

The issues of transparency and performance are in conflict. From the transparency standpoint one would like to keep a consistent, single-name, user interface for replicated and non-replicated objects. One way to do this, whether working at object level or kernel level, is to treat the non-replicated case as a single-copy replicated case, but this implies burdening the non-replicated applications with the overhead of the replication mechanism. Another way is to use another layer of indirection that allows the system to differentiate between replicated and non-replicated objects and branch to code specialized for each case, while keeping the interface to the client uniform. This, too, introduces extra overhead. We can see ways to minimize this extra cost, but not to eliminate it; hence there remains some trade-off between transparency and performance.

We found this to be a more difficult trade-off at the object level than at the kernel level and while we would not yet claim that this is a general effect, we would suggest that the designer be wary. For example, in our object implementation, the client invokes the root of the R2D2 addressing system to translate a string name into a set of capabilities and to set up a transaction manager which deals with the required number of copies. In Eden, these extra invocations can cost around 0.2 seconds. In Eden without replication, a client accesses a directory with a string name to get a single capability for the desired object, thus avoiding the extra overhead of dealing with the transaction manager. Transaction control is not needed, since exclusive access to a single object can be handled by monitors within the object.

Using Replects, which give transparency because the client deals with a single capability for the resource, there still is a price to be paid: The kernel must keep track of the set of passive representations, and select one from which to create the active form that represents the replicated passive representations. One might assume that the user of a non-replicated Eden object could totally bypass this Replect overhead, but subtleties are involved: One would have to forbid conversion of a Replect to a single Eden object while the system was being used. Suppose access to a Replect was attempted just as it was being converted back to a non-replicated object. Suppose further that the conversion failed, in which case the object reverts to being a Replect, but in the meanwhile the object had been accessed and some action was taken on the assumption it was a non-replicated object. To avoid this one obviously would make the conversion under control of a transaction, but that implies that all activations of single objects would in some way have to be aware of this transaction mechanism, hence incurring some extra overhead. One could keep a flag on each passive representation, denoting it either a single object or a member of a Replect. The cost to a non-user of replication to check this flag could be kept small but it is still some finite amount of overhead.

More generally, replication requires binding multiple objects to a single name known to the clients and this implies a cost. Whether replication is defined at the *parent* level, as in R2D2, or the *sibling* level, as in Replects, a price must be paid for maintaining single-name transparency and preventing loss of the resource due to a single crash.

5.3. Performance

We believe that replication can be implemented at either kernel or object level without creating performance penalties for non-users of replication much beyond the normal competition for memory, transmission time, and CPU cycles incurred in any application or system facility. However as noted in the section above, this may call for giving up some aspects of transparency to the client, in the object-level case.

We restrict our conclusions drawn from the relative performance of the two implementations since for many reasons, as pointed out in preceding sections, they are not strictly comparable. Our object-level replicated directory was slower than the non-replicated directory during query operations by around 80%, but we believe this difference could be reduced to less than 10% by restructuring the R2D2 design. We do not see this difference as inherent between object-level and kernel-level implementations.

Some differences were observed in the updating case, with the object-level response time for two copies being longer by 50% than the non-replicated directory. More work is being done to understand the reasons for this delay despite concurrent updating of the two copies. Some of the difference may decrease for updates larger than the 1K bytes that were used, since the existence of multiple active forms in R2D2 provides an advantage over the Replect single active form during checkpoint. (For 1K bytes the contention for access to the single Replect active form by the multiple PODs writing to disk is negligible). The R2D2 performance may be affected not only by the extra invocations to the root and the transaction manager; their mere *presence* may be causing more paging since Eden objects are large. If that is the case there could be an inherent disadvantage in implementing at object-level in our existing Eden environment, but we would not suggest that this would be the case in object-oriented systems in general.

5.4. Implementation Experience

One of the important motivations for our studies in replication was to assess the strengths and weaknesses of the Eden system, a motivation shared with most of the applications programmed in the Eden environment. For replication at the object-level it was useful to have invocation be location independent, but to be able to bind objects to locations so that nodes with independent failure modes could be used. This is a feature that was not included in the original Eden implementation but was added shortly after its birth. In connection with this, the uniform use of capabilities for naming PODS, Hosts, and objects was useful in binding objects to particular parts of the distributed system. We had positive experience with other features of Eden such as object mobility, which was useful when the system configuration changed. The Eden Programming Language[18], and the fact that object structuring made it easy to define modules that seemed natural in the design of R2D2, both proved to be useful. Black made a good assessment of Eden features[17], and our experience generally supports his conclusions. Similarly, the slowness of the checkpoint operation, the lack of incremental logging to stable storage and the isolation from the disk that was imposed by building Eden on top of Unix caused high overhead in the replicated resources.

If the underlying system cannot handle partitions, it is difficult but not impossible to do so with replication systems built on top, by using voting to restrict updates to one portion, or using a version comparison mechanism during combination of partitions. The Eden system was not designed to handle partitions. If for a given Eden object the active form and the passive representation end up on separate sub-networks, the active form cannot transfer data to the passive representation to checkpoint. However, the passive representation (after suitable timeouts) can create a second active form. When the partitioned sub-nets are merged, the two active forms have to be dealt with. This is not a serious problem within a single Ethernet, due to the small probability of partitions, but can become a problem with gateways or with other types of communication hardware.

The two approaches to replication that we implemented vary in their ability to compensate for this inability to deal with partitions. This is due to interacting factors that are best discussed separately. First consider the general effect of the recovery method on a replicated system's response to partitioning. Using Regeneration, all partitions that contain a copy will be able to continue to operate if the partition contains an adequate number of operable machines. Then one would need methods to adjudicate among competing versions when partitions merge. If one uses voting methods, the partition that contained the required quorum would be able to operate, whereas the others would not. This would allow simple recombination of partitions. A second factor has to do with caching, represented in Eden by the object's active form. This does not affect the above description of partitioning using Regeneration. With Replects, using voting, it is possible that a partition might contain a quorum of passive representations but if the active form is gone it is not possible to tell if it is dead or in another partition. To be safe, one would not go ahead and create another active form without also having merging techniques to handle competing versions, since the isolated active form might be updated with no attempt to checkpoint. With R2D2, on the other hand, if one were to use voting methods the system would allow a partition containing a quorum to go ahead and operate since each of the replicas can have its individual active form as well as its passive representation.

Implementation at kernel level was more difficult than at object level. Again, no quantitative statement can be made, because two different implementations by two different persons working in different programming environments give no statistically significant data. However, the modularity, uniformity of invocation, and object location independence made the object-level implementation distinctly easier. *Design* efforts were comparable.

One would like not to implement transaction management twice in the system, once for replication and once as a general tool, and indeed our experience has shown that it is not necessary. Both of our replication implementations used concurrency control methods that were specializations of a more general approach, although only in the R2D2 case was this more general facility exported to the user level. This specialization allowed bypassing of the features necessary for user interface. In the Replect case further simplifications came about because of dealing only with replicas of a single object rather than keeping track of a list of objects.

We recommend provision of a general transaction manager tool with components of it specialized for use for replication control. However, the generally available tool should have user override so that application programmers have the option of either using the general tool or experimenting with special transaction techniques, making use of the semantics of the application.

In summary, kernel level implementation of replication appears preferable to object level if the following conditions hold:

1. Transparency to the client is important.
2. Upward compatibility is important. Applications might be written without replication followed by a later decision to replicate some or all of the objects involved, in which case one would like to do it with no change to the application's objects.
3. Kernel size is not an overriding issue.
4. System programming staff is available to deal with the additional complexity in writing the kernel.

Object level implementation of replication is preferable to kernel level if:

1. Kernel programmers are scarce compared to object programmers.
2. Faster implementation and easier maintenance are important. (All points related to programming are heavily influenced by the availability of a high level programming language for object programming. In the Eden case EPL provided a considerable advantage at object level compared to the use of C at the kernel level.)
3. Increased kernel size cannot be tolerated.

6. Observations on Related Work

Relative to the "new-wave" of object-oriented systems being designed and developed that incorporate various features of replication, crash recovery and transaction control, our experience leads us to comment on several of the efforts, to the extent we understand the work, much of which is just emerging in reports and papers.

The ISIS project[10] is designing replication and crash-recovery into the layers that provide and maintain the object level - i.e., what we have called the kernel-level approach. Apparently the client is not offered the option of *not* using these built-in fault tolerant features in order to improve performance. Similarly, the client is restricted to the built-in nested transaction mechanisms, although concurrent updating of replicated data (when using pessimistic concurrency control, gathering locks in advance) is provided to improve transaction performance. As noted above, we would vote for providing options in these areas, to encourage experimentation with transaction control mechanisms that take advantage of application semantics.

For replication of procedures, rather than of objects containing both data and code, Cooper's *replicated procedure call* mechanism[23] calls several replicated servers when one replicated procedure call is made; the call succeeds if just one of the servers remains functional. In the Eden case, objects include data and code. Both Replects and R2D2 provide a special case of replicated procedure call, the one-to-many call. For example, if a copy of R2D2 directory is inaccessible, the R2D2 transaction manager simply invokes the next copy in line. Cooper also supports many-to-many calls, in which several client processes make the same replicated procedure call.

The Clouds project[13] is building atomic transaction control into the kernel and developing a high level language (Aeolus) to make them available to users. The users will have the option of selecting the kernel's synchronization and recovery techniques or to develop their own, to take advantage of the semantics of the application. The emphasis in Clouds appears to be on *reliability* of results, in the go/no-go sense of atomic transactions, rather than *availability* in spite of crashes. The reference implies that studies of replication at a level above the kernel are being made.

There are several projects building support for transactions, such as Argus[24], TABS[11], and PROFEMO[12]. Argus implements nested transactions (as defined by Moss[25]) on top of Unix. TABS is built on Accent Kernel and supports distributed transactions. PROFEMO will build nested transactions into the operating system level, which will have hardware support for object management, crash recovery, and concurrency control. These systems do not support replication in the kernel, but provide powerful primitives to build replicated resources. For example, a replicated directory object is being built as an application server in TABS.

In summary, the results of our experiments in the Eden environment lead us to favor many of the features we see being included in this new wave of object-oriented designs and implementations, although as far as we have seen, no one of them encompasses all the features we feel are desirable. Our "wish list" for such features is the following:

1. Kernel support of replication, or support of primitives that make replication easy at object level. These include location-independent invocation, ability to pin an object to a location, mapping of a resource name into a set of object names, and a concurrency control method.
2. User choice of replication, including none at all.
3. Uniform interface to the system for the use of single or replicated objects.
4. Minimum performance penalty for users of replication.
5. Very little performance degradation for non-users.
6. Provision of high-level language for applications programming, including easy control of what is replicated and where copies are placed.
7. Export of a general-purpose transaction mechanism for use at the applications level.
8. Export of the underlying atomic actions that allow users to build their own transaction mechanisms to take advantage of application semantics.

7. Summary and Conclusions

The Eden distributed system has provided the means to implement two different approaches to object replication, one at the object level, and one in the kernel that supports the object environment. Both implementations succeeded in making resources available in spite of network node crashes.

The implementation at the kernel level was more difficult than at the object level, which also appears to be easier to maintain. Modularity and the programming environment seem responsible for this. A number of Eden features were very helpful at the object level; the nature of the objects, including the fact that they contain active processes; the high level language for programming objects; location-independent invocation; object mobility, and uniform naming of objects, Hosts and disk repositories.

Eden also had some shortcomings for our purposes. The slowness of checkpointing, and the lack of incremental logging to stable storage were handicaps at the object level, although logging was used at kernel level. The Eden system was not designed to handle partitions, and neither of the implementations overcame this limitation, although the experience shows us ways to do so. An R2D2 implementation using voting would allow a majority partition to operate; means for detecting and resolving updates on separate partitions would allow more general solutions.

There are trade-offs between performance and the transparency of access obtained by using a single name for a replicated resource. Problems arise in retaining single-name access, forcing either the use of a layer of indirection, or the system to broadcast to locate a copy. To hide such problems from the client and provide uniformity of access for either replicated or non-replicated resources implies a performance cost.

The choice of object or kernel level implementation depends on the relative importance of transparency, performance, implementation time, kernel complexity and size, as well as the relative ease of programming and the languages used at the two levels. We believe that replication can be implemented at either level with small and comparable performance penalties for the client not wishing to use replication. Our experiments lead us to favor inclusion of more functions in the kernel than Eden provides; either complete kernel support of replication or provision of a number of primitives that aid implementation of replication at the object-level.

8. Acknowledgments

The Eden system is the result of the work of many faculty, staff members, and graduate students whose efforts and insights have made the work possible. Andrew Black and Ed Lazowska made very helpful suggestions on drafts of this paper, although the authors are to be held responsible for the final result. In addition to our acknowledgment of the contributions of our colleagues, we appreciate the support of the Coordinated Experimental Research program of the National Science Foundation.

Abstract

Changes in the user population continues the trend to more simplicity for the user and increased sophistication of the computer systems. In addition, advances in data storage technology have enforced the growth and creation of incomplete data files. A growing number of users require information from the database which cannot be obtained through the operators found in traditional query languages. Such needs have increased the expectation that a system should be able to assist the user in gathering and interpreting the appropriate data. The recent discussion of null values and maybe algebra is an attempt in this direction. However, the current literature has not addressed the practical issues of such theoretical concepts. This presentation examines the inclusion of the maybe algebra operators in a database machine. In addition, modifications designed to increase the time and space efficiency of the maybe algebra operators as well as the quality of the results are discussed.

1. Introduction

Incomplete information continues to be a problem for systems involved in information utilization. The problem of how to handle missing information has been studied by a number of researchers [5,6,8,9,16,17,18,26,27]. The current discussion of the use of the universal relation assumption (URA) [7,13,14,20,22,25], has increased the interest of dealing with null values.

A number of different uses for null values have been given in [1,22], but the problem of unknown data value represents the most common usage of null values. Codd [6] introduced a comprehensive extension to relational algebra that allows the user to examine potentially interesting data relationships based in part on unknown (incomplete) data. The theoretical foundations of Codd's new maybe algebra have been examined by Biskup [2].

While these works have developed a strong theoretical basis for maybe algebra, they have not taken into consideration the practical impact of such operations. In addition, recent developments in technology have led researchers to seek a hardware solution to the design of database systems, namely, the database machines [3]. Such machines have been developed with the purpose of improving the performance of the database operations. However, designers of such systems have not addressed many of the current issues that have surfaced recently in relational database design theory.

This presentation is an attempt to incorporate the concepts of null values and maybe algebra into the design of a relational database machine to extend its usefulness to the user population. Some practical restrictions of such an approach are also discussed. The database machine used as the basis of our discussion is the Associative search Language Machine (ASLM) [12]. The choice of ASLM stems from the fact that ASLM is highly parallel, and in many cases, the tuple search time is almost the same as relation search time (Associative Search).

The architecture of ASLM is briefly overviewed in Section 2. The basic concepts of maybe algebra are investigated in Section 3. The issues and practical considerations of implementing maybe algebra on ASLM are examined in Sections 4 and 5.

2. Database Machines

Several different classifications of database machines have been proposed. Rosenthal [23] has classified these machines as large backend, distributed network data node, and smart peripheral systems. Champine [4] has a similar classification using four classes: backend system, storage hierarchy, intelligent controllers and database computers. Su et. al. [24] have classified database machines as cellular logic systems, backend computers, integrated database machines and high speed associative memory systems. These classifications are similar in that for the most part they are based on how the database machine will be used. Bray and Freeman [3] have proposed a classification based on the concept of parallelism and the location where the data is searched. Based on this criteria, we have the following five groups: single processor indirect search, single processor direct search, multiple processor direct search, multiple processor indirect search and multiple processor combined search.

CH2345-7/86/0000/1210$01.00 © 1986 IEEE

These classifications suffer from the fact that there is some overlap between the categories. For example, there is no clear way to determine when a smart peripheral system becomes a backend computer as functions are moved from the host to the peripheral system.

However, one common feature of such classifications is the existence of a special purpose hardware system designed to manipulate the database. This approach is based on the need to remove the database functions from the host machine. The hardware specification of the database operations in the backend computer, the ability to overlap operations between the host and the backend, and elimination of the problems associated with the 90-10% rule [11] have made the backend approach more promising than the other categories. In the remainder of this section, the design of a backend database machine, ASLM, is discussed.

2.1 ASLM - a backend database machine

ASLM (Associative Search Language Machine) is a backend database machine [12]. The system is composed of a general purpose frontend machine supported by ASLM (Figure 1). The frontend system acts as the interface between the user and the backend machine. Security validation of the user and the user's query, translation of the user's query into ASL primitives and transmission of the final results to the user are the major functions of the frontend system.

Reducing the semantic gap and alleviating the transportation problem have been the general motivations behind the design of ASLM. Semantic gap reduction has been achieved through: i) the one to one relationship between the set operations and associative operations. ii) hardware implementation of the basic relational operations and iii) elimination of the address accessability of the data. The transportation problem has been resolved by screening the data close to the secondary storage. Solving these problems has determined the organization of ASLM.

ASLM is composed of four modules: i) controller, ii) secondary storage interface, iii) an array of preprocessors, and iv) a database processor.

Controller: The controller is a microprogrammable control unit. The contents of the writable control memory will be determined by the user's program. More specifically the controller: i) stores the ASL microinstructions generated by the ASL compiler, ii) decodes the ASL microinstructions, and iii) propagates the control sequences to the appropriate modules in the backend. The simplicity of the controller is primarily due to the use of associative hardware for the execution of the ASL primitives, since there is no need for address generation and the majority of the operations are strictly sequential.

Secondary Storage Interface: The secondary storage interface is a collection of random access memory modules, augmented by some hardware facilities. This module is an interface between secondary storage and ASLM. It accesses blocks of data from secondary storage and distributes them in a tuplewise fashion among the preprocessors.

Preprocessors: Because of the practical limitation on the size of the associative memory, it may not be possible to store all available data in the associative memory in order to perform an operation on the data items. Due to this restriction, all the systems proposed earlier based on fully associative memory, are not capable of handling large databases. In contrast, the design of ASLM overcomes this problem through consideration of two points. First, queries almost always refer to a subset of attributes in the tuples. Second, in each query, a small subset of tuples will satisfy the search criteria [11].

The preprocessors act as a filter which screens the data, selecting the valid data. The valid data is then placed in an associative stack in the database processor. In addition, the preprocessors perform a projection over the relevant attributes. In a database operation the attributes of a relation can be classified into three groups: i) members of the search argument (SA), ii) members of the output set (OS), and iii) the remaining attributes. It is the task of the preprocessors to validate tuples, on the basis of the SA attributes and to project them over the OS attributes.

The module is composed of an array of identical and independent processors which communicate with the database processor and the secondary storage interface. The preprocessors are initialized by the controller according to the query. After the preprocessors have been initialized, they perform operations on the tuples independent of any direct supervision from the controller.

Database Processor: The database processor is composed of a set of associative stacks enhanced by some hardware capabilities for direct implementation of the relational operators. The result of the operations of the array of preprocessors on a relation r with relation scheme R is a relation r_s with relation scheme R_s, which is stored in an associative stack.

$$R_s \leq R \text{ and } \forall t_s \; \varepsilon \; r_s \; \exists \; t \; \varepsilon \; r \text{ such that}$$

$$t_s = t[OS] \text{ and } t[SA] \equiv \text{search criteria.}$$

The associative stacks act as intermediate storage which holds part of the relation in order to perform the required relational operations on it. The database processor receives the database operations from the controller and performs them on the data stored in the appropriate associative stacks. At the end of the operations defined by

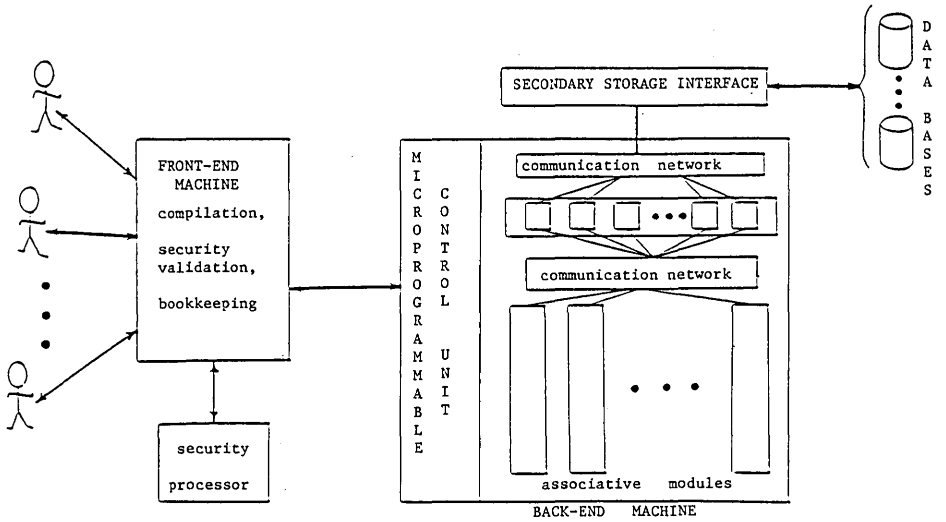

Figure 1: Overall Architecture of ASLM.

the query, the result is transferred to the general purpose computer.

The module is a set of identical and independent associative stacks of size w*d (where w is the width and d is the depth) augmented by some hardware circuits. The associative stacks can be linked together to make a memory size (K*w)*d ($1 \leq K \leq n$, where n is the number of associative modules) capable of holding d tuples of size K*w bits, or they could be linked to form a memory of size w*(K*d) capable of holding K*d tuples of size w bits. Because of the generality of the tuple sizes in a database, this facility enables the system to adjust the available memory modules based on the length of the tuples and the cardinality of the relation. In addition, this increases the space efficiency of the database processor. The independence of the associative modules enhances the modularity and as such the fault tolerance of the system.

Database processor is enhanced by a group of small special purpose modules to facilitate the direct implementation of the relational operators. One of these modules is used to reformat and realign tuples in the associative stacks. Such an action is necessary during some operations such as join, where the join attributes in the source tuples should be organized according to the position of join attribute(s) in the target tuples. The reformat unit is capable of performing basic logic operations on a collection of shift registers (4 units). The function of this unit will be discussed in more detail in Section 5.

ASLM is based on the concept of variable length tuples, where tuples and attribute fields are separated from each other by tuple separator markers and attribute separator markers, respectively. The null value is represented in this format as two adjacent attribute separator markers. The fields of a tuple t defined by t[OS] are expanded by the preprocessors to their predefined size in the normal manner. Fields containing null values are expanded to their appropriate size with don't care symbols.

The ASLM architecture is used in Section 4 to examine the implementation issues of Codd's maybe algebra [6]. The basic concepts of maybe algebra are examined in the next section.

3. Maybe Algebra

A great deal has been written about the relational model in recent years. We will assume that the reader has examined the basic concepts, in particular, relational algebra at the level of [26]. We will adopt Maier's notation [19] for partial information in the relational model. A partial tuple is one that contains zero or more null values ($\perp$). A tuple t is said to be total if it contains no null values. A tuple t whose scheme includes attribute A is definite on A (written $t(A){\downarrow}$) if t has a non-null value for A. We write $t(X){\downarrow}$ when $t(A){\downarrow}$ $\forall A \varepsilon X$ and $t{\downarrow}$ when t is total. If $t \varepsilon r$, where r is a relation defined by the relation scheme R, then $DEF(t) = \{A \mid A \varepsilon R \text{ and } t(A){\downarrow}\}$. A tuple t subsumes a tuple u ($t \geq u$) if $u(A){\downarrow}$ implies $u(A)=t(A)$. If $t \geq u$ and $t{\downarrow}$, then t is an extension of u ($t{\downarrow}\geq u$).

These concepts can be directly extended to relations as well. A relation r is total ($r{\downarrow}$) if all of its tuples are total. A relation r subsumes a relation s ($r \geq s$) if for every $t_s \varepsilon s$ there is a tuple $t_r \varepsilon r$ such that $t_r \geq t_s$. A relation r is an extension of s if $r \geq s$ and r is total. If r can be obtained from s by changing some null values in s to data values, then r augments s ($r \succeq s$). A relation r is a completion of s if $r \succeq s$ and $r{\downarrow}$.

Missing information presents a problem for any data model and as the relational model has matured, researchers have examined the question of how to handle missing data. Codd [6] developed an extension to relational algebra that allows a user to retrieve information based on partial results. Such a capability allows the user to probe the database for potential data relationships that might be useful to the user, but cannot be retrieved directly by true relational algebra. Recently, Biskup [2] has made maybe algebra more appealing by establishing its theoretical foundations.

A number of different interpretations of null values are possible [1,22], but maybe algebra is only concerned with missing or unknown data. Using this interpretation of null values, Codd [6] defines a 3-valued logic where

T - condition is true,
F - condition is false, and
ω - maybe - data values are unknown.

The truth tables for the boolean operations are given as:

AND	T	ω	F
T	T	ω	F
ω	ω	ω	F
F	F	F	F

OR	T	ω	F
T	T	T	T
ω	T	ω	ω
F	T	ω	F

NOT	
T	F
ω	ω
F	T

The null substitution principle [6] then can be stated as:

> A truth-valued expression has the value ω if and only if both of the following conditions hold:
>
> 1) Each occurrence of a null value in the expression can be replaced by a non-null value so as to yield the truth value T for the expression.
>
> 2) Each occurrence of a null value in the expression can be replaced by a non-null value so as to yield the truth value F for the expression.

Relational operators using a search condition to select tuples will base the search on a set of attributes, say X, that fall within a single relation scheme. Clearly, the selection of a tuple (t) based on a given condition will depend on the state of the values for t(X). If there exists A ε X such that $t(A)\downarrow$ and t(A) disagrees with the search condition, then the truth value associated with t is false (F). A truth value of true (T) would be generated for t if $t(X)\downarrow$ and t(X) matches the search argument. The truth value maybe (ω) is assigned if ∀A ε X such that $t(A)\downarrow$, the values t(A) match the search condition and there exists at least one element of X, say B, such that t(B) = ⊥.

Two operators that make use of a search condition to manipulate a relation are the select and join. The following examples illustrate the maybe and true relational algebra select, join and division operations.

r(R)

A	B	C
a_1	b_1	1
a_2	b_2	⊥
a_3	b_3	2

s(S)

C	D
1	d_1
⊥	d_2

a) True select r
where C=1

A	B	C
a_1	b_1	1

b) maybe select r
where C=1

A	B	C
a_2	b_2	⊥

c) True join of
r and s over C

A	B	C	C	D
a_1	b_1	1	1	d_1

d) maybe join of
r and s over C

A	B	C	C	D
a_1	b_1	1	⊥	d_2
a_2	b_2	⊥	⊥	d_2
a_3	b_3	2	⊥	d_2
a_2	b_2	⊥	1	d_1

Maybe division is treated in a similar manner as shown by the following example.

r(R)

A	B	C
a_1	b_1	c_1
a_2	b_1	c_1
a_1	b_2	c_2
a_2	b_2	⊥

s(S)

B	C
b_1	c_1
b_2	c_2

a) True division
($r \div s$)

A
a_1

Maybe division
($r \div_{\omega} s$)

A
a_2

A somewhat different view of the null value is taken for the remaining relational algebra operators. For these operations, null values in different tuples are interpreted as being equivalent. As such, we have no change in these operations over their use in traditional relational algebra. The following example illustrates this interpretation for the project operator.

r(R)

A	B	C
a_1	⊥	c_1
a_1	⊥	c_2
a_2	b_2	⊥
a_3	b_3	c_3

Project r over A and B

A	B
a_1	⊥
a_2	b_2
a_3	b_3

Codd [6] has also addressed the issue of using null values to bring the so called dangling tuples into the join process and to make relations union compatable. The outer theta join [6] will be used here to motivate the concept. Similar join operations have been proposed by Merrett [21], Zanilo [29] and LaCroix and Pirotte [15].

The outer theta join (denoted by $\textcircled{\theta}$) for r(A,B) and s(C,D) over BθC (i.e., B and C are defined over the same domain and θ is the test condition) is defined by Codd as:

$$r \circledcirc s = T \cup (R_1 X(C{:}\bot, D{:}\bot)) \cup ((A{:}\bot, B{:}\bot) X S_1)$$

T = the true join of R and S over $B\theta C$
$R_1 = r - T(AB)$ $S_1 = s - T(CD)$.
(where θ is equality)

r	A	B
	a_1	b_1
	a_2	b_2
	a_3	b_3

s	C	D
	b_1	d_1
	b_2	d_2
	b_4	d_3

T	A	B	C	D
	a_1	b_1	b_1	d_1
	a_2	b_2	b_2	d_2

R_1	A	B
	a_3	b_3

S_1	C	D
	b_4	d_3

$r \circledcirc s$	A	B	C	D
	a_1	b_1	b_1	d_1
	a_2	b_2	b_2	d_2
	a_3	b_3	$\bot$	$\bot$
	$\bot$	$\bot$	b_4	d_3

If we think of the traditional relational algebra as true (T) algebra, then we can view Codd's maybe algebra as retrieving tuples with unknown critical values. The search conditions for such tuples evaluate to maybe (ω). Since the subset of the search condition attributes that is definite matches the search criteria and the remainder are null, it is unclear whether or not such tuples are of use to the user. Maybe algebra gives the user the opportunity to investigate the set of tuples and draw his/her own conclusions. The impact of implementing the maybe algebra operators in the ASLM environment is examined in Section 4.

4. Implementing Maybe Algebra in ASLM

In this section, the ASLM implementation of maybe algebra is examined. We ignore the obvious changes required to the query language and concentrate on the compilation process and the architectural changes required to add the maybe algebra operators to ASLM.

i) The null value is simply taken as a data value by relational operators such as union, intersection, difference and projection. Such an interpretation of null values means there is no change in the implementation of the operators over traditional relational algebra. The details of these operators can be found in [12].

ii) The result of a maybe select operation is the set of tuples that yield the maybe truth value for the select condition under Codd's null value substitution principle [6]. A query of the form:

maybe select from r where
A = "a" AND B = "b" AND C = "c"
can be written as

select from r where
(A = "a" OR A = $\bot$) AND (B = "b" OR B = $\bot$)
AND (C = "c" OR C = $\bot$) AND (A = $\bot$ OR B = $\bot$
OR C = $\bot$).

In the event the condition is defined over a single attribute, the result in ASLM can be determined by an equality search against $\bot$. For more general search conditions, the maybe select can be implemented in the database processor as a sequence of 2^d-1 select operations, where d is the number of definite attributes used in the search condition. The sequence of operations will be determined by the compiler and hence will be passed to the database processor prior to execution. The results of the selects are placed together on the resultant associative stack. The operation

Maybe select from r where a<1 AND b>2
would require

select from r where a<1 AND b=$\bot$;
select from r where a=$\bot$ AND b>2;
select from r where a=$\bot$ AND b=$\bot$.

Such an approach means that the maybe select operator can be implemented directly in the current design of ASLM. No architectural changes are required to implement the operator. Since the search condition is introduced into the process by the user's query, the 2^d-1 select conditions required can be generated directly by the compiler. Naturally, an increase on the number of searches reduces the performance of the maybe select operator. However, since no changes have been introduced into the design of ASLM, no degradation of performance of the true algebra operators will be experienced.

iii) The maybe join·operation places a tuple in the result relation when the test for a join between two tuples results in a maybe truth value. For each tuple in r_1 (source relation), the relation r_2 (target relation) is search 2^d-1 times, where d is the number of definite attributes in the join set. As in the maybe select, the searches are looking for tuples in r_2 with different combinations of the definite attributes of the join set that contain one or more null values.

In the ASLM design, the join of relations r_1 and r_2 is initiated by loading the relevant data from each relation into two associative stacks. The tuples from the source relation are popped one at a time and passed to the reformat module. The reformat module realigns the join set attributes to conform to the positions they have in the target relation. Then, for each reformatted set of attribute values the target relation is searched in associative fashion. In our new environment, compiler distinguishes the true join and the maybe join during the compilation. For true join, additional select operations will be initiated to exclude all the tuples in the source and target relations which have at least one null value in their join set attributes. For the maybe join, the reformat module is triggered to enumerate all possible permutations of the join set attributes in the source relation tuple (i.e. $2^{d}-1$ cases as above). This enhancement to the reformat module is the only hardware overhead of the maybe algebra over the original design of the system.

maybe join r_1 and r_2 ($A_1 = A_2$ and $B_1 = B_2$)

r_1	$(A_1$	B_1	$C)$
	a_1	$\perp$	c_1
	a_2	b_2	c_2

r_2	$(A_2$	B_2	$D)$
	a_1	b_1	d_1
	a_2	$\perp$	d_2
	a_2	b_2	d_3
	$\perp$	b_2	d_4

maybe join r_1 and r_2

A_1	A_2	B_1	B_2	C	D
a_1	a_1	$\perp$	b_1	c_1	d_1
a_1	$\perp$	$\perp$	b_2	c_1	d_4
a_2	a_2	b_2	$\perp$	c_2	d_2
a_2	$\perp$	b_2	b_2	c_2	d_4

Maybe join has the potential to have drastic effects on the resource utilization and the performance of a database system. For example, if we wish to use the maybe join to join r_1 and r_2 over A = B, where R_1 and R_2 are the respective schemes and $A \varepsilon R_1$ and $B \varepsilon R_2$, then we get one copy of r_2 for each tuple t_1 in r_1 where $t_1(A)$ is null. Similarly, we get a copy of r_1 for each tuple t_2 in r_2 where $t_2(B)$ is null. We can find the size of the maybe join result for this example by:

$m*n_1 + n*m_1 - m_1*n_1$
where
$m = |r_1|$, $n = |r_2|$ and
n_1 = the number of nulls in r_2 for B
m_1 = the number of nulls in r_1 for A.

The potential for drastic loss of performance is apparent from the following example.

Example: Suppose m=n=1000
with 1% nulls for A and B
1000*10 + 1000*10 - 10*10 = 19,900
tuples in the maybe join result.

with 5% nulls for A and B
1000*50 + 100*50 - 50*50 = 97,500 tuples
in the maybe join result.

with 10% nulls for A and B
1000*100 + 100*100 - 100*100 = 190,000
tuples in the maybe join result.

Interestingly, the loss in physical performance is paralleled by a loss in logical performance. The value of such an operator must be rated by its ability to supply a "useable" set of tuples which the user can examine to see the potential relationships between data values. The relation sizes suggested by the previous example fall beyond the useable category. Zaniolo's generalized join removes the join over two nulls, but still has the potential to produce extremely large relations [29].

If we consider the probability of a relationship appearing in the maybe join result, given that one or more of the join set attributes are unknown, we can consider the information content of the operation by using Shannon's formula [10]

$$H = - \sum_{i=1}^{n} p_i \log_2 p_i$$

where P_i is the probability of a configuration's occurence.

Consider the case where the join set is a singleton attribute. When a tuple from one of the relations has a null value in the join attribute, we have a probability of one that the tuple will be joined to all of the tuples in the second relation. Using the interpretation from information theory, we can say that it is possible to guess the set of relationships produced by the maybe join and as such the information value of the operation is zero. From the database point of view, this means that we can use other operators that require significantly less resources to produce the same result.

Based on this discussion, we present a practical restriction on the maybe join operator. In its current form, the operator will likely cause stack overflow in ASLM when either the number of attributes in the join set is small or the two relations have a high percentage of null values for the join attributes. To deal with this problem, two solutions are being incorporated into the ASLM design.

a) Maybe join over a single attribute is detected by the ASL compiler and ignored. The user is notified that such an operation is expected to result in a low information result.

b) During the maybe join operation on two or more attributes, the system will be able to detect that a large percentage of nulls are resulting in a large number of maybe joined tuples. When the stack containing the maybe join result reaches a predefined load density, the operation is terminated and the user is notified of the low information quality of the data. By using the relative sizes of the two relations involved in the join, the system can set the predefined load density for the stack in question.

The use of these two restrictions will result in higher information value results. The first decision can be made during the compilation while the second decision is determined during the execution time. This can be done by the reformat module which controls the sequence of the maybe join operations.

iv) The maybe division operator can be implemented using the operators previously defined. The following algorithm provides the sequences of operations for r(R) maybe ÷ s(S) in ASLM:

```
Algorithm maybe divide;
begin
(maybe join r(R) and {$t_1$ ε s(S)}) U (join r(R)
and {$t_1$ ε s(S)});
  place result in stack $S_1$;
  project $S_1$ over R-S;
i=2;
while there is an unprocessed tuple in s do
begin
(maybe join r(R) and {$t_i$ ε s(S)}) U (join r(R)
and {$t_i$ ε s(S)});
  place result in stack $S_2$;
  project $S_2$ over R-S;
  intersect $S_1$ and $S_2$ placing the result in $S_1$;
  i:=i+1
end
Place r÷s on stack $S_2$;
Place $S_1$-$S_2$ on stack $S_1$
end.
```

Example

r(A	B	C)
a_1	b_1	⊥
a_2	b_2	c_2
a_1	b_2	c_2
a_2	b_1	c_1
a_3	b_1	c_1

s(B	C)
b_1	c_1
b_2	c_2

Stack S_1	a_1	Stack S_2	a_1	$S_1 \wedge S_2$	a_1
after	a_2	after	a_2		a_2
projection	a_3	projection			
over R-S		over R-S			

Stack S_2 r÷s	a_2	S_1-S_2	a_1

The maybe divide operation is extremely slow, but does not require any additional hardware changes beyond the changes required to implement the maybe join operator. As such, it offers no further degradation of the performance of the true algebra operators.

v. The outer join operation is designed to bring the so called dangling tuples into the join process. When the relations r_1 and r_2 are joined with the outer join, we have each dangling tuple of r_1 extended with null values for the attributes defined for r_2 that do not appear in r_1. Similarly, the dangling tuples from r_2 are extended with null values to make them union compatible with $r_1 ⟗ r_2$.

In ASLM, the outer join can be performed by testing both relations. In the traditional join operation, dangling tuples in r_1 are encountered by the process when the tuples are tested for a match in r_2. The outer join simply requires extending the tuples and placing them in the appropriate stack. On the other hand, the dangling tuples in r_2 are not located by the present join operation. To do this, it requires using the tuples of r_2 to test whether or not a tuple is a dangling tuple. When a dangling tuple is encountered, it is extended with null values and placed in the stack.

r_1 (A	B	C)
a_1	b_1	c_1
a_2	⊥	c_2
a_3	b_3	c_3

r_2(A	D	E)
a_2	d_2	e_2
a_4	d_4	e_4

using the outer join of r_1 and r_2 in ASLM, we have

A	B	C	D	E
a_1	b_1	c_1	⊥	⊥
a_2	⊥	c_2	d_2	e_2
a_3	b_3	c_3	⊥	⊥

after the first step.

Searching the result for a_2 @ @ d_2 e_2 (where @ means the fields are masked out on the search), a match tells us that the tuple participated in the join. On the other hand, searching for a_4 @ @ d_4 e_4, we find that the tuple needs to be extended and added to the stack. The final result of the outer join would be

A	B	C	D	E
a_1	b_1	c_1	⊥	⊥
a_2	⊥	c_2	d_2	e_2
a_3	b_3	c_3	⊥	⊥
a_4	⊥	⊥	d_4	e_4

5. Maintaining the database

The use of null values in a database system increases the complexity of the insertion policy (i.e., concepts such as tuple subsumption and null replacement as well as traditional concerns like duplicates must be considered). Recent literature has addressed a wide variety of such techniques [19]. Creating an insertion policy from the available techniques requires establishing the assumptions on how the system will be used. Our approach is to use somewhat of a compromise of the available techniques based on the following assumptions:

i) A new tuple can be inserted into an ASLM relation if it is not already subsumed by a current tuple.

ii) There are no hard violations of the database semanties in the current copy of the database.

The first assumption means that if a tuple such as $t_1 = < a_1 \perp \perp \perp e_1 >$ currently exists in an ASLM relation with scheme $\{A, B, C, D, E\}$ then the insertion of a new tuple $t_2 = < a_1 \perp c_1 \perp e_1 >$ means that the tuple $t_1 = < a_1 \perp \perp \perp e_1 >$ is no longer needed since $t_2 \geq t_1$. Let $s = \{t \mid t \varepsilon r$ and $t_2 \geq t\}$, the relation s can be found by applying a variation of the maybe select over the relation scheme for t_2. For example, the query for t_2 would be:

Select from r where
  (A = a_1 or A = $\perp$) AND (B = $\perp$) AND (C = c_1 OR
  C = $\perp$) AND (D = $\perp$) AND (E = e_1 OR E = $\perp$).

The resulting relation, $r' = (r-s) \cup \{t_2\}$, subsumes the relation r. The relation r does have a larger possibility set, but the completions of r' will all appear in the possibility set of r.

The second assumption allows the tuples in the current relation to be used to determine the true value of null values in the insert tuple, based on the existing set of functional dependencies. For example, given the existence of the functional dependency A→B, a query such as:

Select from r where A = a_1

would generate the set of tuples with the same A value. The system can then test the resulting set of tuples for a non-null value of B. Based on assumption ii) if such a value exists, there should be only one such value (ignoring null values which are considered soft violations). If such a non-null value exists, the backend system can then use the value to replace the null value in t_2 for the attribute B.

Null value replacement as discussed can be extended beyond just changing insertion tuple. The definite values of the insertion tuple can be used to replace null values in the tuples of the current relation. Such a policy is clearly more time consuming, since, first it requires that the user interface generates test conditions for all functional dependencies for which the left side attributes of the insertion tuple are definite and then the definite right side attributes in the insertion tuple are used to replace nulls in the tuples of the current relation. The policy rests on the assumption that the insertion tuple is valid. Notice that such an assumption is consistent with assumption (ii). Inserting a tuple that has an incorrect data value will result in an incorrect relation.

The null replacement policy used in ASLM will not provide replacement of all of the nulls that might be replaced under a more comprehensive replacement policy such as the one described by Maier [19]. The more comprehensive replacement algorithms, such as the one described by Maier, make use of marked (indexed) null values to increase the situations where nulls can be replaced. In considering the overall performance of ASLM, the use of marked nulls does not seem to offer sufficient advantages to offset the increased cost.

6. Conclusion

The inclusion of the maybe algebra operators into the design of the Associative Search Language Machine (ASLM) has been examined. It is shown that the system can be upgraded to include the operators with only modest changes. Practical restrictions for the implementation of the maybe join have been given.

The primary concern in adapting ASLM to include the maybe algebra operators, is that any required changes should not degrade the performance of the traditional relational algebra operators. To this end, the implementation of maybe algebra is slow. Current work centers around attempts to solve this problem.

PROS AND CONS OF OPERATING SYSTEM TRANSACTIONS FOR DATA BASE SYSTEMS

Gerhard Weikum

Computer Science Department
Technical University of Darmstadt
D-6100 Darmstadt, West Germany

Abstract

Recently, several proposals have been made to integrate the well-known notion of transaction into operating systems. A general transaction service could serve as a common basis for various client types, including data base systems. In this paper, benefits as well as drawbacks of such an operating system facility are discussed. A major contribution is to investigate the suitability of three basic kinds of DBS server concepts with regard to the utilization of OS transactions. To overcome some of the problems of building DBS transactions on top of OS transactions, we propose a multi-level transaction methodology. Single DBS requests are handled as transactions by the OS layer. Management of entire DBS transactions is done in the DBS supported by basic OS services. This multi-level transaction management method seems to have certain performance advantages over pure OS transactions.

1. The Notion of Transaction in Operating Systems

The notion of transaction has proven to be one of the key concepts of modern data base systems (DBS). It enables application programmers to overlook all effects of multi-user mode as well as the possibility of certain classes of failures including a system crash. The DBS transaction manager guarantees that each transaction appears isolated from concurrent executions and ensures atomicity and persistence of transactions [21]. Application programs simply have to indicate begin and end of a transaction, usually denoted BOT, standing for 'Begin of Transaction', and EOT, standing for 'End of Transaction', or RBT, standing for 'Rollback Transaction', in the case of a deliberate abort. Thus, transactions are an easy to use concept for fault tolerance in a multi-user environment [15].

At the moment, many people believe that transactions need not necessarily be tied to the framework of data base systems, but could be useful for other types of applications too [36]. This idea has given rise to various approaches aiming at a general transaction management service within the operating system (OS) as a common basis for all kinds of applications. A number of projects on this issue, both in the context of commercial systems (e.g. [38], [41], [46], [51]) and focussing on research prototypes (e.g. [8], [27], [28], [32], [37]), are in an advanced stage or have already been finished. Basically, all designs suggest an architecture similar to that of figure 1. Besides a DBS, possible clients of the OS transaction manager could be a DC-System managing a network of terminals (cf. [19], [45]), file servers in a distributed environment [43] or even mail service as a component of advanced office information systems [47].

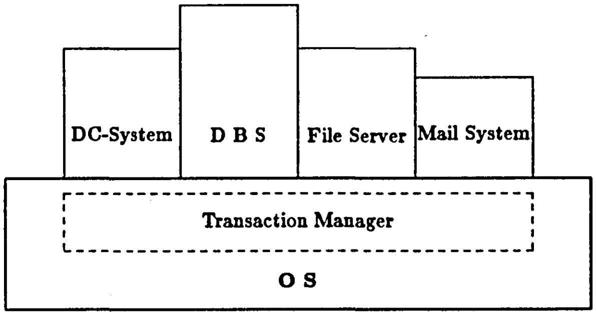

Fig.1: System architecture based on OS transactions

The above architecture seems to be a very promising direction for future OS development. On the other side, today's DBSs often ignore OS services or even circumvent the OS interface because of performance reasons, thus reimplementing functions like buffer management and scheduling [39]. Sometimes DBSs even use special channel programs to optimize critical I/O requests [29]. Usually, the argument is that general-purpose OS facilities cannot meet the requirements of a DBS, which for example has to schedule thousands of transactions in a very short time without the overhead of OS processes. The crucial question arising here is whether an OS transaction management service is suitable for DBSs, also w.r.t. performance. To be more precise, we actually should ask whether there is a good chance to implement OS transactions efficiently enough without semantic knowledge about data and DBS operations. In the case of a negative answer, DBSs are likely to ignore OS functions once more, keeping their own transaction mechanisms (cf. [41]).

This paper discusses benefits of as well as objections to OS transactions from a DBS point of view. One major issue is the correlation between transactions and the DBS process structure. Since, in most proposals, a process can run OS transactions only one after the other, difficulties to utilize this new OS feature arise when a single DBS process or a small group of DBS server processes performs the scheduling of transactions. On the other side, having done all the scheduling by the OS would require one DBS process per transaction which seems not to be feasible in common OSs due to high process management costs. We point out an efficient solution based on a multi-level approach.

The paper is structured as follows. Section 2 considers basic OS services supporting DBS transactions. The emphasis of section 3 is on drawbacks of a direct mapping of DBS transactions to OS transactions. A different kind of mapping is presented in section 4 taking into consideration the process structure of a DBS. Design considerations for the proposed multi-level transaction approach as well as preliminary performance estimations are given in section 5. We conclude with the recommendation of a revised system architecture on the basis of figure 1.

2. Operating System Services for DBS Transactions

A first step towards an OS transaction management service would be to provide at the OS level basic functions for both compoments of a DBS transaction manager, concurrency control and recovery. As concurrency control is mostly implemented by locking and recovery is usually based on logging or shadow storage, this means that two kinds of services should be offered: lock management and a facility to backout and redo actions. Implications of such OS functions for a DBS transaction manager are discussed in this section. We make no attempt to give an exhaustive survey on various systems or proposals, which usually are very hard to compare with each other, but restrict ourselves to a discussion of typical issues.

2.1 Locking Services

State-of-the-art OSs provide functions that allow processes to operate on global resources in a synchronized way (e.g. [9]). These functions are:

LOCK < *resource name* > < *mode* >
UNLOCK < *resource name* > < *mode* >

At least two lock modes, shared access and exclusive access, should be supported. Additionally, special modes may be useful for hierarchical locking protocols [13]. When a process wants to acquire a lock on a resource that is already locked by a different process in an incompatible mode, the process is enqueued on a FIFO waiting list and deactivated. It is made dispatchable again as soon as the lock can be granted.

All this is essentially the very same as in DBS concurrency control. At a second glance, however, some subtle differences become apparent. OS lockable resources must have a unique name upon which all processes agree. In a DBS, most resources have unique names such as page numbers or tuple identifiers, but also proposals have been made to lock predicates or key values and key intervals in an index (e.g. [5]). If, for example, a reader scans the key interval [10,300], then, in order to achieve serializability, a writer inserting key 120 must be prevented from running concurrently. To recognize such a situation, both the interval and the single key have to be mapped to the same resource name. Thus, besides the OS locking service such a DBS would need some table management of its own. However, as most DBSs use page locking, this seems not to be really a serious disadvantage of OS lock management. Even the widely discussed phantom problem can be handled properly by page locking, since predicate oriented operations are inevitably transformed into either an index scan or some kind of relation scan on an implementation level (cf. [2]).

More serious is that building upon OS locking solely requires an OS kernel call, i.e. an SVC in the common /370 architecture, for each LOCK operation, even in the nowaiting case. If instead locks were managed in a common memory pool by the DBS itself, this overhead can be avoided whenever a lock request is granted immediately. As far as we know, no figures about this specific SVC overhead have ever been published. We are convinced, however, that, by microcoding frequent instruction sequences or with a better design of hardware, the costs of OS locking service functions can be reduced by an order of magnitude compared with today's figures (cf. [23], [31]). In the common case of (virtual memory) page locking, special hardware support has been suggested [40]. The proposed hardware automatically marks a virtual memory page as locked on the first machine instruction referencing this page, either in exclusive or shared mode depending on the kind of reference. This method seems to be practicable provided that locked pages remain in virtual memory, i.e. the OS has a 'one-level storage' file system [44], this is what the method originally was proposed for, or locked pages always could be pinned to the DBS buffer pool. Please note that this approach would require an explicit OS kernel call only for UNLOCK operations.

OS locking services can be used by DBSs in two ways. Most DBSs need a small number of semaphores (sometimes called 'latches') to synchronize access to common adminstration pools such as the lock table or the buffer pool LRU chain. These semaphores are typically acquired very often and released again after some hundred machine instructions. When a DBS process is deactivated by the OS scheduler, e.g. due to time-slice runout, while holding such a semaphore, all other processes soon enqueue on this semaphore, thus forming a kind of convoy. It has been observed that convois are a lasting phenomenon and hence have a very negative influence on the overall performance [3]. If DBS semaphores were known to the OS, the OS scheduler could easily avoid deactivating a process that would block other processes. Semaphores should be implemented by the OS locking service therefore.

The second way to use OS locking is for data items. This seems to be the method of the relational system INGRES to implement page locking [30]. We have already discussed inherent limitations of this approach above. On the other side, two advantages over DBS locking can be imagined. As the OS has knowledge about CPU utilization, it could try to run a deadlock detection 'demon', i.e. to check for cycles in a waiting-graph, whenever the CPU would be idle otherwise. Such an approach, of course, is not feasible for a DBS, that would have to start deadlock detection in regular intervals, or, even worse, at each lock wait. In addition to this, we observe that global deadlocks, e.g. involving data base locks and file locks, can be easily detected if resource locking is performed entirely in one subsystem, viz. the OS.

Another benefit of OS locking is simplification and potential performance improvement of resource unlocking. When the DBS executes an EOT operation, it has to release all locks held by the committed transaction, and has to notify all transactions that have been waiting for one of these locks and are now ready to run. The second step usually is a costly event, since all DBS processes acting on behalf of these transactions must be signaled via OS kernel calls. This requires as many interprocess messages as there are waiting processes. Probably, it would be much more efficient, if a process committing a transaction calls the OS locking service once, leaving it to the OS to make waiting processes dispatchable again. We would simply have to extend the UNLOCK operation to release a set of resources in one call.

It seems that OS locking would not only be far from being a bottleneck for DBS transactions, but could really improve the overall performance.

2.2 Recovery Services

The purpose of an OS recovery service is twofold. First, it provides clients with the facility to go back deliberately to a previous system state, either by reconstructing the state of all objects that have been changed since then or by compensating all update operations through their inverses. The second task is to secure object states, i.e. to protect them against crashes by forcing all necessary data to stable storage.

These two facilities are called UNDO and REDO functions in DBS terms. As in DBSs, rollback need not be expected to any previous state nor need resiliency be guaranteed for every single action. For most clients it seems to be sufficient, if states to be secured and backup states must be indicated explicitly. A special form of this facility is the notion of a 'recovery sphere' which is a unit of work with the properties of atomicity and persistence. Recovery spheres enable a client to go back to a single previous state, marked by a 'BRU' call denoting 'Begin of Recovery Unit', until it reaches a commit point, marked by an 'ERU' call denoting 'End of Recovery Unit' [46]. Only committed states are secured.

Recovery spheres closely resemble the notion of transaction. The difference is that the former need not be synchronized with each other. Thus, recovery spheres plus strict two-phase locking provide an OS transaction service. In the following, we exclude nested recovery spheres [26, 27] from our discussion.

Obviously, an OS service providing recovery spheres can adopt DBS recovery techniques which mostly are based on shadow storage or logging. The basic idea of shadow storage is to map updated pages, i.e. current but not yet committed page versions, to disk blocks different from those of the original, i.e. old page versions which become so-called 'shadow pages' [44]. This mapping usually is done through two versions of a translation table. The necessity of additional I/Os for these page tables has been considered as a main bottleneck of shadow storage mechanisms [14].

Integration of shadow storage into a virtual memory OS could help to reduce the table management overhead drastically. As virtual address spaces typically are based on a page-to-disk block mapping too, it seems very advantageous to combine both kinds of tables (e.g. [8]). Please note, however, that this would require a complete file to be bound in virtual memory, which is the basic idea of 'one-level storage' systems (cf. [44]). No DBS buffer pool is necessary in such an approach, as all I/Os are done via virtual memory paging. Thus, the problem of double-page faults [10] is resolved incidentally. One point of criticism of this technique has been that virtual memory replacement algorithms, usually LRU-like, are not suitable for DBS page reference patterns [39]. We leave it to the reader's judgement whether this issue could be remedied or rather is a persistent objection.

Even with a more conventional file system in mind, the OS could decrease shadow storage table overhead combining it with the mapping of extents, i.e. collections of consecutive disk blocks, to disk addresses. This would at least help to shorten page table entries, and consequently saves I/Os (cf. [24], [32]).

The other main approach to recovery - logging - requires an UNDO log record to be written each time before updating a disk page in place and REDO log records to be written before committing a transaction [13]. The first kind of I/Os due to the write-ahead log principle often can be avoided when buffer pools are large enough to fix updated pages until they are committed. This is the idea of the 'Cache/Safe' strategy [11] and is termed a NO-STEAL buffer policy in [21]. So, as UNDO log records can be kept in main memory until they are no longer needed, forcing REDO log records to disk during the commit phase of transactions remains the major bottleneck of log-based recovery techniques.

The I/O time to write REDO log records of a transaction can be decreased considerably through the use of special channel facilities, e.g. 'chained I/O' (cf. [11]). In fact, some DBSs have implemented highly sophisticated channel programs (e.g. [29]). It is our strong opinion that low-level I/O driver routines are the responsibility of the OS kernel and actually should not be executed directly by a non-trusted process like a DBS normally is. So the natural place for optimizing REDO loggging I/Os is in the OS.

An even higher performance enhancement is achievable through a method called 'group commit' [7]. When a client of the OS recovery service requests to commit, it could be deferred until a certain number of clients is ready to commit. Then, REDO log records of these clients are altogether written to disk in one chained I/O operation, thus drastically decreasing I/O costs. DBSs have already utilized this technique too [12,22]. The overall performance gain could be still higher yet in an OS recovery service, as not only DBS processes but also clients such as DC system processes and file servers (cf. fig.1) participate in group commit.

Recovery services in the OS kernel seem to be very attractive because of possible optimization due to its closeness to hardware. In addition to special I/O drivers, non-conventional disk architectures such as associative search disks (cf. [32]) or non-volatile semi-conductor disks (cf. [34]) will have an impact on recovery performance and maybe even recovery algorithms. It has been a traditional task of OSs to provide device independence for user processes. We think that this should hold for DBSs too, also in view of novel device types.

3. Drawbacks of OS Transactions

To summarize the results of the last section, we consider OS locking service and OS recovery service as a basis that is well-suited for DBS transaction management. Since both services are complementary to each other, they can be integrated to provide a complete OS transaction facility. Clients of such a service, particularly DBS processes, only have to issue BOT and EOT or RBT operations. The OS transaction service acquires all necessary locks automatically, and is fully responsible for recovery measures.

However, any OS transaction concept can only comprise objects and operations that are known to it. As a consequence of this, each client operation on an OS object such as a file must have associated an explicit OS kernel call in order to inform the OS transaction manager about it. DBSs usually refer to pages, i.e. fixed-size (typically 2K or 4K) blocks of a primitive file, as OS objects. This means that each request to fix or unfix a page has to be treated as an OS kernel call, whether it causes an I/O or not. Under these circumstances it seems reasonable to delegate buffer management to the OS too. As we mentioned before, it is not clear whether OS buffer replacement algorithms can achieve results nearly as good as a DBS would. Certainly, the OS has no semantic knowledge about DBS page reference patterns, but it seems that most DBSs essentially use a rather simple LRU policy [10].

Two further consequences are derived from the page orientation of the DBS-to-OS interface. If transaction management is in the OS, then [40]:

- page level locking is performed for all types of data, and
- page level recovery is performed for all types of data.

The first item does not take into consideration 'hot spot' data, i.e. data with a high rate of congestion. Whole pages are even locked when catalog information such as tuple counters are accessed, although the DBS only uses this data for query optimization and thus could tolerate inaccuracies [41]. Similar considerations appear to be valid for recovery. Page logging usually means that full before images and after images are recorded, even if only a few bytes have been changed [40]. We will revise this point in the next section.

[41] proposes a solution to these drawbacks. It recommends that the OS transaction service could be informed to relinquish locking and recovery measures for certain objects. Moreover, it should allow clients to record application-specific events of their own in the log. We suggest a different approach called 'multi-level transactions' that remedies the above mentioned disadvantages and yet tries to profit from the OS transaction service as much as possible. Basically, its idea is to deal with OS transactions as they are, building a higher-level notion of DBS transaction upon them.

As we will show in the next section, multi-level transactions also provide a clean concept to cope with another difficulty of pure OS transactions. The OS has to identify a client for each active transaction by some unique criterion. From an OS point of view, it seems very natural to use process IDs for this purpose (e.g. [27], [46]), as a transaction is always executed in the context of a particular process, or possibly a tree of processes in a distributed system. In order to avoid confusion about transaction clients, this process cannot issue a BOT request for a second transaction unless the one it is executing is terminated first, either by EOT or by RBT. Note that in the nested transaction case, this condition still holds for transaction roots. Thus, in many proposals, client processes are tied to at most one OS transaction for each period of time. Conversely, when a process issues a BOT operation, all subsequent actions of this transaction must be invoked directly, or indirectly in the case of a process tree, from the original process. Implications of this binding scheme are discussed in detail in the following section 4.

4. Mapping of DBS Transactions to OS Transactions

As we indicated at the end of the last chapter, the realization of DBS transactions by OS transactions depends on the DBS process structure. This correlation has its origin in a one-to-one binding scheme between OS transactions and processes. The following three basic types of DBS process structures are used in practice [18,20].

In a **symmetric server process** approach, each DBS transaction is run as its own DBS process. Either the DBS code is executed directly in the application process, or because of code protection a separate DBS process is spawned dynamically and destroyed after the transaction is finished. The first method seems to be implemented in DB2 [17], the second one is followed by INGRES [30] for example. In either case, scheduling is fully delegated to the OS.

At the opposite end of the range of possibilities, a **single server process** method has been successfully implemented e.g. in SQL/DS [4]. One DBS process, permanently running in the background, performs the requests of all transactions. To achieve satisfactory throughput results, such a server must do asynchronous I/Os. It cannot afford being blocked by a request that runs into a lock wait, as the blocking transaction can make progress and eventually release the lock only if this single DBS process is executed further. Hence the DBS has to do some fairly complicated scheduler tasks, e.g. saving context information of interrupted request-processing 'agents'. On the other side, this approach has the virtue of low costs due to process management.

To simplify scheduling and to allow for a multi-processor environment, **multiple server processes** (e.g. [35]) could be installed at system boot time. These processes need not necessarily perform asynchronous I/Os. They could do without internal multitasking, simply deactivating a process in case of a lock wait. Typically, the number of concurrent transactions is higher than the number of DBS processes by a factor of 2 to 5 (cf. [20]). So a good and yet simple strategy for such a server type could be to process any DBS operation request to its end in one of the server processes before this process accepts another request. At each point of time, every DBS process acts on behalf of at most one transaction.

We are now going to investigate the suitability of these various server types with regard to OS transactions. In a symmetric server process system, each DBS transaction can be mapped one-to-one onto an OS transaction running in the DBS process assigned to it. The following example demonstrates a possible process structure.

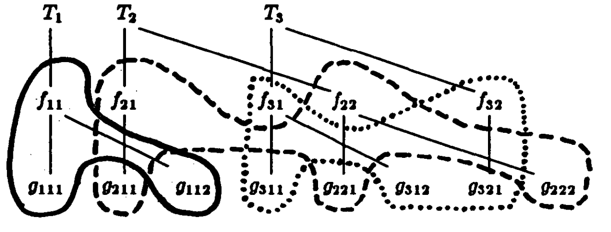

Fig.2: Transactions in a symmetric server process system

The figure shows transactions T_i issuing several DBS tuple operations f_{ij} which in turn result in a number of OS page operations g_{ijk}. Transactions T_1, T_2 and T_3 are processed in three different DBS servers created dynamically. The execution order of actions has to be read from left to right in the above figure. Due to index maintenance, one DBS tuple operation usually corresponds to more than one page operation. Separation of application programs and DBS code in distinct processes is indicated by excluding transaction roots from servers.

Each DBS server can initiate a (page level) OS transaction in this approach. For the scenario of figure 2 the transactions would be:

$T'_1 = < g_{111}, g_{112} >$ in the solid process
$T'_2 = < g_{211}, g_{221}, g_{222} >$ in the dashed process
$T'_3 = < g_{311}, g_{312}, g_{321} >$ in the dotted process

Clearly, the notion of OS transactions fits nicely with a symmetric server process scheme.

In a single server approach there is no possibility to assign a unique process ID to DBS actions, since all requests are handled in the same process. Therefore, OS transactions are not attractive at all for such an environment, as one process would have to act as a client for more than one OS transaction at a time. Actually this is not even surprising, as a single server DBS nearly is an operating system in itself, ignoring most OS functions as e.g. scheduling. For this type of server it would probably be better to run on a small special-purpose OS kernel that only provides most rudimentary facilities and therefore incurs little overhead (cf. [42]). However, this is in sharp contrast to our overall philosophy as indicated in section 1.

In the case of a multiple server process structure we could have a scenario like that of figure 3.

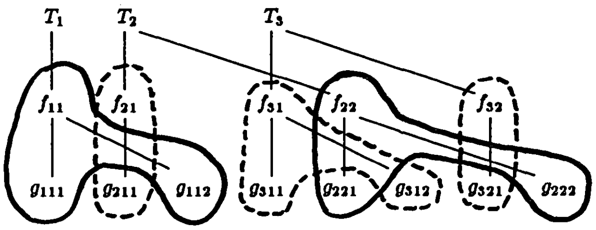

Fig.3: Transactions in a multiple server process system

Obviously, the one-to-one mapping of DBS transactions onto OS transactions, that has worked for the symmetric server type, is not feasible here. Requests of three different transactions are executed in the context of two DBS processes, which are drawn in the above figure with solid lines and dashes respectively. Assignment of requests to servers could be according to some load balancing scheme. Since transaction T_2 migrates from the dashed process to the solid one, treating its page action sequence $< g_{211}, g_{221}, g_{222} >$ as an OS transaction would violate the principle that OS transactions are always bound to one single process.

This binding rule is yet fulfilled by page level actions of each DBS operation request. Therefore, we could treat these requests as OS transactions obtaining:

$T'_{11} = < g_{111}, g_{112} >$ in the solid process
$T'_{21} = < g_{211} >$ in the dashed process
$T'_{22} = < g_{221}, g_{222} >$ in the solid process
$T'_{31} = < g_{311}, g_{312} >$ in the dashed process
$T'_{32} = < g_{321} >$ in the dashed process

But is this actually of any value to a DBS? Fortunately, the answer is yes, as we are going to show now. Our idea is to apply a multi-level transaction methodology [48,49] with two layers here. The OS transaction manager guarantees that single DBS operations appear isolated from concurrent requests and are resilient w.r.t. certain failure categories. From the view of an additional DBS transaction manager this means that single DBS operations can be treated as atomic actions. Hence it is valid for a DBS to use tuple locking without the need to care about interferences on the page level. DBS transactions thus are:

$T_1 = < f_{11} >$
$T_2 = < f_{21}, f_{22} >$
$T_3 = < f_{31}, f_{32} >$

It has been shown elsewhere [1,50] that level-by-level serializability is sufficient for a multi-level concurrency control method to be sound. The DBS transaction manager yields serializability of DBS transactions, and the OS transaction manager ensures serializability of single DBS operations, i.e. OS transactions. Transaction T_3, for example, then actually looks like:

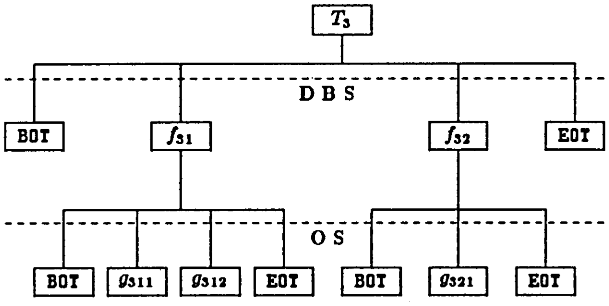

Fig.4: Two-level transactions based on OS transactions

Details of this kind of transaction management are discussed in the next section 5. The multi-level transaction approach is also applicable in the symmetric server process case. We are getting into difficulties, however, with the multiple server type, when DBS processes perform internal multitasking, e.g. to avoid becoming deactivated in case of a lock wait (e.g. UDS [35]). The problem is illustrated in the following figure.

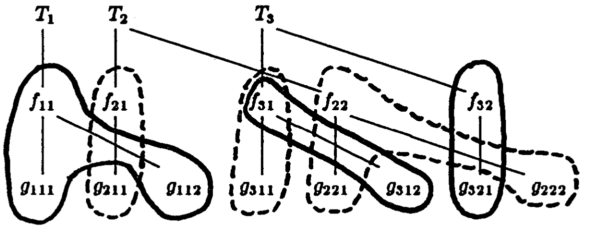

Fig.5: Transactions in a multiple server process system with internal multitasking

In this scenario even a single DBS operation, viz. f_{31}, migrates from the dashed process to the solid one. Therefore, the multi-level transaction methodology is rendered impracticable in this case.

5. Multi-Level Transaction Management

Multi-level transactions not only overcome the problem of binding OS transactions to processes, but have another major virtue. Page locks are released at the end of each OS transaction, i.e. at the end of each DBS tuple operation. Only tuple locks must be held until EOT of the DBS transaction. In most cases this results in increased parallelism. One of the major objections to OS transactions (see chapter 3), viz. pure page locking, is remedied this way. However, it is still not possible to use special locking techniques for special DBS-like data structures within the OS, e.g. a B-tree locking protocol, unless the OS has semantic knowledge about these structures. On the other hand, such protocols are hardly used in real DBSs today, since for recovery reasons one has to keep locks on updated tree nodes until EOT anyway (cf. [33]). We claim that also our multi-level locking protocol prevents B-tree roots from becoming 'hot spots', just by releasing page locks at the end of each DBS tuple operation.

Log space may be saved by recording tuple changes only instead of whole pages (cf. [16]). However, as tuple actions are in turn made resilient by page logging, effectively reducing the log size requires some more refined technique than straightforward multi-level recovery. We will not discuss this issue further here.

To be fair, disadvantages of our multi-level transaction approach should not be withhold. As page locks are released prematurely, UNDO of an unfinished DBS transaction through OS page level recovery, i.e. restoring page before images for example, could result in anomalies such as lost updates. Instead DBS operations have to be compensated by their inverses. Undoing an 'INSERT' operation means to execute a 'DELETE' operation on the inserted tuple (cf. [14]). Admittedly, this is a costly method, but as transaction UNDOs, e.g. due to deadlocks, normally are infrequent events, we do not consider this as a serious drawback and are willing to accept this price in return for enhanced concurrency.

Another objection could be that the DBS transaction manager needs its own locking and recovery services [41]. This is true for locking, but, apart from certain restrictions mentioned in section 2.1, the OS lock manager could be used for this purpose if it is made available as an independent OS service. DBS operation logging could be performed within OS transactions like any other page level operation. A DBS operation inserting a tuple t into a page p and causing index maintenance operations on pages q and r would look like:

$$< \mathtt{BOT}, read(p), write(p), read(q), read(r), write(r), write(s), \mathtt{EOT} >$$

where s is a log page containing an entry for the inverse DBS operation, viz. 'DELETE t'. Atomicity and persistence of OS transactions ensure that after a crash this UNDO entry will be contained in the DBS operation log if and only if tuple t has really been inserted and all indices have successfully been updated. Thus, log management functions of the OS transaction service need not be duplicated in the DBS.

However, building DBS logging into OS transactions also has disadvantages. As the OS does not distinguish between data pages and DBS log pages, it enforces page locking on the DBS log too. Fortunately, potential lock waits on a log page are very short, because DBS log records are always written as the very last action of an OS transaction. By splitting the DBS log into n separate logs, where n is the maximum number of concurrent OS transactions, contention on this ressource could be totally eliminated, but, on the other hand, this would not allow for packing log records of several processes into a single page. In either case, in a rigorous realization of our multi-level transaction approach, two DBS processes cannot write their DBS log records together using only one single I/O.

An essential drawback of our multi-level transaction scheme is that it will pretty surely increase I/O rates due to REDO logging. Our approach splits one DBS transaction into a number of short OS transactions. Each time such an OS transaction commits, page level REDO log records must be forced to disk. These I/O costs are inevitable and can only be reduced to a certain degree. A clever technique based on the 'Cache/Safe' strategy of [11] could be to record only changed byte strings (cf. [25]) instead of whole page after images in a log buffer. Such a log entry can be computed without knowing anything about the DBS update operation that has caused the page modification, simply by comparing the page with its before image at commit time. This comparison causes no additional I/O since in the Cache/Safe approach before images are kept in the buffer pool throughout the duration of a transaction. Please note that such a NO-STEAL strategy [21] is more likely to be practicable when page level transactions are rather short as is the case in our multi-level scheme. Then, using group commit and sequential chained I/O for the REDO log buffer might reduce EOT costs to a tolerable rate.

In order to get quantitative results about the trade-offs of the proposed multi-level transaction approach, a number of simulation experiments have been performed. Since we have no OS offering transactions available, we misused a DBS for page level locking and recovery as well as for mapping tuple operations into sequences of page I/Os. On top of this layer, tuple level locking and logging has been implemented as sketched above. Measurements were performed with a mix of DBS transactions from a real-world application against a 130 MB data base of real-world data. As underlying process structure we used a variant of the symmetric server concept, combining it with a simple load generating mechanism. More technical details about this performance study are contained in [6].

In the experiments, two basic techniques were applied and compared with each other: using page level transactions directly for application transactions vs. our multi-level transaction approach. A series of measurements has given rise to the following key observations:

- On the average, multi-level transaction management increased the throughput of application transactions by 12 percent.

- Pure page level locking resulted in an unexpectedly high number of deadlocks, whereas the multi-level technique hardly suffered from deadlocks at all. Obviously, for short-lived subtransactions the danger of a page level deadlock is extremely low, and usually only few deadlocks occur due to tuple level waiting situations.

- With pure page locking, the lock wait probability, i.e. the frequency of lock requests resulting in a lock wait, was fairly low, viz. about 1 percent. This result, however, was clearly outperformed by the multi-level locking protocol which achieved less than 0.2 percent on pages, just by releasing locks early. Of course, in the latter case one has to consider the lock wait probability on the tuple level too, which ranged from 1 to 2 percent. However, as the absolute number of lock waits on tuples was extremely low, compared with lock waits on pages, the crucial performance impact seems to arise from page conflicts.

- The inherent increase of I/Os for the multi-level technique was even worse than expected. Our measurements indicated a factor of 3 per application transaction. In particular, the number of I/Os caused indirectly by tuple level logging was tremendous. Basically, this had two reasons: The underlying page level recovery system forced before-images to disk before modifying pages in the buffer, and flushed committed pages to the permanent data base immediately at EOT. Therefore, each tuple level log record caused two additional I/Os.

Our simulation results have been very encouraging so far. Although the underlying page level recovery method actually has been totally unsuitable for short (sub-) transactions, the multi-level technique was the winner w.r.t. throughput. The next step will be to investigate potential performance gains of implementation techniques such as the Cache/Safe approach and the group commit mechanism. These concepts are supposed to reduce the I/O bottleneck substantially.

6.Conclusion

Several consequences might be concluded from our discussion of benefits and drawbacks of OS transactions in the various DBS server process structures.

- A first conclusion could be that process management costs have to become much lower in next generation OSs. Under this precondition, the symmetric server architecture would certainly appear most favourable, as it is easy to implement, delegates all scheduling tasks to the OS, and seems to fit best with the concept of OS transactions.

- If a very high number of concurrent processes still causes intolerable overhead, a multiple server solution would probably yield better performance results, especially in combination with a DC system (cf. [19]). This approach, however, should be implemented without internal multitasking, in order to allow for the utilization of OS transactions according to our multi-level transaction methodology.

- As pointed out in chapter 4, the trouble with OS transactions and DBS servers primarily comes from binding OS transactions to processes. If instead each BOT operation returns a system-wide unique transaction ID, this ID could be used as a client identification in all subsequent service calls that refer to the same transaction. Thus, clients could migrate from one process to another without interfering with OS transaction management, and, on the other hand, a DBS server process would be allowed to act on behalf of more than one OS transaction in an arbitrarily interleaved way.

Of course, we vote for the first two conclusions, whereas the third one is debatable. Our personal opinion is, that from an OS point of view, binding service functions, like OS transactions are, to processes seems to be the most natural and manageable approach as long as processes themselves are considered a suitable concept to structure program executions in a multi-user OS. Therefore, it is likely that future OSs will indeed expect transactions to be bound to processes. DBSs, like any other client, will have to make the best of it.

Altogether, OS transactions seem to be a really useful service for various kinds of clients. Whether DBSs in particular will accept this facility, will probably depend on performance issues. As we have argued mostly qualitatively in this paper, more efforts should be taken to gain quantitative results.

Our own work will concentrate on the promising direction of multi-level transactions. For this method, the architecture of figure 1 has to be expanded slightly. In addition to the transaction service, the OS should offer locking as a common service to be used by higher layers. Avoiding reimplementation of functions in different subsystems certainly outweighs minor performance issues in this case. Furthermore, to reduce the costs of DBS logging in the multi-level transaction framework, it could be advantageous to allow direct use of the OS logging service from the DBS level too, though this actually violates the spirit of the multi-level transaction approach to some extent. The main conclusion is that to improve the overall performance of multi-level transactions, an OS transaction kernel should be oriented towards a high number of short-lived (sub-) transactions rather than handling DBS transactions entirely.

MAIN MEMORY DATABASE RECOVERY

Margaret H. Eich

Department of Computer Science and Engineering
Southern Methodist University
Dallas, Texas 75275

ABSTRACT

The idea of having entire databases reside in main memory, or *main memory databases (MMDB)*, has recently been an active research topic. It is recognized that in this framework the issues concerned with efficient database recovery are more complex than in traditional DBMS systems. While several authors have looked at different methods for MMDB recovery, an examination of MMDB recovery functions and how they differ from traditional DBMS recovery has not been performed. This paper examines MMDB recovery, identifies differences from traditional DBMS recovery, composes a "wish list" of MMDB recovery requirements, describes why previously proposed techniques do not satisfy these requirements, and proposes a new MMDB recovery technique which does.

Introduction

The declining cost of main memory and need for high performance database systems have recently inspired research into systems with massive amounts of memory and the ability to store complete databases in main memory [1,3,8]. The use of memory resident databases, or *main memory databases (MMDB)*, can achieve significant performance improvements over conventional database systems by eliminating the need for I/O to perform database applications.

Database recovery techniques are used to ensure that any erroneous database state due to transaction, system, or media failure can be repaired and restored into a usable state from which normal processing can resume [2,9,11,18]. Due to the volatility of main memory, MMDBs complicate database recovery issues. This problem has been recognized and several new techniques for MMDB recovery have been proposed [3,5,6,15]. The objectives of this paper are to examine recovery requirements in a MMDB environment, provide a survey of proposed techniques, and then propose a new MMDB recovery technique which better meets these requirements than previous methods.

The approach used in this paper is different than that in previous papers on MMDB recovery. Prior to defining a technique, we investigate what is meant by MMDB recovery. With MMDBs, the primary database copy is memory resident. This change in perspective from secondary storage to main memory not only causes problems with the recovery operations, but also changes some of the accepted methods for recovering from various failures. In the next section we identify the MMDB model to be used throughout the paper, defining the various database components used. Section 3 then uses this model to define MMDB recovery and compare it's requirements for recovery to those in traditional database systems. From this evaluation, we construct a "wish list" of MMDB recovery requirements which we feel a MMDB recovery technique should satisfy. Section 4 reviews existing MMDB recovery proposals and shows that none meet all requirements on the wish list. Finally, in section 5 we propose a new recovery technique which does satisfy the wish list items.

MMDB Model

The DBMS model under evaluation is one where entire databases being accessed reside in main memory. Although only recently receiving much research interest, the concept is certainly not new. IMS has supported main memory databases, Main Storage Data Bases, for quite some time [12]. Unlike the IBM approach, however, we assume no practical limitation on the size or structure of a main memory database.

Figure 1 shows the MMDB model used throughout this paper. Sometime prior to access, a database must be loaded into main memory. To achieve this purpose, an *Archive Database* exists on secondary storage. The archive database is a complete image of some prior database state and is used solely for loading main memory. Since no access of the archive is made during database processing, the organization of this file should be for efficient loading of memory. Due to the volatility of main memory, all updates to main memory must be recorded on a *Log* located in some stable memory. Figure 1 shows the log on a secondary storage device, but it may actually exist in a nonvolatile main memory supported by a backup power supply, or in a combination of the two. During recovery processing, the log can be used to achieve UNDO and REDO processing and thus may contain *before Images (BFIM)* and/or *after images (AFIM)* of modified data [11]. Together, the archive and log provide the ability to recover from a

CH2345-7/86/0000/1226$01.00 © 1986 IEEE

main memory failure. In actual use the archive database may be updated directly from data in main memory or from data in the log.

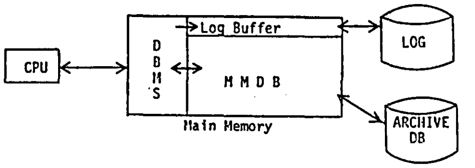

Fig. 1. - MMDB Model

This view of a MMDB may seem almost identical to that of a conventional database. However, there exist several major differences:

1. Main memory is assumed to be large enough to hold all databases currently being accessed.
2. Any recovery schemes must deal with restoring the MMDB not data on secondary storage.
3. No database access can be performed against the archive database. It's use is strictly as a backup to the main memory database.

There are several advantages to the use of MMDBs. Obviously, processing time and throughput rates should improve due to the elimination of I/O overhead. It has been suggested that the improved performance can eliminate the need for concurrency control by allowing the serial execution of MMDB transactions [7]. While we don't agree with this observation, it is certainly conceivable that concurrency control mechanisms specifically designed for the MMDB environment can reduce the overhead and complexity usually associated with concurrency control techniques [3].

Some problems not existing in conventional DBMS systems are introduced in the MMDB environment. The major problem deals with the volatility of main memory. To reduce the impact of this problem, it has been proposed that a small stable main memory be used to support recovery processing [3,6]. If a stable memory is assumed, its size must be large enough to contain all updates of active transactions. Another major problem is the excessive overhead needed to initially load a database into memory for processing. This procedure requires merging data on the archive database and the log to obtain data needed to recover to the most recent consistent state. To reduce the time, archives should be created very frequently and could be distributed across several secondary storage devices. Additional concerns center around the increase in the number of main memory components and the resulting reliability problems and increase in access time. A unique architecture is currently under investigation at Princeton to address these issues [7]. We are currently only addressing what appears to be the major problem: MMDB recovery.

MMDB Recovery Defined

The issues concerning traditional database recovery are well known and understood [2,9,11,18]. The purpose of this section is to examine aspects concerning database recovery under the MMDB assumption. We investigate the various types of failures effecting database processing, describe recovery operations necessary for MMDBs, and conclude by listing the desired features a MMDB recovery technique should possess.

When discussing MMDB recovery, it is important to realize that the objective is that of recovering data in main memory. With conventional databases, the current database state exists partly in main memory and partly in the secondary storage. With MMDBs, the current state completely exists in main memory. Secondary storage is used solely for recovery purposes. Since MMDB processing incurs no I/O, any I/O required to ensure recoverability can have a significant impact on system performance and become the major bottleneck during processing.

As with traditional database processing, a *transaction* is assumed to be the unit of recovery and consistency, and the failures which must be anticipated are transaction, system, and media failures. The differences between conventional DBMS recovery and MMDB recovery are introduced when the specific operations required to accomplish recovery are examined. TABLE 1 shows the operations needed to recover from the three failure types in both the tradtional and MMDB environments.

TABLE 1
DATABASE RECOVERY OPERATIONS

Failure Type	Recovery Operations Required	
	Traditional DBMS	MMDB
Transaction Failure	Transaction UNDO	Transaction UNDO
System Failure	Global UNDO Partial REDO	Global REDO
Media Failure	Global REDO	Global REDO Partial REDO

Transaction failure occurs when a transaction does not successfully commit. This type of failure occurs more often than the other two, and thus efficient recovery from it is essential. A rule of thumb is that recovery should occur in a similar time frame to that of successful completion of the transaction [10,11]. The normal procedure for recovery after a transaction failure is a *Transaction UNDO.* This implies that all effects the aborted transaction has had on the primary database copy must be removed. The major concern existing with transaction UNDO in a MMDB environment is that it be done with as little I/O as possible. If the rule of thumb is to be achieved, no I/O should be required to accomplish transaction UNDO. Additional processing during transaction UNDO involves the removal of any dirty data from the log or archive database. These would also like to be performed with no I/O.

Recovery from a *system failure* is quite different with MMDBs than with traditional DBMSs. Traditionally, the effects of any interrupted transactions must be undone, *Global UNDO*, and any completed transactions which have not had updates reflected in the database need to be redone, *Partial REDO*. When a system failure occurs, the entire MMDB contents are lost. MMDB recovery must therefore perform a *Global REDO* by completely reloading all databases in main memory. The archive database is used to reload the databases to some prior state and then any committed transactions reflected in the log are redone. The Global REDO operation is required in conventional systems only after a media failure causes the loss of the primary database copy on secondary storage.

System failures occur less often than transaction failures and more often media failures [11]. A goal for system failure recovery is that it be accomplished in a time comparable to that required for successful completion of all active transactions. With MMDBs, a Global REDO requires I/O from the archive database, and thus it seems impossible to achieve this goal. One way to reload the MMDBs as quickly as possible is to ensure as much of recent database updates as possible are reflected in the archive database. This implies that log data must be frequently flushed to the archive database.

In traditional database systems a checkpoint is often used to reduce the work needed to recover from system failures [2,9,11,18]. We view a *MMDB Checkpoint* as recording all data concerning a prior database state into the archive database and writing a corresponding checkpoint record on the log. These checkpoints should be done with as little impact on transaction processing as possible. Frequent flushing to the archive database thus requires frequent checkpointing.

Global REDO loads MMDBs into main memory. However, not all transactions require all data, therefore transactions can begin processing as soon as some of the data they need is available. This problem is similar to the fetching strategies associated with virtual memory management. At least four possibilities exist when loading databases into main memory:

1. Database Prefetching - Loading an entire database into main memory prior to scheduling any transactions accessing it.
2. Page Prefetching - Prefetch some subset of database pages and allow transactions to begin access of them as the remainder of the database is loaded.
3. Demand Loading - Only load a database when some transaction first accesses it.
4. Demand Paging - Load database pages after first access to them.

More research is needed to determine which of these provides the best performance for Global REDO. The method to be used depends on such factors as database storage structure, access methods used, storage location on disk, and whether any transactions have immediate need of the data.

Although *media failure* may only occur once or twice a year, the impact on recovery of traditional databases can be severe [11]. A memory failure with MMDBs can be treated as a system failure and a Global REDO performed. However, if the specific location of the failure can be identified, a Partial REDO of only the effected area would be warranted. This indicates that the archive database should be physically structured to correspond with memory addresses. Perhaps partitioning of memory and archive databases and the ability to recover by these partitions is needed. Future research will examine this idea of partitioning for partial redos. Media failures can effect the archive database or log. Restoring these files creates similar problems for conventional and MMDB systems. Differences do exist in that the archive database may be needed more frequently than in conventional DBMSs and thus it's quick recovery is more important with MMDBs. With the existence of prior archive databases and corresponding log data, recreation of archives simply requires redoing checkpoint processing.

Authors have ignored the problems associated with failure of stable memories. The use of stable memories does imply that overhead for recovery from system failures is greatly reduced, however, there is really no such thing as a "forever stable" memory. Thus any reliable recovery technique must prepare for the failure of stable memory. This implies that any MMDB recovery technique needs to provide the facilities for Global and/or Partial REDO of all of memory - stable and non-stable.

Another issue concerning MMDB recovery is when log I/O operations occur. It is important that any I/O needed be performed asynchronously to normal database processing. This implies that log I/O not occur only at commit time, but that it be performed throughout transaction processing. Transaction processing should not be dependent on or held up by I/O to the log.

We close this section by summarizing the major requirements for MMDB recovery in the following wish list:

1. No I/O required to accomplish transaction UNDO.
2. Frequent checkpoints performed with minimum impact on transaction processing.
3. Asynchronous processing of log I/O and transaction processing.

Certainly an additional requirement be that a minimum amount of redundant data be used. For example, the use of before images on the log should be avoided if possible.

Previous MMDB Recovery Techniques

Prior to introducing the new MMDB recovery method, we examine previously proposed techniques and compare their processing to the items on the wish list.

As stated earlier, IBM has as implemented MMDBs in the IMS/VS Fast Path Feature [12,13]. At initialization of IMS, the MMDBs are loaded into main memory. Updates are performed in special database buffers and MMDB pages are not modified until commit time. Commit processing ensures that all after images are written to the log prior to updating the MMDB. System wide transaction-consistent checkpoints (TCC) [11] are accomplished by an asynchronous IMS task running in parallel with MMDB processing. The major disadvantages of this scheme are that log I/O is only performed at commit time and entire MMDBs must be read to perform checkpoints.

The Massive Memory Machine (MMM) project at Princeton University has described an architecture specifically designed to support massive amounts of primary storage [7,8,17]. Associated with this project is the design of a MMDB recovery scheme based upon a hardware logging device, HALO [6]. HALO intercepts all MMDB operations and creates BFIM and AFIM log data initially written to a nonvolatile main memory, and as time permits written out to the log on disk. The use of the stable main memory implies that commit processing need not wait until the log buffers have been flushed. The BFIM log data is needed to accomplish transaction UNDO. Continuous action-consistent checkpoints (ACC) [11] of log data to the archive database is made. The asynchronous updating of the log and parallel, continuous updating of the archive database are certainly advantages of this scheme. However the requirements for specialized hardware and stable main memory, the interception of all database calls, and the requirement for BFIM log data to accomplish transaction UNDOs are disadvantages.

Researchers at the University of California at Berkeley, have investigated some of the implementation concerns for a MMDB [3]. Their recovery scheme assumes the use of a log with BFIM and AFIM plus frequent checkpointing. The notion of a *pre-committed transaction* is used to achieve asynchronous logging and database processing. When a transaction commits, the commit record is placed in the log buffer and other conflicting transactions are allowed to progress even though the log buffers have not been flushed to disk. The transaction completes commit processing only when this is done. ACC checkpointing occurs continously and in parallel with transaction processing by reading the entire MMDB and identifying modified pages. Although not specifically discussed, it appears that an entire database must be loaded into main memory prior to access.

The concept of a *Database Cache* has been proposed for database systems with large amounts of main memory [5]. It is assumed that there is sufficient memory space to store all dirty pages plus some other pages which have been fixed for reading. The database cache and disk database together represent the current database just as with traditional DBMS systems. Even though this approach is not strictly a MMDB, an unusual recovery scheme appropriate to MMDBs is proposed. This approach recognizes that "shadow" main memory pages [16] can be used to eliminate the need for transaction UNDO. To avoid the overhead of loading entire databases, a demand paging technique is used to bring pages into main memory. No log is used, rather a *safe* located in nonvalatile memory containing data needed to reconstruct part of the cache after failure is maintained. As a minimum, the safe contains all pages not currently residing on the disk database. When memory pages are to be modified, a main memory shadow page is used for updating if the disk database does not contain a copy of the page to be modified. In the event of transaction failure, these shadow pages are simply deleted in the cache. Subsequent transactions will either access the other page in the cache or incur a page fault to bring in a new copy of the page. To commit a transaction all modified pages are written to the safe. Novel procedures are used to limit the number of records on the safe and to determine the exact state of each page in main memory. Only when a page is targeted for replacement is it written back to the disk database.

Design for a MMDB including data structure representation and recovery technique has been propsed at IBM [1]. It is assumed that a MMDB relation is loaded into main memory at the first reference and, if modified, written to disk at commit time. All recovery overhead is restricted to the commit operation achieving a type of transaction-oriented checkpoint (TOC) [1]. No separate log is suggested, rather the use of shadow pages on the archive database. At commit time, all modified relations are written to shadow areas on the archive database. Once this has been accomplished the new directory structure is updated and old database areas released.

Design for a MMDB system, MM-DBMS, is currently under way at the University of Wisconsin-Madison [14,15]. This study includes the design of an architecture, query processing, data structures, and recovery technique for a MMDB. Recovery processing uses a stable log buffer as well as a special log processor to perform checkpointing. Further details concerning the recovery strategy used are not yet available.

TABLE 2 summarizes the different MMDB recovery techniques described. Although some unique recovery ideas are introduced, none of the techniques satisfies all items on our wish list. The Fast Path Feature, DB Cache, and Ammann techniques don't meet the asynchronous log I/O and transaction processing requirement because all log I/O overhead occurs at transaction commit. The MMM and Berkeley methods require BFIM and AFIM log data and must have log I/O operations to accomplish a transaction UNDO. The information shown in the last row of TABLE 2 describes the type of checkpointing performed by the various techniques. Part of this data indicates whether checkpointing is accomplished by reading the MMDB or log data. Checkpoints for the Fast Path and Berkeley

TABLE 2
COMPARISON OF PREVIOUS MMDB RECOVERY TECHNIQUES

Recovery	Recovery Technique				
Operation	Fast Path	HALO	Berkeley	DB Cache	Ammann
Loading (Global REDO)	DB Prefetch	DB Prefetch	DB Prefetch	Demand Paging	Demand Loading
Shadow	Yes	No	No	Yes	No
Log I/O	Commit	Asynchronous	Asynchronous Pre-Commit	Commit	Commit
Checkpoint	TCC Parallel MMDB	ACC Parallel Continuous Log	ACC Parallel Continuous MMDB	Page Replacement MMDB	TOC MMDB

techniques require examining all MMDB pages and therefore must impact transaction processing when checkpointing occurs.

A Better Technique

In this section we describe preliminary results concerning a new MMDB recovery technique which better satisfies the requirements identified in section 3 than previously proposed methods. The highlights of this new method are:

1. Main memory shadow pages
2. Pre-committed transactions
3. Automatic checkpointing
4. Recovery processor

Each of these is discussed in the following paragraphs. A followup paper will define this technique in more detail as well as provide simulation results examining its performance. We assume that no stable main memory exists, but note any changes which would be needed in the event nonvolatile main memory were available. The impact of concurrency control is not included in this discussion. It may be assumed that transactions are either run serially or that two-phase locking at the page level is used.

Main memory shadow pages (similar to that proposed for the DB Cache [5]) are used to achieve the goal of no I/O for transaction UNDO. Duplicate copies are made of any pages updated by a transaction and all modifications occur on these pages. As pages are modified, AFIM records are written into the log buffer for output to disk. At commit time, a commit record is also written in the buffer for output. Subsequent conflicting transactions can begin processing as soon as this occurs. They will use the data in the dirty pages and, if needed, create new copies for their updating. If a transaction commits (commit record written to disk), the previous clean pages are released and the dirty pages become the new clean ones. When a transaction abnormally terminates, the dirty pages are released.

To accomplish asynchronous log I/O and transaction processing, the pre-commitment technique is used. As explained above, transactions need not wait until a conflicting transaction has completely commited prior to beginning execution. Also, log I/O is performed throughout a transaction execution rather than just at commit time. Indeed, a transaction can not commit until all log buffers are written to disk, but without a stable main memory for the buffer this can not be avoided. If stable main memory were available, the pre-commitment technique would not be necessary and completely independent log I/O and transaction processing would be possible.

The log contains Begin_Transaction (BT), Commit_Transaction (CT), Abort_Transaction (AT), Checkpoint, and AFIM records. All log records except the checkpoint contain the ID of the corresponding transaction. The BT record contains a flag that indicates the state of the corresponding transaction. It is initially written with an indication that the transaction is active, when commited or aborted it is appropriately modified. This random access to the log implies that a random access device must be used. As explained below, this flag is used during checkpointing to avoid flushing dirty data to the archive database. It also eliminates the need for removing this dirty data during transaction UNDO.

To accomplish *automatic checkpointing*, the logger keeps track of the state of the log. Assuming an initial state of 0, state transitions occur when BT, CT, or AT records are written to the log. The BT record increments the state value by 1, while the CT and AT decrement it by 1. A state value of 0 indicates that a TCC state exists on the disk. When the logger detects a state value of 0, a checkpoint record is written out to the disk before any other records already in the buffer. To find the most recent checkpoint record on the log, the logger also notes the address of this checkpoint record and records it along with its unique checkpoint ID in a predefined fixed disk address. Performing this automatic checkpointing only requires two additional I/O operations and is performed independently of transaction processing. To ensure that TCC checkpoints occur, the logger may need to periodically force checkpoints even though the checkpoint state has not occurred. To accomplish this, the logger must write all log records for actively executing transactions to be written to the log, before allowing any new transactions to begin writing to the log. Unlike the techniques used in current database systems where processing is quiesced to reach a TCC, this technique has no impact on executing transactions.

Actual checkpointing to the archive database is accomplished by a separate *Recovery Processor (RP).* Checkpointing is a two step process: creating a new copy of the archive database and then applying log AFIM records for committed transactions to bring the new archive database state up to that indicated by the latest checkpoint on the log. When an archive database is first created, the checkpoint ID and associated address of the latest log checkpoint record are written into a predefined location on the archive database. All AFIM records for successfully committed transactions (as identified by the BT log record) between the checkpoint address on the previous archive database and the address of the latest checkpoint are applied to the archive. If a checkpoint is attempted, but the checkpoint ID on log is the same as that on the prior archive, then the RP must wait until a new checkpoint is taken. To avoid the overhead of copying the entire archive, many checkpoints could be applied to the same copy and at periodic time intervals request the creation of a new archive database.

Figure 2 shows the model of the MMDB recovery system proposed. The use of main memory shadow pages ensures that only AFIMs are needed on the log and that no I/O is required for transaction UNDO. Checkpoint records are automatically written to the log, and continous checkpointing to the archive database is performed by the RP. Both of these operations are performed in parallel with and asynchronously to MMDB transaction processing. Without stable main memory, pre-commitment of transactions and continous writing to the log buffer provide asynchronous log I/O and transaction processing. With the use of stable memory, a nonvolatile log buffer removes the need for precommitment but achieves a true asynchronous operation of log I/O and transaction execution.

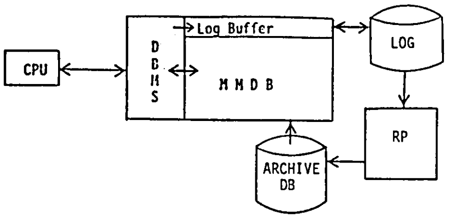

Fig. 2. - Model of Proposed MMDB Recovery System

Summary and Future Research

After defining MMDB recovery, identifying its requirements, and surveying the literature, we have proposed a new MMDB recovery technique which better meets these requirements than previous methods. Our technique requires no transaction UNDO processing after a transaction failure, uses asynchronous I/O and transaction processing to reduce recovery overhead during transaction processing, and provides continuous system checkpoints in parallel with yet no impact on transaction processing. Recent MMDB recovery performance studies have shown that the major factor concerning efficient recovery is the use of stable memory [4,17]. Next to stable memory, the use of additional logging and checkpointing processors can also impact performance [4]. This is the only known technique proposing the use of a special checkpoint processor.

Many areas for future research remain. A major area of study will address the issue of efficient loading for MMDBs including the idea of partitioning. This will examine methods for distributing log and archive database information across multiple secondary storage devices. Along this line we also intend to evaluate various storage techniques to be used for the archive databases.

Currently, a simulation study is being performed to more accurately compare the proposed technique to previous ones. A future paper will more precisely define our proposed technique and present the results of the simulation experiments.

Abstract

When we try to implement a relational database system on a conventional von-Neumann computer, we face the gap between the relational model and the computer architecture.

This paper presents a relational database machine organization for the execution of relational algebra operations. The proposed database machine is composed of several processing modules and an interconnection network. The processing module is a special unit and can efficiently execute any relational algebra operation except *selection* on a uniform architecture. For given queries, several processing modules are connected to each other through the interconnection network. Queries are then executed in a parallel pipelined fashion by going through these processing modules.

The effectiveness of the system has been proved through a simulation. The evaluation results are also given.

This proposed system shows sufficient flexibility to be able to cope with the enormous increase in demand for the development of large-scale database machines anticipated in the future. It can also be said that the system organization is relevant from the viewpoint of cost-effectiveness when the recent progress of hardware technologies is considered.

1. Introduction

As the social demand for database utilization expands, implementation of database systems becomes more and more important. When we try to implement a relational database system on a conventional von-Neumann computer, however, we face the gap between the relational model and the computer architecture. This has been accelerating development of special hardware for database manipulations [1], [2].

Database machines developed at an earlier stage, RAP [3] and CASSM [4] for example, execute relational operations directly on the disk by attaching a logic to each disk head. Although these machines contributed to an improvement in execution performance of simple relational operations such as *selection*, still the performance of complex operations such as *join* and *projection* was not satisfactory. Recent approaches toward finding a breakthrough are DIRECT in which relational operations are processed on the internal memory by means of multiple general purpose processors [5], and some special modules for the execution of relational operations [6]-[8].

Meanwhile, the necessity of improving improve the execution performance of relational operations increases as database applications expand. The extension of a relational database system so that it can handle a semantic aspect of data, for example, requires that it is able to execute relational operations efficiently [9], [10].

The authors have proposed a special module which executes *join* efficiently in a parallel fashion [11], and have investigated a processing module for the execution of all other relational algebra operations, and an organization of a relational database machine as the next step.

This paper presents a relational database machine organization for the execution of relational algebra operations. The database machine we propose is composed of processing modules and an interconnection network. Each of the processing modules can efficiently execute any relational algebra operation except *selection* on a uniform architecture. The reason that *selection* is excepted is that each tuple can be processed independently of the others, so an improvement in the execution performance of *selection* should therefore be achieved in connection

CH2345-7/86/0000/1233$01.00 © 1986 IEEE

with secondary storage devices.

For a given query, the system translates it in a form of the relational algebra tree, and after that several processing modules are connected to each other through the interconnection network according to the generated tree. Queries are then executed in a parallel pipelined fashion by going through these processing modules.

In Chapter 2, the organization of the database machine is presented. The architecture of the processing module and algorithms embodied in it for performing relational algebra operations are described in Chapter 3. In Chapter 4, the execution management of the system is described. Finally, in Chapter 5, the evaluation of the system performance is given.

2. System Organization

The organization of the database machine we propose is shown in Fig. 1. The system is composed of multiple processing modules, multiple I/O and overflow buffers, a set of staging buffers, and an interconnection network. Each of the two input lines of the processing module for the input of the operand relations can be connected to any buffer via the interconnection network, and each of the two output lines are directly connected to the I/O and overflow buffers.

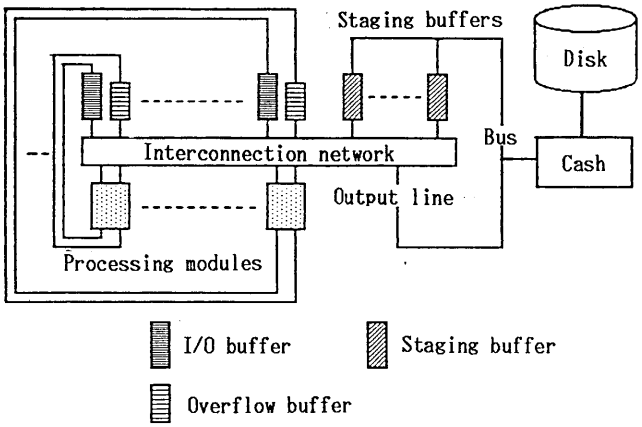

Figure 1 System Organization

The processing module is a special unit and executes relational algebra operations except *selection*, that is, *join*, *projection*, *division*, *union*, *intersection*, *difference*, and *Cartesian produci* on a uniform architecture. The reason that the execution of *selection* has been left out of our investigation is that *selection* can be carried out directly on secondary storage devices. The attachment of a logic to disk heads or the use of indices effectively improves the performance of *selection* [1], [12]. This also contributes to a reduction in the volume of data to be transferred into the staging buffer for processing.

The interconnection network is constructed by 2x2 switching elements in a multistage organization. Each switching elements enables the connection of either one-to-one or one-to-two correspondency between input and output ports. Therefore, it takes one of the four states [13] shown in Fig. 2 .

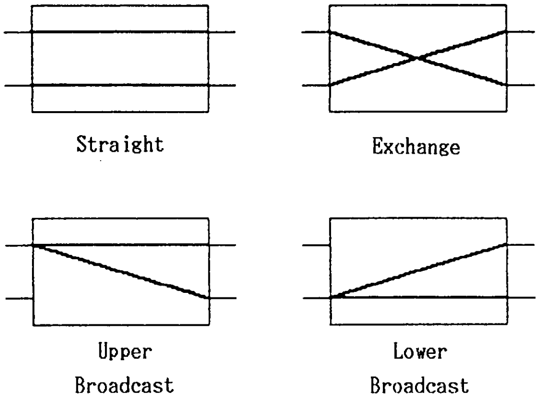

Figure 2 States of Switching Element

Relations to be manipulated are stored in the staging buffer through the cash memory after *selection* has been fully evaluated. In parallel to the evaluation of *selection*, the reduction of attributes which will not be used any more in the following database manipulation is also carried out to reduce the amount of disk I/O. And the resultant relations are fed into the processing modules through the interconnection network. The I/O buffer is used to route the resultant relation of an operation to other processing modules. The overflow buffer is used when memory overflow has occurred. A memory overflow handling scheme will be given in 4.2.

The advantages of the proposed database machine are as follows:

(1) The system is easily constructed, and can easily be extended. There is no need to worry about the correspondency between the processing modules and the specific operations required for the execution of a query in advance. What we have to take into consideration is the number of processing modules

needed in order to get a satisfactory processing performance. Furthermore, the system can easily be extended by attaching additional processing modules.
(2) The unified processing module is functionally flexible and is efficient. Thus, the system shows fairly good adaptability in the execution of arbitrary queries, and can process any type of query efficiently.

3. Dedicated Hardware Module

The processing module is a special unit which is designed to execute seven relational algebra operations, that is, *join*, *projection*, *division*, *union*, *intersection*, *difference*, and *Cartesian product*. Parallel comparison of the condition enables the processing module to execute relational algebra operations efficiently.

3.1 Architecture

Figure 3 shows an organization of the processing module. The processing module consists of S-memory, T-memory and Comparator. Both S-memory and T-memory are divided into *n* segments. Here, S-memory is random-access memory and T-memory is shift-register memory. Two operand relations are input independently to S-memory and T-memory, which will hereafter be referred source relation and target relation, respectively. Each tuple in a relation is stored in a segment, and *n* segment pairs of S-memory and T-memory are compared by means of *n* comparators in parallel.

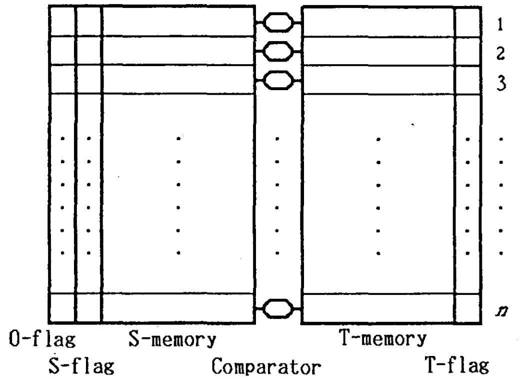

Figure 3 Organization of Processing Module

Furthermore, three flags, that is, S-flag, T-flag, and O-flag are provided for each memory segment pair. S-flag and T-flag are used for the duplication removal of tuples during the execution of *projection*, *union*, *difference*, and *division*. If the flag is on, the same tuple as the tuple indicated must have already existed. O-flag is used to indicate the result of comparison. If the condition of the comparison is satisfied, the corresponding O-flag is set on and the resultant tuple is output.

3.2 Algorithms

In this section, we describe a hardware algorithm provided for the processing module. Before giving details of the algorithm of each relational algebra operation, we will explain a basic algorithm applicable to all relational algebra operations. Let S denote source relation which has an attribute A, and T denote target relation which has an attribute B.

The basic algorithm is listed below:

STEP 0: *INITIALIZATION.*
Initialize the processing module.

STEP 1: *INPUT.*
Input tuples of S and T to the segments of S-memory and T-memory in the following way: For any *i*-th input cycle, the *i*-th tuple of S is input to the *i*-th segment of S-memory, and the *i*-th tuple of T is always input to the 1st segment of T-memory.

STEP 2: *COMPARISON.*
Compare *n* memory segment pairs by means of *n* comparators in parallel. According to the results of the comparison, S-flag and T-flag are changed depending on their preceding states. If the result of comparison meets the output condition, the corresponding O-flag is set on.

STEP 3: *OUTPUT.*
Output the resultant tuples from the segments of S-memory and/or T-memory whose corresponding O-flag are set on. O-flags are set off immediately after the tuples are output.

STEP 4: *SHIFTING.*
Shift the whole contents of both T-memory and T-flag.

STEP 5: *CONDITION for ITERATION.*
Return to STEP 1 when there are still tuples to be input.

STEP 6: *CONDITION for TERMINATION.*
Return to STEP 2 when there are still tuples to be compared. Figure 4 shows the final state when termination will occur.

STEP 7: *TERMINATION.*
End algorithm.

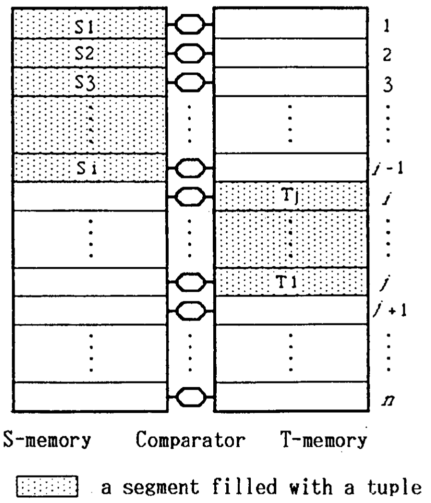

Figure 4 Final state of Processing Module

In the algorithm given above, initialization at STEP 0, operand relations to be served to S-memory and T-memory at STEP 1, and state transition of flags in STEP 2 differ depending upon each operation. In STEP 3, when several O-flags are set on simultaneously, tuples corresponding to the O-flags are output in sequence. However, if the output buffer is large enough to store tuples temporarily, there is no degradation of execution performance. The details of each relational algebra operation are as follows:

(1) ***Projection***: S[A]

In *projection*, S is served to both S-memory and T-memory. Each tuple of S is input to both S-memory and T-memory in STEP 1. In STEP 2, the comparison is made for every pair of segments of S-memory and T-memory, partially on the contents specified by the attribute A under the condition "=". If the condition is satisfied, S-flag, T-flag and O-flag change their states as shown in Table 1 depending on their preceding states. The tuple is output only when O-flag is set on. The state transition specified above prevents duplication of the same tuple output.

Table 1 Transition of Flag States in Projection

S-flag	T-flag	O-flag		S-flag	T-flag	O-flag
0	0	0	⟶	1	1	1
1	0	0	⟶	1	1	0
0	1	0	⟶	0	1	0
1	1	0	⟶	1	1	0

(2) ***Join***: S[A θ B] T

In *join*, S and T are served to S-memory and T-memory, respectively. Each tuple of S and T is input to S-memory and T-memory respectively in STEP 1. In STEP 2, the comparison is made for every pair of segments of S-memory and T-memory, partially on the contents specified by the attributes A and B under the condition θ ("=", "≠", ">", "≥", "<", or "≤"). If the condition is satisfied, O-flag is set on. In STEP 3, tuple pairs whose O-flags are set on are output.

(3) ***Union***: S∪T

Union is regarded as *projection*, where S and T are combined into a single relation and served to both S-memory and T-memory.

(4) ***Difference***: S - T

Difference is regarded as *projection*, where all tuples of T are input to S-memory by setting the corresponding S-flag on in STEP 0. After that, in STEP 1, S is served to both S-memory and T-memory.

(5) ***Intersection*** : S∩T

Intersection is regarded as *join* under the condition that the values of all corresponding attributes are equal to each other.

(6) ***Cartesian product*** : S x T

Cartesian product is considered as *join* with no condition for comparison.

(7) ***Division***: S[A ÷ B] T

Division is carried out in two phases, requiring two modules for the processing. In Phase-1, dividend relation S is grouped according to the value of attribute B of divisor relation T. In Phase-2, intersection among groups of the relation derived from Phase-1 is performed. This process is illustrated in Fig. 5.

The details of the process can be explained as follows:

Phase-1 (grouping)

All tuples of dividend relation S are input to S-memory in STEP 0. In STEP 1, one tuple of relation T is input to the 1st segment of T-memory, and copied for all segments of T-memory. The comparison is made for every pair of segments of S-memory and T-memory under the condition "=", in STEP 2. In STEP 3, the tuples which satisfy the condition are output. STEP 1 through STEP 3 are repeated *m* times by inputing an individual tuple of T at each cycle, where *m* is the cardinality of T. Furthermore, at each end of STEP 3, a special symbol is output as a separator.

Phase-2 (intersection)

In STEP 1, a tuple of the first group of the relation derived from Phase-1 is input to S-memory by setting the corresponding O-flag on, and a tuple of the

remains (from second to the last groups) of the relation derived from Phase-1 is input to T-memory. At the comparison in STEP 2, change of the flag states differs depending on whether or not the content of the segments is the separator derived from Phase-1. If it is the separator, the state of the flag changes as shown in Table 2 (a). If not, for the segment pair which satisfies the condition "=", the state changes as shown in Table 2 (b). Meanwhile, STEP 3 is skipped while there are still tuples to be compared. The output is generated only once at the end of the repetition.

4. Query Execution Management

4.1 Parallel pipelined execution of queries

In the system, a given query is translated into a form of the relational algebra tree and put into an execution waiting list. If there are enough processing modules not in use, some of them are assigned for the execution of the query. Here it is assumed that at least one processing module is available for the execution of each relational algebra operation of the relational algebra tree representing the query. Moreover, *selection* is not taken into account in the process of module assignment because the execution of *selection* could be achieved directly in connection with secondary storage devices.

After that, read requests are sent to secondary storage devices for obtaining the relations needed. The relations are transferred to staging buffers page by page. If the query includes *selection*, it is assumed that the *selection* is completed while the transference of the relations is carried out.

During the execution of a query, processing modules are connected to each other through the interconnection network according to the relational algebra tree representing the query. Each processing module gets tuples from the I/O buffer or the staging buffer which is connected to it through the interconnection network, and transfers the resultant tuples to the I/O buffer which is directly connected to it.

The following is an example to explain the management of the query execution. Figure 6 shows a sample query Q1 in a form of the relational algebra tree. Figure 7 explains the process of executing the query in Fig. 6. Here it is assumed that processing modules PM1, PM2, and PM3 are assigned for the execution of *joins* J1 and J2, and *projection* P1, respectively. Furthermore, staging buffers SB1, SB2, and SB3 are assigned for relations R1, R2, and R3, respectively.

Relations R1, R2, and R3 get into to the staging buffers SB1, SB2, and SB3, respectively, after *selection* of R1 and R3 has been fully evaluated. The processing module PM1 gets tuples from SB1 and SB2, and outputs resultant tuples of J1 to the I/O buffer B1. The processing module PM2 gets tuples from B1 and SB3, and outputs resultant tuples of J2 to the I/O buffer B2. And the processing module PM3 gets tuples from B2, and outputs resultant tuples of P1 to the I/O buffer B3, which shows the final result for the given query.

In this way, the processing modules execute a query in a pipelined fashion by transferring tuples through the I/O buffers. Furthermore, the system can process several queries in parallel. Accordingly, queries are executed in a parallel pipelined fashion by means of multiple processing modules.

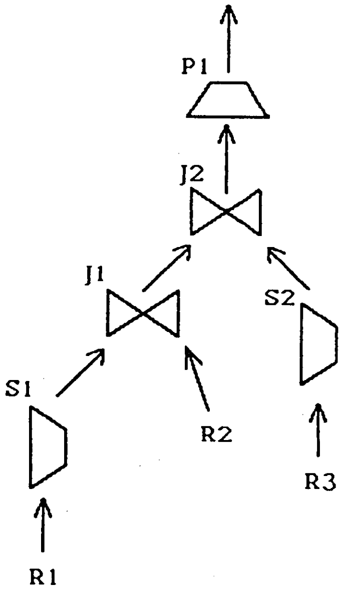

Figure 6 An Example of Query - Q1

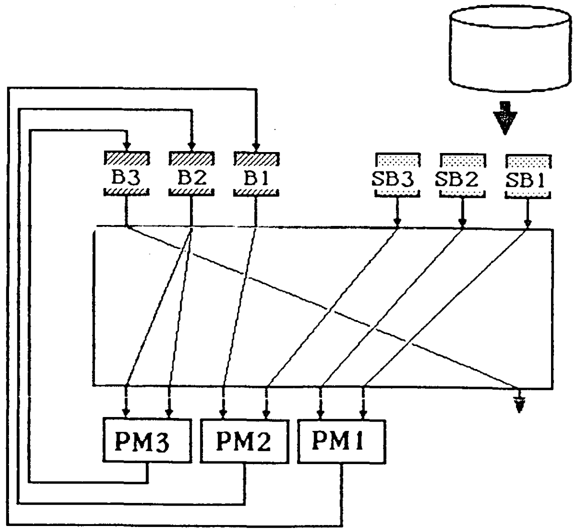

Figure 7 Process of Executing the Query in Fig.6

4.2 Overflow handling

The segment size of a processing module is generally not large enough to contain a whole operand relation, and therefore a countermeasure is required to cope with it. The system offers two types of overflow handling algorithm as follows.

When the cardinality of an operand relation exceeds the number of memory segments, a memory overflow occurs. Here the consideration will be limited to the case of S-memory because the tuples which are shifted out from T-memory must already have been compared with all tuples of S-memory. In the case of a memory overflow, two or more processing modules work together for the execution of a single operation. The tuples in a source relation are sequentially distributed among processing modules with *n* tuples as a unit, and the tuples in an entire target relation are transferred to all processing modules. Here *n* is assumed to be the number of segments in a processing module. The processing is carried out in the internal memory.

Suppose that the number of processing modules necessary for the execution of an operation exceeds the number of available processing modules. We call it a module overflow. In the case of a module overflow, the processing is carried out by limiting the number of tuples in a source relation to the size of S-memories of the processing modules, and the same process is repeated for the remaining source relation. The algorithm described above works externally.

In the following, we explain the memory overflow handling algorithm in detail.

When memory overflow occurs, tuples which have overflowed from T-memory are temporarily stored in the overflow buffer, and connections inside the interconnection network are changed in order to newly utilize an unused processing module. The overflow buffer is used to transfer the overflowed tuples to the additional processing module through the interconnection network. The process of memory overflow handling is described formally as follows (see Fig. 8).

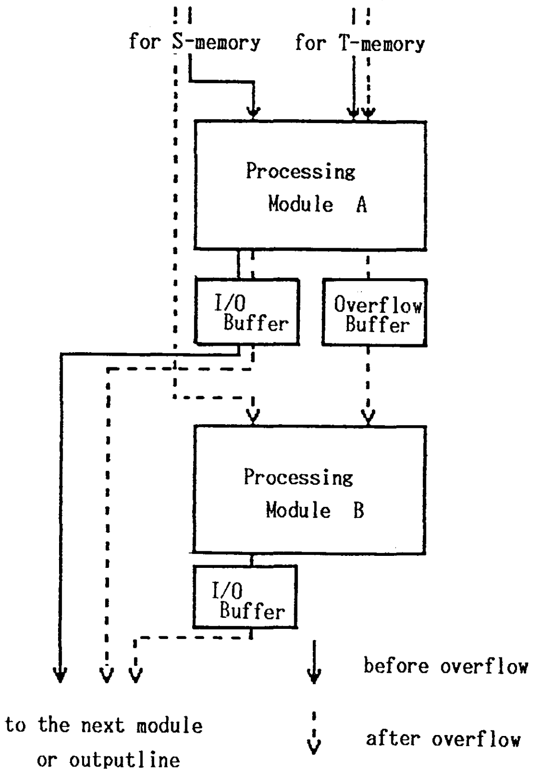

Figure 8 Overflow Handling

The I/O buffer which is connected to the input line for S-memory of the overflowed processing module A will be switched to that of the additional processing module B, and the overflow buffer which is connected directly to the overflowed processing module A will be connected to the input line for T-memory of the additional processing module B. In the overflowed processing module A, only tuples of a target relation are input to T-memory, and the execution continues. Tuples which are shifted out from T-memory are transferred to the overflow buffer. On the other hand, in the additional processing module B, tuples of a source relation and tuples in the overflow buffer are input to S-memory and T-memory, respectively. The execution of the processing is then carried out.

When memory overflow occurs again, the same procedure is invoked. The operation can be executed without any degradation of the execution performance even though the memory overflow occurs, since each processing module executes the operation independently of others. Furthermore, it is possible to manipulate a large relation as long as there are unused processing modules.

The two algorithms described above guarantee the consistency and flexibility of the system in the manipulation of very large databases. Finally, the resultant relation is split into several I/O buffers when the memory overflow occurs, since each processing module transfers the results to its corresponding I/O buffers. This requires the interconnection network to manage recombining of several independent resultant relations into a single relation.

5. Analysis

5.1 Analysis criteria

In this chapter, we will analyze system performance in terms of execution time. The following are the parameters needed for the evaluation.

t_{cb} : page transfer time from cache to buffer
t_{dc} : page transfer time from disk to cache
t_{mc} : message communication time for disk I/O operation
h_r : cache hit ratio (read)
h_w : cache hit ratio (write)
t_m : time to move a tuple between buffer and processing module
t_c : time to compare a pair of tuples
t_s : time to shift tuples
CS : cardinality of source relation
CT : cardinality of target relation
CR : cardinality of resultant relation
n_s : number of segments in a module
n_t : number of tuples in a page
s_p : page size

Then n_s' is defined by n_s multiplied by the number of processing modules used for the execution of a single operation. It is noted that the operation can be executed without any degradation of the execution performance if n_s' is greater than or equal to CS.

The basic tasks used in evaluating the performance of the system are the I/O time, the communication time, and the CPU time.

(1) I/O time

A read request moves a page into a staging buffer from the cache. When the required page is not in the cache, it must be fetched first from a disk. The average cost, T_R, to read a page in the staging buffer is estimated by assuming a cache hit ratio h_r [14].

$$T_R = h_r*t_{cb}+(1-h_r)*(t_{cb}+t_{dc})$$

Similarly T_W, the average cost to write a page, is

$$T_W = h_w*t_{cb}+(1-h_w)*(t_{cb}+t_{dc}),$$

where h_w is a probability for the existence of an available page frame in the cache during a write operation.

(2) Communication time

Page transfer is regarded as I/O operation. Therefore, we take the cost for communicating I/O related (page request and reply) messages into account. This message communication cost, t_{mc}, is added to the I/O cost. Thus, T_R is replaced by T_R+2*t_{mc}, and T_W by T_W+2*t_{mc}.

(3) CPU time

Execution costs of each relational algebra operation are formulated as shown in Appendix I. For a query containing several relational algebra operations, however, it is difficult to formulate the costs for executing it because dynamic aspects of the behavior of the system must be taken into consideration. Therefore, we have implemented a simulation system on a minicomputer. Execution costs of the query are estimated by using it.

5.2 Results

Parameter values which we assume here for the evaluation are as follows: t_{cb}=5[ms], t_{dc}=25[ms], t_{mc}=10[ms], h_r=0.85, h_w=0.35, t_m=64[μs], t_c=128[μs], t_s=0.7[μs], n_s=1024, n_t=256, and s_p=16k[byte].

Table 3 summarizes the execution costs of each relational algebra operation. The sizes of the source and target relations and the size of the resultant relation are changed depending on the operation. In the table, the first row shows the costs for the case that n_s' is large enough to contain a whole relation of S. The second row shows the costs for the case that n_s' is limited to 4096. CS_1 in Phase-2 of *division* denotes the number of tuples of the first group of the relation derived from Phase-1.

Tabel 3 Execution Times (seconds) of Relational Algebra Operations

	Projection	Join	Union	Difference

	CS = 10000
	CR = 7000
		CS = CT = 10000
		CR = 10000
			CS = CT = 10000
			CR = 17000
				CS = CT = 10000
				CR = 7000

$n_s' \geq$ CS	5.7	9.4	12.0	7.5
n_s' = 4096	13.0	14.6	44.5	21.4

	Intersection	Cartesian Product	Division (Phase-1)	Division (Phase-2)

	CS = CT = 10000
	CR = 3000
		CS = CT = 1000
		CR = 1000000
			CS = 10000
			CT = 20
			CR = 5000
				CS = 5000
				CS_1 = 250
				CR = 25

$n_s' \geq$ CS	6.0	392.1	43.3	1.5
n_s' = 4096	11.2	392.1	43.3	2.4

In particular, the execution costs of *join* are shown in Fig. 9, varying the operand relation sizes. The sizes of two operand relations are assumed to be the same i.e., CS=CT, and the size of the resultant relation, CR, is assumed to be the same as CS (and CT). Three curves in the figure show the costs for three different numbers of processing modules. It appears that the costs are proportional to the sizes of the operand relations when the relation sizes are smaller than n_s'.

Next we describe the evaluation result of the performance in executing a query. Each query can be executed independently from others, and hence the evaluation is limited to a single query in the following experiment.

We assume the same query Q1 used in Fig. 6 again for the evaluation, which contains two *joins* and one *projection*. The sizes of the relations served to those two *joins* are assumed to be the same i.e., CS=CT. The sizes of the resultant relations of *joins* are assumed to be the same as CS (and CT), and the size of the resultant relation of *projection* is assumed to be 0.7*CS. The configuration of the system comprises 10 processing modules.

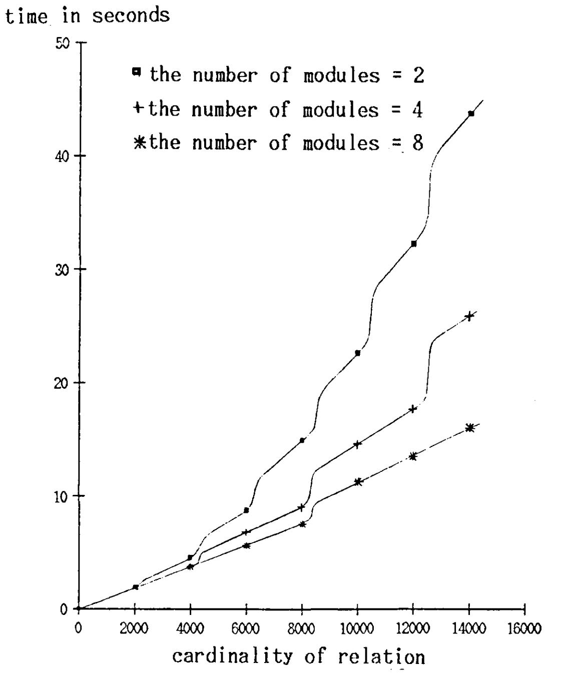

Figure 9 Execution Times (seconds) of Join

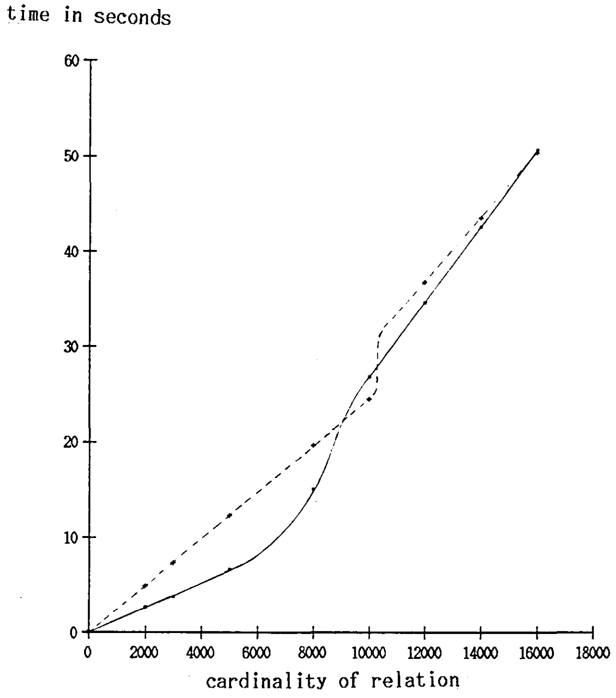

Figure 10 Execution Times (seconds) of the Query in Fig.5

Our result is illustrated in Fig. 10. A solid line curve in the figure shows the cost for the query. A dotted line curve shows the cost when pipelined execution capability is not assumed, and the query Q1 is executed in a sequence of J1, J2, and P1 by using all 10 processing modules for each operation. We would say that pipelined execution is superior when the relation size is smaller than about 10240. This critical value can be estimated in terms of the segment size (1024) multiplied by the number of available processing modules (10). If the relation size is larger than the critical value, the costs based on those two strategies become almost the same because I/O costs significantly influence the total processing costs.

Furthermore, in order to prove the effectiveness of parallel pipelined processing, we compare the execution performance of the query Q1 used in Fig. 6 with that of the query Q2 in Fig. 11 which contains three *joins* and one *projection*. In Q2, *join* J3 is added to Q1. Parameters are assumed to be the same as used in the previous example.

The result of this comparison is shown in Fig. 12. It shows that the performances of the two queries are almost equal to each other, if the cardinality of input relations is smaller than 10000 (almost the total number of segments of the processing modules). Moreover, even though the cardinality of the relations exceeds the total number of segments, it could be said that the system provides relatively good performance by means of parallel pipelined execution.

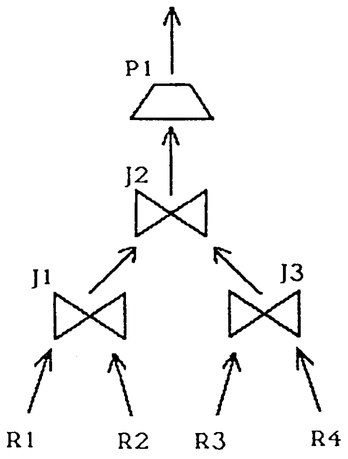

Figure 11 An Example of Query - Q2

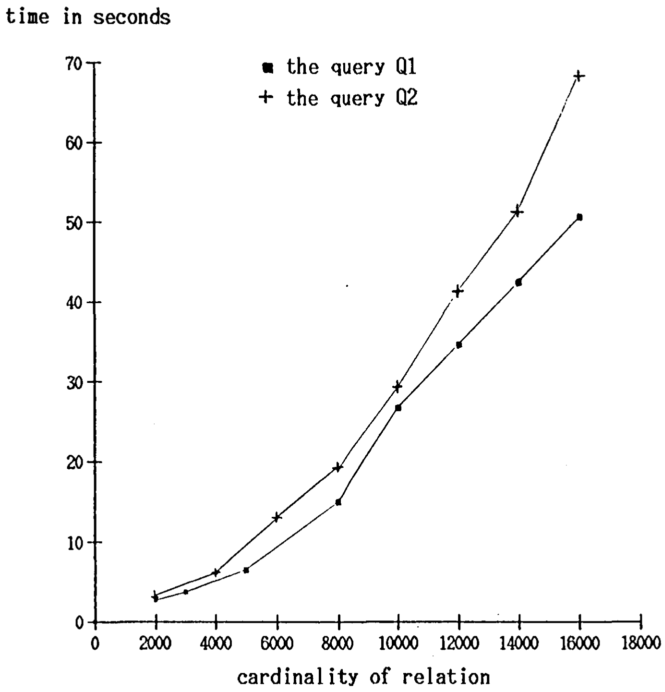

Figure 12 Execution times(seconds) of Q1 and Q2

5.3 Consideration

In this section, we discuss the comparison of the performance for computing equi-join operation in the proposed system and a conventional database management system. Here the conventional system is assumed to use a hashing algorithm. The reason we choose a hashing algorithm is that it is the most suitable when a main memory is large enough to perform the operation [15].

The hashing algorithm used in the conventional system is explained as follows: First, a hash table is constructed by applying a hash function to every tuple of a source relation S independently. S is then partitioned into *m* subsets in such a way that any tuples which have the same hash values lie in the same subset. After the completion of the partition, each tuple of a target relation T is hashed and compared with tuples in the corresponding subset of S by using the hash table. If the comparison is satisfied, pairs of tuples are moved to an output buffer. The cost of this algorithm is shown in Appendix II.

The estimation result is shown in Table 4. It could be said that the proposed system is better than software hash-join method when the number of segments available for the operation is larger than aproximately half the cardinality of S. In the estimation, however, hardware costs are not taken into account. When hardware costs are considered, the software hash-join method may be reasonably acceptable for equi-join operations.

Table 4 Estimation results

CS = CT = CR = 10000
t_{hash} = 40 [μs]

proposed system			hash-jion		
n_S' /CS			*m*		
1	1/2	1/3	10000	8000	5000
9.4 [s]	11.2 [s]	18.3 [s]	12.9 [s]	13.3 [s]	14.2 [s]

However, the application of a hashing technique is limited to equi-join operations. The use of a hashing technique does not effectively reduce the execution cost for non-equi-join operations. In our system, on the other hand, non-equi-join operations can also be processed efficiently.

Furthermore, the system capability could be extended by applying a hashing technique. Both source and target relations are partitioned into *m* disjoint subsets by using a hash function. Each pair of subsets which have tuples with the same hash value is assigned to a processing module, and processed in it. Then an operand can be executed in parallel in cooperation with *m* processing modules. We can improve the performance without preventing the execution in a parallel pipelined fashion.

6. Conclusion

In this paper, the authors have presented a relational database machine which is composed of multiple processing modules and an interconnection network.

The processing module is a special unit for the execution of relational algebra operations. Relational algebra operations except *selection* can be executed efficiently on a uniform architecture. The reason that *selection* has been excepted here is that an improvement in execution efficiency of *selection* should be achieved in connection with secondary storage devices.

For a given query, the system translates it in a form of the relational algebra tree, and after that, several processing modules are connected to each other through the interconnection network according to the tree. The query is executed in a pipelined fashion by going through the processing modules. Furthermore, multiple queries are executed in parallel. Queries can then be executed in a parallel pipelined fashion. When a memory overflow occurs, the system changes the connection of the interconnection network so as to combine two or more processing modules for the execution of a single operation.

Furthermore, the effectiveness of the system is proved through a simulation. Pipelined execution capability greatly contributes to the improvement of the execution performance of the query.

The problems which will remain the future investigation are the scheme of an external storage device management to support efficient data transfer and a mechanism which functions for cases in which the tuple size is greater than the size of the memory segment.

In conclusion, the proposed system shows sufficient flexibility to be able to cope with the enormous increase in demand for the development of large-scale database machines anticipated in the future. It can also be said that the system organization is relevant from the viewpoint of cost-effectiveness when the recent progress of hardware technologies is considered.

Appendix I

We formulate the execution costs of each relational algebra operation as follows:

PROJECTION

$$T= \frac{CS}{n_t} \times T_R + CS \times t_m + 2 \times CS \times t_c + CR \times t_m + \frac{CR}{n_t} \times T_W + 2 \times CS \times t_s$$

$$T'= \left\lceil \frac{CS}{n'_s} \right\rceil \times CS \times t_m + \frac{2 \times CS - n'_s}{n_t} \times T_R + \left\lceil \frac{CS}{n'_s} - 1 \right\rceil \times \frac{CS - n'_s - n_t}{n_t} \times T_R$$
$$+ \left\lceil \frac{CS}{n'_s} \right\rceil \times CS \times t_c + n'_s \times t_c + CR \times t_m + \frac{CR}{n_t} \times T_W$$
$$+ \left\lceil \frac{CS}{n'_s} \right\rceil \times CS \times t_s + n'_s \times t_s + \left\lceil \frac{CS}{n'_s} - 1 \right\rceil \times \frac{CS - n'_s - n_t}{n_t} \times T_W$$

JOIN

$$T= \frac{CS+CT}{n_t} \times T_R + \max(CS,CT) \times t_m + (CS+CT) \times t_c + 2 \times CR \times t_m$$
$$+ \frac{2 \times CR}{n_t} \times T_W + (CS+CT) \times t_s$$

$$T'= \left\lceil \frac{CS}{n'_s} \right\rceil \times \max(n'_s, CT) \times t_m + \frac{(n'_s+CT)}{n_t} \times T_R + \left\lceil \frac{CS}{n'_s} - 1 \right\rceil \times \frac{SEG(CT, n'_s+n_t)}{n_t} \times T_R$$
$$+ \left\lceil \frac{CS}{n'_s} \right\rceil \times \max(n'_s, CT) \times t_c + \min(n'_s, CT) \times t_c + 2 \times CR \times t_m + \frac{2 \times CR}{n_t} \times T_W$$
$$+ \left\lceil \frac{CS}{n'_s} \right\rceil \times n'_s \times t_s + \min(n'_s, CT) \times t_s + \left\lceil \frac{CS}{n'_s} - 1 \right\rceil \times \frac{SEG(CT, n'_s+n_t)}{n_t} \times T_W$$

UNION

$$T= \frac{CS+CT}{n_t} \times T_R + (CS+CT) \times t_m + 2 \times (CS+CT) \times t_c + CR \times t_m + \frac{CR}{n_t} \times T_W + 2 \times CS \times t_s$$

$$T'= \left\lceil \frac{CS+CT}{n'_s} \right\rceil \times (CS+CT) \times t_m + \frac{2 \times (CS+CT) - n'_s}{n_t} \times T_R + \left\lceil \frac{CS+CT}{n'_s} - 1 \right\rceil \times \frac{(CS+CT) - n'_s - n_t}{n_t} \times T_R$$
$$+ \left\lceil \frac{CS+CT}{n'_s} \right\rceil \times (CS+CT) \times t_c + n'_s \times t_c + CR \times t_m + \frac{CR}{n_t} \times T_W$$
$$+ \left\lceil \frac{CS+CT}{n'_s} \right\rceil \times (CS+CT) \times t_s + n'_s \times t_s + \left\lceil \frac{CS+CT}{n'_s} - 1 \right\rceil \times \frac{(CS+CT) - n'_s - n_t}{n_t} \times T_W$$

DIFFERENCE

$$T= \frac{CT}{n_t} \times T_R + CT \times t_m + \frac{CS}{n_t} \times T_R + CS \times t_m + 2 \times CS \times t_c$$
$$+ CR \times t_m + \frac{CR}{n_t} \times T_W + 2 \times CS \times t_s$$

$$T'= \frac{CT}{n_t} \times T_R + CT \times t_m + \left\lceil \frac{CS+CT}{n'_s} \right\rceil \times CS \times t_m + \frac{2 \times CS - n'_s}{n_t} \times T_R + \left\lceil \frac{CS+CT}{n'_s} - 1 \right\rceil \times \frac{CS - n'_s - n_t}{n_t} \times T_R$$
$$+ \left\lceil \frac{CS+CT}{n'_s} \right\rceil \times CS \times t_c + n'_s \times t_c + CR \times t_m + \frac{CR}{n_t} \times T_W$$
$$+ \left\lceil \frac{CS+CT}{n'_s} \right\rceil \times CS \times t_s + n'_s \times t_s + \left\lceil \frac{CS+CT}{n'_s} - 1 \right\rceil \times \frac{CS - n'_s - n_t}{n_t} \times T_W$$

INTERSECTION

$$T= \frac{CS+CT}{n_t} \times T_R + \max(CS.CT) \times t_m + (CS+CT) \times t_c + CR \times t_m + \frac{CR}{n_t} \times T_W + (CS+CT) \times t_s$$

$$T'= \left\lceil \frac{CS}{n'_s} \right\rceil \times \max(n'_s.CT) \times t_m + \frac{n'_s+CT}{n_t} \times T_R + \left\lceil \frac{CS}{n'_s} - 1 \right\rceil \times \frac{SEG(CT.n'_s+n_t)}{n_t} \times T_R$$
$$+ \left\lceil \frac{CS}{n'_s} \right\rceil \times \max(n'_s.CT) \times t_c + \min(n'_s.CT) \times t_c + CR \times t_m + \frac{CR}{n_t} \times T_W$$
$$+ \left\lceil \frac{CS}{n'_s} \right\rceil \times n'_s \times t_s + \min(n'_s.CT) \times t_s + \left\lceil \frac{CS}{n'_s} - 1 \right\rceil \times \frac{SEG(CT.n'_s+n_t)}{n_t} \times T_W$$

CARTESIAN PRODUCT

$$T= \frac{CS+CT}{n_t} \times T_R + \max(CS.CT) \times t_m + (CS+CT) \times t_c + 2 \times CR \times t_m$$
$$+ \frac{2 \times CR}{n_t} \times T_W + (CS+CT) \times t_s$$

$$T'= \left\lceil \frac{CS}{n'_s} \right\rceil \times \max(n'_s.CT) \times t_m + \frac{n'_s+CT}{n_t} \times T_R + \left\lceil \frac{CS}{n'_s} - 1 \right\rceil \times \frac{SEG(CT.n'_s+n_t)}{n_t} \times T_R$$
$$+ \left\lceil \frac{CS}{n'_s} \right\rceil \times \max(n'_s.CT) \times t_c + \min(n'_s.CT) \times t_c + 2 \times CR \times t_m + \frac{2 \times CR}{n_t} \times T_W$$
$$+ \left\lceil \frac{CS}{n'_s} \right\rceil \times n'_s \times t_s + \min(n'_s.CT) \times t_s + \left\lceil \frac{CS}{n'_s} - 1 \right\rceil \times \frac{SEG(CT.n'_s+n_t)}{n_t} \times T_W$$

DIVISION (Phase-1)

$$T= \frac{CS+CT}{n_t} \times T_R + (CS+CT) \times t_m + (CS+1) \times CT \times t_s + CT \times t_c + CR \times t_m + \frac{CR}{n_t} \times T_W$$

$$T'= \frac{(CT-1) \times (CS-n_s-n_t) + (CS+CT)}{n_t} \times T_R + (CS+1) \times CT \times t_m + (CS-1) \times CT \times t_s$$
$$+ \left\lceil \frac{CS}{n'_s} \right\rceil \times CT \times t_c + CR \times t_m + \frac{CR}{n_t} \times T_W$$
$$+ \frac{(CT-1) \times (CS-n_s-n_t)}{n_t} \times T_W$$

DIVISION (PHASE-2)

$$T= \frac{CS}{n_t} \times T_R + CS \times t_m + 2 \times CS \times t_c + CR \times t_m + \frac{CR}{n_t} \times T_W + 2 \times CS \times t_s$$

$$T'= \left\lceil \frac{CS_1}{n'_s} \right\rceil \times CS \times t_m + \frac{2 \times CS - n'_s}{n_t} \times T_R + \left\lceil \frac{CS+CT}{n'_s} - 1 \right\rceil \times \frac{CS - n'_s - n_t}{n_t} \times T_R$$
$$+ \left\lceil \frac{CS_1}{n'_s} \right\rceil \times CS \times t_c + n'_s \times t_c + CR \times t_m + \frac{CR}{n_t} \times T_W$$
$$+ \left\lceil \frac{CS_1}{n'_s} \right\rceil \times CS \times t_s + n'_s \times t_s + \left\lceil \frac{CS+CT}{n'_s} - 1 \right\rceil \times \frac{CS - n'_s - n_t}{n_t} \times T_W$$

Here let T and T' be the execution costs for CS < n_s' and CS > n_s', respectively. SEG(x, y) is the function taking a value either x - y for x > y or 0 for other cases. CS_1 in Phase-2 of *division* denotes the number of tuples of the first group of the relation derived from Phase-1.

Appendix II

We formulate the execution costs of software hash-join algorithm. Here, we take the following parameters for the estimation.

m : the number of subsets of the relation which is partitioned by a hash function

t_{hash} : time to hash a tuple

The cost formulates as follows:

HASH-JOIN

$$T= \frac{CS+CT}{n_t} \times T_R + (CS+CT) \times t_{hash} + 2 \times (CS+CT) \times t_m$$
$$+ \left(\frac{CS}{m} \times \frac{CT}{m} \right) \times m \times t_c + \frac{2 \times CR}{n_t} \times T_W$$
