This 1986 edition of the proceedings of the Fall Joint Computer Conference, published on the 50th anniversary of the writing of the paper

"On Computable Numbers, with an Application to the Entscheidungs Problem,"

is dedicated to the memory of

ALAN M. TURING

who wrote:

"My contention is that machines can be constructed which will simulate the behaviour of the human mind very closely. They will make mistakes at times, and at times they may make new and very interesting statements, and on the whole the output of them will be worth attention to the same sort of extent as the output of a human mind."

How close are we to his vision today?

Table of Contents

EDUCATION ARENA

TRACK ED–1: New Technology in Education. Track Chair: Lionel Baldwin, President, National Technological University

Session 1 - Education by Satellite. Session Chair: Lionel Baldwin, National Technological University (1-B)

Session 2 - Computers in Education. Session Chair: Arthur Melmed, Consultant (4-B)

SOFTWARE SYSTEMS ARENA

TRACK SS-1: Software Engineering. Track Chair: Laszlo Belady, MCC

Session 1 - Object-Oriented Software. Session Co-Chairs: Clarence Ellis and Ted Biggertsaff, MCC (2-C)

SUPERCOMPUTING ARENA

TRACK SC-1: Parallel Computation. Track Chair: Kai Hwang, University of Southern California

Session 1 - Parallel Processing for AI. Session Chair: Kai Hwang, University of Southern California (1-D)

Session 2 - Parallel Algorithms for Supercomputing. Session Chair: Benjamin Wah, University of Illinois at Urbana-Champaign (2-D)

TRACK SC-3: Multiprocessors. Track Chair: Daniel Siewiorek, Carnegie Mellon University

Session 1 - Multiprocessors I. Session Chair: Zary Segall, Carnegie Mellon University (4-D)

Session 2 - Multiprocessors 2. Session Chair: Pat McGehearty, Microelectronics and Computer Technology Corporation (5-D)

Session 3 - High-Speed Techniques. Session Chair: William Brantley, IBM T. J. Watson Research Center (6-D)

TRACK SC-4: Optical Computing. Track Chair: C. Lee Giles, AFOSR/NE

Session 1 - Optical Computers. Session Chair: John Caulfield, University of Alabama (1-A)

Session 2 - New Directions in Optical Computing. Session Chair: C. Lee Giles, AFOSR/NE (2-A)

Session 3 - Optical Interconnections for Computing. Session Chair: John Neff, DARPA/DSO (3-A)

TRACK SC-5: Networks. Track Chair: Michael Willett, IBM Corporation

Session 1 - Implementing a Token-Ring Local Area Network, Session Chair: Michael Willett, IBM Corporation (4-A))

ALGORITHMS ARENA

TRACK AL-1: Artificial Intelligence Algorithms. Track Chair: Tony A. Marsland, University of Alberta

Session 1 - Computer Chess Techniques. Session Chair: Tony A. Marsland, University of Alberta (3-H)

TRACK AL-2: Numerical Methods. Track Chair: David R. Kincaid, University of Texas at Austin

Session 1 - Vector and Parallel Algorithms. Session Chair: David R. Kincaid, University of Texas at Austin (7-D)

Session 2 - Finite Differences, Finite Elements, and Grid Generation — A Tutorial. Session Chair: Linda J. Hayes, University of Texas at Austin(8-D)

TRACK AL-3: General Algorithms. Track Chair: Paul Purdom, Indiana University

Session 1 - Searching. Session Chair: Cynthia Brown, Northeastern University (7-I)

Session 2 - Data Structures. Session Chair: Michael Loui, University of Illinois (8-I)

TRACK MM-2: The State of the Art of Capacity Management in MVS Systems. Track Chair: Kenneth Kolence, Kolence Associates

Session 1 - Capacity Management 1. Session Chair: Kenneth Kolence, Kolence Associates (3-G)

Session 2 - Capacity Management 2. Session Chair: Kenneth Kolence, Kolence Associates (4-G)

COMPUTER DESIGN ARENA

TRACK CD-1: Fault-Tolerant Computing. Track Chair: John Meyer, University of Michigan

Session 2 - Evaluation. Session Chair: Kishor S. Trivedi, Duke University (5-E)

Session 3 - Testing. Session Chair: Edward J. McCluskey, Stanford University (6-E)

INTERNATIONAL DEVELOPMENT ARENA

TRACK ID-1: Computer Developments in Japan. Track Chair: Ryoichi Mori, University of Tsukuba, Track Secretariat: Mr. Kenji Naemura, NTT Electrical Communications Laboratories

Session 1 - Fifth Generation Computers I: Language Architecture. Session Chair: Koichi Furukawa, ICOT (4-F)

Session 2 - Fifth Generation Computers II: Applications. Session Chair: Koichi Furukawa, ICOT (5-F)

Session 3 - Advanced Microcomputer Developments. Session Chair: Iwao Morishita, University of Tokyo (6-F)

Session 4 - Supercomputing Systems. Session Chair: Yoshikuni Okada, Electrotechnical Laboratory (7-F)

Session 5 - Interworking Systems. Session Chair: Kenji Naemura, NTT Electrical Communications Laboratories (8-F)

OPERATING SYSTEMS AND DATA BASES ARENA

TRACK OSDB-1: Operating Systems. Track Chair: James Peterson, MCC

Session 1 - Applications of Petri-Nets. Session Chair: Paul Reynolds, University of Virginia (7-H)

Session 2 - Security and Protection in Computer Systems. Session Chair: James Peterson, MCC (8-H)

TRACK OSDB-2: Distributed Operating-Systems. Track Chair: Jack Stankovic, Carnegie Mellon University

Session 1 - Distributed-Operating Systems. Session Chair: Jack Stankovic, Carnegie Mellon University (5-H)

Session 2 - Distributed Databases. Session Chair: Hector Garcia-Molina, Princeton University (6-H)

TRACK OSDB-3: Data Bases. Track Chair: Anil Nigam, IBM T. J. Watson Research Center

Session 1 - Data Bases. Session Chair: Anil Nigam, IBM T. J. Watson Research Center (1-H)

The 1986 Fall Joint Computer Conference—
A Conference for the Profession

Stanley Winkler
Conference Chairman

A professional, technical conference is the term we have used to describe the 1986 Fall Joint Computer Conference (FJCC '86). It was our aim to prepare the finest conference of the decade. Sponsored by two great professional computer associations, the Association for Computing Machinery (ACM) and the Computer Society of the IEEE, the FJCC was conceived as a conference-for-all-members. Specifically, the FJCC combines two meetings of the Societies customarily held in the fall season: The ACM National Conference and the COMPCON Fall meeting of the Computer Society of the IEEE. The ACM Council and the Computer Society Governing Board will meet during FJCC '86, as will various Boards and Committees, following the tradition of conducting Society business during the annual Fall Meeting.

Professional, technical conferences in the United States have a long and honorable history that can be traced back to the Mechanics Institutes of the 1800s. These Institute meetings, made necessary by the rapid technical advances of the Industrial Revolution, allowed professionals in the field of engineering to gather together and share problems and experiences. As the workforce became more specialized, it was no longer adequate for industry to rely on the transfer of technical knowledge from father to son or from master to apprentice. Today, in the computer field, professional conferences remain an important, if not the most important, means of exchange of ideas, information, and knowledge within the profession. While classroom education can provide the basis for entry into the profession, the essential continuing education is best acquired by interaction with one's peers. This interaction among peers is at once the function and the *raison d'être* of professional, technical conferences.

Of course, times have changed, and our computing profession has changed with it. Thirty-five years ago at the first joint meeting, in Philadelphia, the topics discussed encompassed most of the field as it was known then. That completeness would be impossible to accomplish today. Nonetheless, it seemed important to try, during FJCC '86, to provide a broad-based review of the most significant topics that confront the computing profession and industry. The salient feature of the 1986 Fall Joint Computer Conference is its broad-based nature. Equally important is the fact that, broad-based though it is, FJCC '86 presents full in-depth discussions of the topics selected. The technical program for FJCC '86, so ably developed under the leadership of Harold S. Stone, is a cornucopia of technical delights prepared by experts for their fellow practitioners of the art of computing.

In his introduction to the FJCC '86 technical program (in this volume), Harold S. Stone refers to FJCC '86 as "a new beginning." Since by definition all beginnings are new, one cannot quarrel with this phrase. I think, however, that the French saying "the more things change, the more they remain the same" also applies. I had the pleasant and comfortable feeling, on first seeing the finished FJCC '86 technical program, that the program is a return to the best traditions of the past. It is, indeed, a thoroughly modern program, broad-based and in full detail. It displays, without compromise, the current state-of-the-art. A casual look at the Conference-at-a-Glance confirms this assertion. But the technical program of the 1986 Fall Joint Computer Conference does more than provide a static snapshot of the world of computing today. It describes and represents the directions that the leaders of the computing profession are taking.

This illumination of the directions that the computing profession is taking is the most important function of an FJCC. Significantly, this illumination is not a prediction of the future gained by gazing into a crystal ball, or by the reading of tea leaves. It is, in fact, a self-fulfilling prophecy. The participants in FJCC '86, the speakers, panelists, discussants, and attendees, are not just talking about professional leadership in the 1990s—they are making it happen. They can make it happen because "they" are the leaders, the top, key people in the profession and in the industry. The content of

FJCC '86 in its breadth and depth is outstanding—probably exceeding that of any conference held in the last decade. This unprecedented breadth and depth is achieved through the nine conferences that are held simultaneously during FJCC '86.

Each of these nine conferences is a front-line, major event of its own. The nine conferences are: Artificial Intelligence, Supercomputing, Software Systems, Algorithms, Modeling and Measurement, Computer Design, Computer Developments in Japan, Operating Systems and Data Bases, and Education.

The fact that these nine conferences are going on at the same time is a significant added dimension to the FJCC '86 experience. Not only can FJCC participants meet the experts in their own specialty, but they can interact with the leaders in other specialties. This provides an enrichment for the individual, and, at the same time, is very good for the profession. The interpersonal communication among specialists in various fields of computer science and engineering stimulates thinking and creativity. This "cross-cultural" communication induces the propagation of ideas and concepts from one field into another, adding robustness and vibrancy to our profession.

This Proceedings provides a permanent record of the technical papers presented at the Conference. As such, it is a valuable addition to the shelves of our personal and organizational libraries. It does not, however, capture the other dynamic and exciting aspects of FJCC '86; absent are the discussions following each presentation of a technical paper, the poster sessions where last minute ideas are put forth, and the conversations in the hallways and lounges during coffee breaks and after sessions. Also not reflected in the Proceedings are the special events such as the world class Chess Tournaments—the 17th North American Computer Chess Championship and the 6th World Microcomputer Chess Championship.

The FJCC was designed to provide a complete educational experience. Complementing the technical program, Toni Shetler and her committee arranged an unparalleled Professional Education Program (PEP) and a very interesting Exhibitor Technical Forum. The Professional Education Program, which took place during the first two days of the Conference, gave attendees the opportunity to learn new skills and to sharpen old ones. There were one- and two-day courses, many of the hands-on variety. The Exhibitor Technical Forums provided the opportunity for vendors to discuss and explain the technology imbedded in their principal products. All of these activities were part of the effort to attain the objective of FJCC '86: to expand the professional horizons and capabilities of the conference attendees.

It was my privilege to chair a Conference Committee of capable, dedicated individuals, who contributed their time and effort in the service of the profession by creating the FJCC '86. They are listed elsewhere in this volume. To each of these friends I want to say, "Thank you." There were many others who helped us and to all of them I want to express my sincere appreciation. And finally, I want to thank the participants because, in the final analysis, it is they who are the Conference.

The 1986 Fall Joint Computer Conference—A New Beginning

Harold S. Stone
Program Chairman

The Conference Role

The 1986 Fall Joint Computer Conference is a conference of the future and of the past. The future is embodied by the conference theme — Exploring the Knowledge-Based Society — and the past by its popular predecessor conference of the 1960s. In looking forward, the conference offers technical papers, panels, and tutorials to cover the topical areas that form the technology base for the next decade. Such areas as Artificial Intelligence, supercomputers, design automation, computer graphics, and networks are among the topics of special attention. In looking backward to the FJCC's of 20 years ago, the vast changes in the discipline are evident, which underscores the importance of providing state-of-the-art information in subject areas destined to form the core of the field in coming years.

Consider the change in the hardware technology from the 1960s to the 1980s. The supercomputers of the 1960s are the micros and minis of the 1980s. Who would believe then that such computing power would be available on the desk tops of virtually every researcher, analyst, programmer, and student. The workhorse of a typical scientific installation in 1960 had 128K of 10 microsecond memory. A low-cost microprocessor of 1986 has 256K of 150 nanosecond memory. A supercomputer of 1965 had 2M bytes of 1 microsecond memory. A typical workstation of 1986 has 4M bytes of 120 nanosecond memory. The dramatic improvements in cost and performance made possible through VLSI technology were truly unimaginable in the days of the former FJCC.

The impact of such changes on the computing field are not yet fully assimilated, but the trends are clear. In days of expensive hardware, software was viewed to be inexpensive, more or less by default. Where hardware was too costly to commit to a special-purpose job, or where the functional requirements were too vague to lock into hardware, the often-used solution was to build hardware to do approximately what was desired, and to leave the final tailoring to software. That is, constrain the major cost by freezing the hardware at some stage, and fill in the remainder of the implementation with "inexpensive" software.

All too often this approach had costly surprises in store for the system developers. With hardware frozen, the only freedom available to make such systems work was in software development, enhancements, and maintenance. Software costs climbed continually during the life of systems since software costs never ceased. In long-lived systems, software costs eventually dwarfed the hardware investment. Moreover, the inherent flexibility attributed to software became a myth, as changes to existing large-scale software became substantially more difficult and eventually impossible to implement. On the other hand, hardware became far more flexible, as each new generation of computers was succeeded by faster and less expensive generations, each upward compatible with its predecessors. The relative flexibility of hardware and software as viewed in the 1960s had turned upside down by the 1970s.

To improve the software situation, substantial efforts in high-level languages increased programmer productivity, but, productivity as measured in lines of code, failed to attain high multiples that was once viewed necessary to prevent the massive cost of software production from swamping the industry. Who would have predicted how this view would change after widespread introduction of the microprocessor? With millions of potential users instead of hundreds, the sales price of software could be kept relatively low per user, in spite of high costs for development. Moreover, as new microprocessors were introduced, it was totally impractical to rewrite a new software base for each new offering. Survivability of the microprocessor was largely tied to the ability to move a complete software base to the microprocessor, and this in turn created the market for portable software. With relatively little effort, it is possible today to move a complete operating system plus compilers, editors, and supporting tools to a totally new microprocessor with a unique instruction set.

Instead of writing new code that reinvents old software, the field has developed techniques to reuse software that does the job. The net result is that most software has become inexpensive on a per-user basis. Expensive software still exists, however, where user communities are small, and where techniques are embodied in software for the first time.

Having reflected on the changes in computing technology from when the FJCC was at its former height to the present time when the FJCC has been reborn, can we conceive of the changes that will take place in the next several years? For example, what will happen to programming as a profession? Will it be a profession that supports a population that seems to grow exponentially? Or will there be a limit to that growth that holds the population constant? Or will the numbers collapse? All three of these models are possible, depending on how the field places computer power in the hands of the user. The exponential growth models the growth in the number of computers, and is a model in which each computer system requires individual programming. The constant-population model is a model in which a fixed pool of people is able to supply a growing population of machines, and is probably an accurate reflection of the industry in the next few years as portable software becomes more widely used in place of specially tailored software. The last model in which fewer programmers are able to supply a growing pool of machines is one in which a relatively few "super" systems created by highly skilled programming teams account for large fractions of software use. The remaining software can be supplied by a much smaller pool of programmers under the first or second models.

The potential for this last model clearly exists today. If the model eventually becomes reality, the industry will be far different from the one we know. Are we ready for that event?

The 1986 FJCC is a conference where we can examine the recent trends, hear the projections, discuss the possibilities with the experts in each field, and then prepare for the future. The key to the FJCC is the technical focus. We must be an informed profession, and we must look forward in technology.

The growth of the computer profession has brought diversity, and the diversity has splintered the profession a hundred ways into the SIGs and TCs that form the technical leadership of the disciplines within the profession. The diversity has created journals, newsletters, conferences, and workshops with single themes directed to the experts in the various areas. Each of these activities has had its positive benefits within the narrow focus area, but the single-focus activities cannot provide for advances that require the synthesis of ideas from multiple disciplines. The FJCC is, by design, a multiple-focus conference. Its purpose is to bring together the experts across a range of disciplines so that the mix of ideas can provide impetus for new projects attaining new plateaus that are not readily achievable within any one discipline.

Consider, for example, four different ways of representing information. Individually, we might have information represented as

- text,
- voice,
- graphics, or
- data base.

For each representation we can build a discipline that deals with that representation exclusively, and we create such disciplines as publishing, telephony, computer graphics, and on-line information utilities. Now reconsider the four representations, and consider what happens when you join any two together. A whole new discipline is created. If you join text and voice, you obtain the voice-operated typewriter, voice-data communications networks, or spoken output from written text. If you combine graphics and text, you create computer publishing, intelligent copiers, and electronic encyclopedias. But there is no need to focus on just the four data representations. Pick any collection of special-interest areas and consider what new challenges can be formed by combining any two or three areas. This gives an inkling of what can happen when you bring together active thinkers from a variety of areas and let the pot boil. This is the FJCC.

Conference Management

How was the technical conference put together? With a new conference we have no history from last year, no experienced program committee to draw upon, and no expectant audience ready to submit materials to the annual gathering of the clan. This conference was mounted as thirty tracks in the major areas of computer science and engineering. Each track chair had the charge to create a track that best illuminated the area, whether through solicited refereed papers, panels, or through invited papers from recognized innovators. The conference call also produced papers in abundance, and these were distributed to the tracks for refereeing according to the subject matter of the papers. In all, 248 submissions were processed for the conference. Of these, approximately 150 were unsolicited and went through the conference refereeing processing. Roughly one third of these papers were accepted for the proceedings. The remainder of the papers in the proceedings were generated by the collective energy of the track chairs. These were treated either as invited papers not subjected to an external review or as solicited papers that were reviewed and possibly modified prior to publication in the proceedings. A number of solicited papers were dropped from consideration after the reviewing process, but the exact numbers of such rejections is not known because such papers were not coordinated centrally.

With a large fraction of solicited papers at this conference, there became a potential for abuse of the refereeing system. To assure high technical quality, it is essential that papers receive fair, independent assessments by competent reviewers. Invited papers were not refereed, so the basis for invitation had to be on the basis of past performance. Chairs of sessions have been selected for their contributions, and they themselves are candidates for invited papers in their own sessions. However, for ethical reasons, no person at this conference was permitted to accept a paper in which that person or a close colleague was among the authors. In each such instance in this proceedings, the paper underwent independent review and was accepted by a party other than the session chair.

The success of the program is due entirely to the efforts of the program committee members (listed on page vii). Finally, I thank each of the following for their contributions:

Sheldon Akers
Lionel V. Baldwin
Laszlo Belady
Ted Biggerstaff
Barry Boehm
Pradip Bose
Cynthia Brown
William Brantley
Luis Felipe Cabrera
John Caulfield
Lori Clarke
Paul Cohen
Kenneth De Jong
Louis Doctor
Clarence Ellis

Andries van Dam
Benjamin Wah
Richard L. Wexelblat
John R. White
Robert Wilensky
Michael Willett
Michael Wozny

In a list this long, the nature of the contributions varies widely across the list. All contributions have been important, and each party noted above deserves their share of credit in the success of the FJCC. However, some contributions deserve special mention. I greatly appreciate the work of Ryoichi Mori and Kenji Naemura for producing the papers in the International Developments Arena. Les Belady, Jim Peterson, Jerry Kurtzberg, John Meyer, David Rine, Steve Lavenberg, Jack Stankovic, and Ken Kolence each produced top quality tracks through their resourcefulness and continued efforts. Maureen Ferraro, Executive Program Coordinator, provided the glue that held the team and the participants together. As the conference grew from embryo into infancy and then maturity, Maureen was there with the detailed work to guide the development. Tracking the papers and referees, managing the proceedings, and making personal contacts to assure timely responses were typical of the many tasks she tackled. The magnitude of the job could exceed the capacity of many computers I have known, and only occasionally challenged but never exceeded her capacity to get the job done.

Finally, we come to the referees—anonymous to the authors—recognized here in the proceedings. We gratefully acknowledge the role played by the referees (listed on page vii). No conference can succeed without the wisdom of careful reviews to assure the quality and accuracy of the published material.

AMCEE PROGRAMMING FOR COMPUTER PROFESSIONALS

John T. Fitch
Associate Director

Association for Media-based Continuing Education for Engineers

ABSTRACT

The Association for Media-based Continuing Education for Engineers (AMCEE) is a consortium of 33 engineering universities which provides off-campus education via television and videotape. Clients are engineers, industrial scientists, and technical managers in business, industry, and government. AMCEE operates a satellite delivery system, offering six hours a day, five days a week of non-credit continuing education courses. The bulk of the courses, however, are delivered on videocassettes, accompanied by study guides and textbooks. The majority of these "short courses" are in computer and communication related subjects.

INTRODUCTION

In a session on "Technical Education by Satellite," it seems appropriate to talk specifically about continuing education for computer professionals, because the AMCEE programs aimed at that audience have been among its most successful. But first it might be worth a brief digression to explain AMCEE itself and its mission.

AMCEE is an acronym for the Association for Media-based Continuing Education for Engineers. It is a non-profit, tax exempt consortium of, at present, thirty-three engineering universities. What these schools have in common is programs of off-campus graduate and/or continuing education using television and/or videotape. Most of the members offer master's degree programs and continuing education short courses to practicing engineers, industrial scientists, and technical managers who take their coursework at the job site rather than on campus. The medium that connects the campus classroom with the industrial site or government laboratory is either "live" television using Instructional Television Fixed Service (ITFS) microwave channels, or a set of courier-delivered videocassettes. Most of these materials are in what is commonly called "candid classroom" format, i.e. the courses are broadcast or videotaped as they are being taught to a class of on-campus students. Cameras are fixed to the walls and ceiling of the classroom, and the equipment is often operated by students. Thus, the production costs are marginal.

Bringing the classroom to the student offers convenience and flexibility, as well as significant cost- and time-effectiveness. And all without sacrificing academic quality. Several studies have shown that off-campus students do as well or better than their on-campus counterparts taking the same course.

With a view toward providing better quality materials to "increase the national effectiveness of continuing education for engineers," twelve universities joined together in 1976 to form AMCEE. Its headquarters were placed on the campus of one of its members, the Georgia Institute of Technology in Atlanta. The idea was that an association of schools would make it economically feasible to develop studio produced videocassettes and collateral printed materials for a national rather than a regional clientele. Thus, 1986 is the tenth anniversary of the consortium which has since nearly tripled in size in terms of membership -- and increased by an order of magnitude its services to business, industry, and government. Table 1 is a list of the present AMCEE membership.

Table 1 - Members of AMCEE

University of Southern California
University of Washington

During these first ten years, the medium of delivery has been the videocassette, there being no economical national equivalent of the local, live ITFS. And videocassettes still offer scheduling flexibility that prompts many clients to opt for them, even when live television is also available. Participants who miss a session because of travel or pressing business can catch up with their colleagues by watching the videocassettes on their own.

Today, with over 90 per cent of the engineering universities who offer media-based off-campus education as members, AMCEE publishes an annual catalog listing some 500 video courses in 16 engineering and science disciplines from its 33 members. These disciplines cover all the traditional ones from aeronautical engineering to mathematics as well as a number of interdisciplinary and management subjects. During the last fiscal year, AMCEE logged over 1500 orders from some 850 clients and reached an estimated 22,000 individual participants.

SATELLITE DELIVERY

By 1985 the economics of satellite television had made it feasible for AMCEE to re-evaluate the possibility of live television delivery for its programs. At the same time, a subset of AMCEE member universities formed a sister organization, the National Technological University (NTU) to offer an accredited master's degree program on a national basis. The two organizations agreed to share a transponder on a recently launched satellite in the "Ku" band. Unlike the more widely used "C" band, used by the cable and movie channel companies, the Ku band is used primarily for business communications. Several AMCEE clients were already equipped to receive satellite programs in this higher frequency part of the spectrum. Furthermore, because of the higher power of the particular satellite selected (G-Star I), it was possible to split the bandwidth and power of a single transponder and still provide reasonably good signals to carefully specified and installed receivers -- thus further improving the economics of this new delivery mode.

In September 1985, the two organizations inaugurated the "AMCEE/NTU Satellite Network," NTU providing candid classroom courses for credit towards a master's degree, AMCEE providing non-credit short courses for continuing education. Currently, there are five origination sites where "earth stations" are located that can transmit classes up to the satellite. These are located at Colorado State University; the Universities of Massachusetts, Maryland, Maryland, and South Carolina; and the Georgia Institute of Technology. AMCEE, because it is located at Georgia Tech, relies heavily on the "up-link" there. Each weekday from 11:00 a.m. to 5:00 p.m. Eastern time, AMCEE broadcasts a variety of short courses and seminars, a total of 1500 hours of instruction per year. Many of the courses are prerecorded on videocassette, but some of them are live with participant interaction via telephone with the instructor. These are on engineering and technical management topics, with the most popular being those having to do with computers and communications.

Organizations receiving the telecourses install their own "down-links" and pay for the service through a network registration fee and individual course registration fees. Under license, they can videotape transmissions for delayed use to provide them with the scheduling flexibility available through videocassette delivery. In general, the pricing is similar for the two modes of delivery, though the startup cost for participation in the satellite network clearly makes it more expensive, initially. So, one might ask why a company might choose satellite over videocassette delivery. There is more than one answer. For one thing, it is simply a lot easier to walk into a room and turn on the TV than it is to plan far enough ahead to order a set of videocassettes, take delivery of them, keep them safely, and return them after they've been used. And when the program is a "live" event, there is the added value -- gratification, even excitement, if you will -- in being able to call up the instructor and ask a question that applies to your own particular situation. As of this writing (Spring 1986) there were approximately 60 down-link receiving sites scattered across the country.

But to concentrate on the difference in cost between videotape and television delivery systems obscures a more important point: the dominant cost of education is the participating engineer's time. Anything, then, that can be done to conserve that time, by, for example, eliminating the need to commute to a college campus undoubtedly outweighs the higher cost of media-based delivery.

We have experienced minimal start-up problems with the network, most having to do with the novel split transponder and the necessity for careful purchase, installation, and maintenance of down-link equipment. Training directors regularly call the AMCEE office with their lists of registrants for a variety of courses. AMCEE, in turn, coordinates the shipment of printed materials -- study guides and/or textbooks -- to the receiving sites (usually!) in time for the start of each course.

SPECIAL PROGRAMS

Occasionally (currently about once every other month) AMCEE opens up its satellite network and transmits a short seminar or longer telecourse on a C-band transponder as well as on its Ku-band network. This means that any organization with access to a C-band down-link can receive the programs, and even if they do not have access to such equipment, there are many areas around the country where participants can come to an AMCEE member campus to watch the program. Furthermore, the Hewlett-Packard Corporation has very generously opened many of its plants and offices to outsiders who wish to participate. These special "open network" broadcasts receive far wider promotion than is given the rest of the schedule. Instead of just being listed in the AMCEE publications, the **Monitor** and the **Uplink**, separate brochures are published for each program and mailed to several thousand prospective participants.

These special broadcasts are usually reserved for live events such as an April 1986 program on "Computer Communications and Networking: A Technology Forecast" or a combination of videotape and live broadcasts such as a June 1986 program on "Microcomputer Software for Project Management." The former -- the all "live" programs -- are usually videotaped as they occur and, if the quality of the programs is high and the content likely to have a reasonable shelf life, these videotapes are then advertised for rental and sale. Although these cassettes do not have the advantage of the telephone interaction, they can, nevertheless, be useful to those not able to watch the satellite broadcast.

The latter type of program -- the combination of videotape and live -- is a more frequently followed model. Here, a set of videotaped lectures, often made just prior to the broadcast, are used as the backbone of the presentation. We find that, by videotaping the lectures, the instructor is subject to less pressure, errors can be corrected, and there is time between lectures to collect thoughts and materials. However, the instructor remains in the studio after the taping is completed (or returns at a later date) for the satellite broadcast. Then, after each videotape is run, the instructor appears "live" on camera and takes telephone questions from the participants. The schedule is arranged so that any time not used for questioning serves as a brief intermission before the next videotaped lecture.

We are still developing this mode of operations -- the whole concept of dual-band satellite programs is still relatively new for us -- but the scheme that appears to be emerging is one in which we produce the videotapes at a television studio at the University of Maryland (where we produce most of the AMCEE videotaped courses) and then up-link the actual broadcast from one of the "candid classrooms" across campus at the engineering school, which has a Ku-band earth station, or we take the tapes to the University of South Carolina (which has, in place, both Ku-band and C-band earth stations). Exotic as all this may sound when compared with offering a continuing education program at a local college campus, it is not, marginally, a very costly operation (because the studios and up-links are already "there"). Therefore, it does not require a very large audience to break even (on the order of a few hundred people).

COMPUTERS AND COMMUNICATIONS

As indicated earlier, among the most popular courses delivered over the satellite network are those having to with computers and/or communications. (This is also true to a lesser extent for our videocassette distribution, but the videocassette audience is greater and more diversified; hence a program on metallurgy might do well on tape but fail on the network where the clients are still primarily high-tech companies with a heavy concentration in the computer field.) Table 2 lists the programs offered thus far on the network on computer-related subjects.

Table 2 - Computer Related Courses on the AMCEE/NTU Satellite Network

Applied Kalman Filtering
Communication Networks
Computer Communications
Computer Communications & Networking
DDN & DOD Protocol Standards
Distributed Processor Communication Arch.
Distributed Telecommunication Networks
Effective Use of Small Computers
Fortran 77
Fundamentals of Data Communications
Gallium Arsenide Integrated Circuits
IEEE 802: Local Network Standards
Integrated Services Digital Network
Interactive Computer Graphics
Kalman Filtering
Lisp at Work, Parts 1, 2, & 3
Local Area Networks
Local Network Technology & Selection
Microcomputer Software for Project Management
Microprocessor Interfacing
Packet Switching Networks
Pascal, Part 1
Principles of Modern Software Engineering
Relational Database
Robotics: A Tutorial in Four Parts
16-Bit Microprocessor Programming
Software Management for Small Computers
Software Project Management
Telecommunications & The Computer
Vector Processors & Mini Computers

Neglecting individual lectures -- usually on management skills topics, these 30 courses represent approximately half of all the courses offered on the network during the period from early September through mid May, 1986. In other words, all other disciplines made up the other fifty percent.

CONCLUSIONS

AMCEE currently broadcasts its non-credit courses six hours a day, five days a week on the share AMCEE/NTU satellite network in the Ku band, for a total commitment of 1500 hours a year. In addition, AMCEE offers six or more "special" events each year on both the Ku-band network and on a C-band transponder. These special programs include both three or four hour seminars as well as two and three day short courses. Those tentatively scheduled through June of 1987 are:

	1986
November	Computer Organization & Architecture

1987	
January	Database Management Software for Personal Computers
March	Office Automation
May	Computer & Network Security
June	Microcomputer Software for Project Management: An Update

For these "specials," it is clear that the subject matter is completely devoted to computer related subjects. Should this mode continue to be as successful as it has proved thus far, AMCEE will undoubtedly increase the frequency of these open-circuit transmissions. At the same time, the Ku-band network continues to grow as more corporate sponsors and more sites are added, with the expectation that it, too, will cross over into the black during 1987.

NTU COMPUTER ENGINEERING PROGRAM

Frederic J. Mowle, David G. Meyer, Philip H. Swain

School of Electrical Engineering
Purdue University
West Lafayette, IN 47906

Abstract

Live teleconference from Purdue University describing the Computer Engineering Program offered by the National Technological University. Areas to be covered include the degree program requirements, comments by a course instructor, and comments by a university administrative contact person. A live question and answer session is planned.

Background Information

The National Technological University (NTU) was established in Colorado as a nonprofit corporation in 1984. The academic programs offered by NTU draw upon approved course offerings from the 21 participating universities, all of which are members of the Association for Media-Based Continuing Education for Engineers (AMCEE). Although NTU's charter specifically prohibits offering baccalaureate or doctoral degrees, NTU offers selected undergraduate classes from participating universities to assure appropriate foundation for master's level coursework. NTU uses advanced educational and telecommunications technology to deliver instructional programs to graduate engineers and technical professionals at their employment locations. Each NTU site is operated by a sponsoring organization.

Academic Organization

The National Technological University relies upon a faculty consisting of consultants selected from the faculty of each participating institution. These faculty consultants are organized in discipline groups to form Graduate Faculties, typically with one representative in each discipline from each participating institution. At the present time, NTU offers Master of Science degrees in five disciplines: Computer Engineering, Computer Science, Electrical Engineering, Engineering Management, and Manufacturing Systems Engineering. Three standing Committees support each of the various Graduate Faculties. The Curriculum Committee in each discipline develops study programs and reviews all courses submitted by the participating universities. The Admissions and Academic Standards Committee for each Graduate Faculty sets the policies governing admission and criteria for students to continue as active degree candidates. The Staffing Committee in each discipline monitors activities of faculty consultants to assure that the proper faculty functions are performed.

Participating Universities

At the present time, the following universities are cooperating in the various degree programs offered by the National Technological University. The course suffix assigned each university is used to aid in the identification of course offerings.

University	Course Suffix
Boston University	V
Colorado State University	H
Georgia Institute of Technology	J
Illinois Institute of Technology	K
Iowa State University	U
Michigan Technological University	I
North Carolina State University	P
Northeastern University	F
Oklahoma State University	O
Purdue University	M
Southern Methodist University	N
University of Alaska	G
University of Arizona	E
University of Florida	R
University of Idaho	S
University of Kentucky	L
University of Maryland	B
University of Massachusetts	A
University of Minnesota	C
University of Missouri-Rolla	T
University of South Carolina	D

Method of Delivery

The National Technological University has its administrative offices on the campus of Colorado State University in Fort Collins, Colorado. However, the faculty are located on the campuses of the participating universities and the students are located at their work sites nationwide. Instructional programs are delivered by the faculty from the home campuses to the students through telecommunication technology.

The communication links facilitate student advising, faculty conferences, and special programming.

CH2345-7/86/0000/0005$01.00 © 1986 IEEE

Briefly, the NTU distribution system is satellite-based, using a satellite operating in the 12/14GHz (Ku) band. A series of satellite uplink stations located at participating universities has been installed, and television receive-only terminals are located at each organizational site of participating graduate students. The space segment is provided over existing Ku-band domestic communications satellites. The technical operation of the network is controlled from a central headquarters known as the NTU Network Control Center, where schedules are prepared, satellite channels are monitored for technical quality, and return communications (from student to instructor) are coordinated.

To make optimal financial use of satellite transponder time and the realities of the working student's class time, many course transmissions are recorded at the student's site on videotape for use at the convenience of the student. Teleconferencing and electronic mail, using one of the packet-switched networks, are the primary means of interaction between students and instructors.

Computer Engineering

Program Description. The National Technological University Master of Science Degree Program in Computer Engineering provides the means for engineers with a Bachelor of Science in Electrical Engineering, Computer Engineering, or Computer Science to complete the requirements for Master of Science. Applicants are considered only if sponsored by their employing or affiliated organizations. Applicants for admission to this program must submit Graduate Record Examination (GRE) scores. GRE examinations need only include the aptitude test (morning). Students may submit the advanced test in Engineering or Computer Science (afternoon) if they desire. Students must also provide two or three letters of recommendation. Letters from their supervisor as well as a professor, if the applicant has been out of school for less than four years, are required. The additional reference is the student's choice. The Curriculum Committee designed the approved curriculum around the model developed and published by the IEEE Computer Society (1977) and the ACM (1977). However, The National Technological University Master of Science Degree Program in Computer Engineering has the distinguishing characteristic of required "breadth" courses outside the field of computer engineering *per se.*

The Master of Science Degree Program in Computer Engineering consists of 30 semester credits (or the equivalent quarter credits) distributed through three broad categories of courses: Core, Depth and Breadth Courses. In addition, all successful candidates for the Master's Degree must participate in a noncredit seminar. The curriculum features substantial student choice in all three categories of courses, thereby enabling the students to tailor their programs of study to meet their specific needs and fulfill their particular aspirations, all within a coherent framework assuring academic excellence and state-of-the-art preparation. The Breadth Courses expose the students to a spectrum of topics. In this way, the University insures that students become aware of important and emerging areas that might otherwise be overlooked. The NTU curriculum in Computer Engineering remains open-ended with regard to advanced courses in order to encourage the students to take advantage of recently evolved courses concentrating on the latest developments in the field.

Completion of the curriculum requires approximately one and one-half years of full-time, graduate study. Students enrolled through The National Technological University, whose work schedules prevent full-time study, should expect to fulfill the requirements in five years by registering for at least two three-credit courses each academic year.

Academic Advising. Sound and responsive academic advising constitutes an integral part of every program of study offered by The National Technological University. The Admissions and Academic Standards Committee of the Computer Engineering Graduate Faculty assigns to each admitted student an academic advisor, who is a regular faculty member drawn from one of the participating universities and who contributes to the Master of Science Degree Program in Computer Engineering. The academic advisor assists the student to reach informed decisions about the program of study, including course selections. In addition, the academic advisor must approve all petitions for exceptions to the prescribed program of study. Communication between the student and the advisor occurs, in most instances, by telephone, although other media — including regular mail, electronic mail, and personal contact — are also available, depending upon the circumstances in each instance.

Curricular Requirements. The National Technological University offers courses in Computer Engineering and related fields at the "mezzanine" and graduate levels. A mezzanine course is defined as one appropriate for undergraduate students with senior standing or for entering graduate students. However, *only* graduate courses will count toward fulfillment of the Depth Requirements in the Master of Science Degree Program in Computer Engineering. Further, candidates for the degree can count no more than 12 credits earned in mezzanine courses to fulfill the requirements for the Master of Science Degree.

Each student should expect to enroll in ten or more courses with a minimum of three Core Courses, four Depth Courses, two Breadth Courses, one Elective and a noncredit seminar. A total of 30 credits are necessary for graduation. The required curriculum consists of five parts.

Core Requirements

Each student must complete at least eight credits of required Core Courses, with at least one course in each identified area. Core courses are divided into three general areas:

1. Software Systems
2. Computer Architecture
3. Algorithms and Data Structures

Depth Requirements

Each student must complete at least four additional courses consisting of two courses from each of two areas listed below, and all courses taken to fulfill the Depth Requirements must be graduate courses. Depth courses provide instruction on the most advanced and current topics in seven distinct areas, three of which form the Core Requirements described above:

1. Software Systems
2. Computer Architecture
3. Algorithms and Data Structures
4. Digital Design
5. Graphics
6. Intelligent Systems
7. Mathematics and Computational Methods

With the advice of the academic advisor, the student should plan a program of study that assures appropriate depth in at least two areas.

Breadth Requirements

Each student must complete at least six credits in Breadth Courses. Breadth Courses focus on fields that relate to or support the study of Computer Engineering, including:

1. Business Applications
2. Computer-Aided Design/ Computer-Aided Manufacturing
3. Communications
4. Control and Robotics
5. Electrophysics
6. Mathematics
7. Signal Processing
8. Theory of Computing

With the assistance of an academic advisor, the student should plan an integrated program of study that assures breadth overlaying the depth achieved in Computer Engineering.

Elective Requirements

Each student must complete at least three additional elective credits consisting of a Core, Depth, or Breadth Course to bring the total credits to 30.

Seminar Requirements

Each student must complete one noncredit seminar offered by The National Technological University.

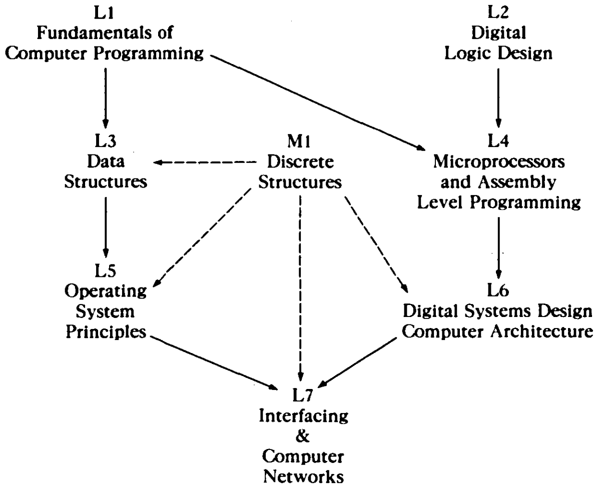
Thesis

The National Technological University offers a nonthesis Master of Science Degree Program in Computer Engineering. However, when desirable and appropriate, as determined by the student in consultation with an academic advisor, a thesis, with a maximum of six credits, can be substituted for the Elective Course and one of the Depth Courses.

Undergraduate Bridging Courses

Applications of computers are pervasive today, affecting the work of most engineers and technical professionals. It is natural, therefore, for people with very diverse technical backgrounds to seek additional education in computing. For that reason, NTU faculty have identified the undergraduate prerequisites which are necessary background for entering graduate study in computer engineering and computer science. Eight undergraduate bridging courses have been identified. Detailed outlines of these courses can be found in the National Technological University Bulletin.

Flow Chart of Undergraduate Computer Science and Engineering Program



L1	Fundamentals of Computer Programming
L2	Digital Logic Design
L3	Data Structures
L4	Microprocessors and Assembly Level Programming
L5	Operating System Principles
L6	Digital System Design - Computer Architecture

L7	Interfacing and Computer Networks
M1	Discrete Structures

The bridging courses are not available for graduate credit.

Courses of Instruction

The National Technological University categorizes the courses of instruction in accordance with the Core, Depth, and Breadth Requirements within the curriculum in Computer Engineering and arrays the courses according to the list that follows. The courses are arrayed by subject matter areas as identified by two-letter prefixes which serve to identify specific subject matter areas (e.g., SS refers to Software Systems, AC to Architecture and Computer Design, DD to Digital Design, *et cetera*). Courses are numbered as they fall within each appropriate subsection. The suffixes following course numbers refer to section offerings and identify the institution offering the individual sections of the course.

Core Courses

Software Systems

SS 10—19	Systems Programming
SS 20—29	Programming Languages

Architecture and Computer Design

AC 30—39	Computer Architecture
AC 40—49	VLSI
AC 50—59	Embedded Computer Systems

Algorithms and Data Structures

AD 60—69	Data Structures
AD 70—79	Analysis of Algorithms

Depth Courses

Advanced Digital Design

DD 10—19	Advanced VLSI Design
DD 20—29	Reliable Computation
DD 30—39	Computer Arithmetic
DD 40—49	High Speed Computation
DD 50—59	Data Communications Systems
DD 60—69	Digital Hardware Design

Advanced Computer Architecture

CA 10—19	Computer Architecture/ Operating Systems
CA 20—29	Distributed Computer Systems
CA 30—39	I/O and Memory Systems Architecture

Systems Programming

SP 10—19	Advanced Techniques in Translator Design
SP 20—29	Advanced Operating Systems
SP 30—39	Data-Base Systems
SP 40—49	Modeling and Performance Evaluation

Mathematics and Computational Methods

CM 10—19	Numerical Analysis
CM 20—29	Computational Methods for Linear Algebra
CM 30—39	Partial Differential Equations and Numerical Techniques for Solving Them
CM 40—49	Stochastic Queuing Theory and Statistical Analysis
CM 50—59	Automata Theory

Advanced Software Techniques

AS 10—19	General Methods for Artificial Intelligence
AS 20—29	Knowledge-Based Systems
AS 30—39	Robotics
AS 40—49	Computer Graphics
AS 50—59	Computer Networks
AS 60—69	Computer Vision
AS 70—79	Programming Languages for AI

Breadth Courses

Electrophysics

EP 10—19	Lasers
EP 20—29	Microelectronics
EP 30—39	Electronic Systems
EP 40—49	Optics
EP 50—59	Field Theory
EP 60—69	Solid State Devices

Communication and Control

CC 10—19	Digital Control Theory
CC 20—29	Digital Communication Theory
CC 30—39	Coding Theory
CC 40—49	Statistical Communications Theory
CC 50—59	Information Theory
CC 60—69	Speech Processing

Special thanks for the success of the program is due to the numerous course instructors, advisors, site coordinators, administrative contact persons, and the staff of NTU who make the program work.

Satellite Presentation

The formal presentation for this session will be divided into three areas. Professor Frederic J. Mowle, Chairman of the Computer Engineering Curriculum Committee, will present an overview of the Computer Engineering program. Professor David G. Meyer, course instructor for CA 30-M, Advanced Microprocessors and System Design Components, will discuss the NTU program from the viewpoint of a course instructor. Professor Philip H. Swain, Director of Continuing Engineering Education at Purdue University, will discuss the NTU program from the viewpoint of a University Administrative Contact Person.

Additional Information

Additional information on the various NTU programs can be obtained from:

THE NTU COMPUTER SCIENCE PROGRAM

SARTAJ SAHNI

UNIVERSITY OF MINNESOTA

ABSTRACT

This paper describes the Computer Science Master's program of the National Technological University, Fort Collins, Colorado.

1. NTU

The National Technological University (NTU) was established as a non-profit private educational corporation in January 1984 in Colorado. Its exclusive mission is to serve the educational needs of graduate engineers and to award master's degrees in engineering related disciplines. Its charter prohibits the award of baccalaureate and doctoral degrees. Currently, NTU offers master's degrees in: Computer Science, Computer Engineering, Electrical Engineering, Engineering Management, and Manufacturing Systems Engineering.

NTU was created with a unique mission: provide graduate engineers a quality master's program in engineering that can be successfully completed by enrollees without leaving their place of employment. It differs from its parent organization AMCEE (Association for Media-Based Continuing Education for Engineers) primarily in that AMCEE does not grant degrees. Through NTU, it is possible for practicing engineers to obtain a master's degree no matter how distant they may be from the university. Further, their progress towards such a degree is not adversely affected by a transfer within their company or between employers that are NTU sponsors. Since all students enrolled in NTU programs must be sponsored by their employers, NTU students changing employers must ensure that their new employer will sponsor them.

In order to best serve its mission, NTU has identified four primary goals [1]: "The discovery, dissemination, application, and preservation of knowledge within designated fields of study, with special emphasis upon those engineering disciplines critical to the continued development and implementation of technology appropriate to an information knowledge-intensive society."

NTU has set itself the following seven objectives [1]:

(1) **The Instructional Objectives**
The University encourages and fosters the development of innovative pedagogical and technological methods to enhance learning and achievement.

(2) **The Creativity Objectives**
The University encourages and fosters the development of creativity among the faculty and students as the most dynamic response to a rapidly changing technological society. In an information, knowledge-intensive age, people must have the developed capacity to glimpse the future as it unfolds and to act to shape it. The National Technological University research seminar is directed to this end.

(3) **The Student Relations Objectives**
The University stresses the responsibility of the faculty to the professional as well as instructional needs of the students and the responsibility of the students for their own individual growth and development.

(4) **The Human Resources Objectives**
The University selects as participating faculty only those persons with reputations for outstanding performance as teachers and scholars, and offers selected programs to assist these faculty members in their own professional development.

(5) **The Support Objectives**
The University provides the facilities and services essential to the fulfillment of the institutional mission. Moreover, the University strives for the refinement and development of technological means to enhance the quality of the facilities and services.

(6) **The Organization and Administration Objectives**
The University maintains a supportive organization and administrative structure that rests firmly upon participatory management and academic programs.

(7) **The Evaluation Objectives**
The University maintains a process of continuous evaluation of programs and services to ensure progress toward the achievement of institutional goals.

There are three distinct aspects to NTU:

(1) **NTU Administrative Services**
These are responsible for policy, admissions, maintenance of records (including grades), award of degress, etc. The NTU office in Fort Collins, Colarode provides these services.

(2) **Participating Universities**
These are schools from which NTU obtains the courses that it provides its students. All courses offred by NTU are regulary offered to graduate students at the participating universities. These courses are typically offered in specially equipped classrooms at the participating university campus. The lectures including any discussion and question/answer sessions are either broadcast live over satellite to sites at which NTU students are located or are taped and then viewed with time delay at these sites. In the case of live satellite broadcast, there is provision for a talk back channel. So, it possible for NTU students to ask questions in real time.

CH2345-7/86/0000/0011$01.00 © 1986 IEEE

(3) **Sponsoring Organizations**
These are the entities that are permitted to enroll their employees in NTU programs. Each sponsoring organization must maintain suitable equipment at each of its instructional sites for the receipt and viewing of the lectures. To receive courses over satellite, a down link is needed.

The universities that are participating in the NTU program are:

(1) Boston University
(2) Colorado State University
(3) Georgia Institute of Technology
(4) Illinois Institute of Technology
(5) Iowa State University
(6) Michigan Technological University
(7) North Carolina State University
(8) Northeastern University
(9) Oklahoma State University
(10) Purdue University
(11) Southern Methodist University
(12) University of Alaska
(13) University of Arizona
(14) University of Florida
(15) University of Idaho
(16) University of Kentucky
(17) University of Maryland
(18) University of Massachusetts
(19) University of Minnesota
(20) University of Missouri-Rolla
(21) University of South Carolina

The sponsoring organizations are divided into two categories: corporate subscribers and major site subscribers. The corporate subscribers are:

(1) AT&T
(2) Digital Equipment Corp.
(3) Eastman Kodak Co.
(4) General Electric Co.
(5) CTE Spacenet Corp.
(6) Hewlett-Packard Co.
(7) Intel Corp.
(8) IBM Corp.
(9) Motorola
(10) NCR Corp.
(11) Tektronix, Inc.

The major site subscribers are:

(12) ALCOA
(13) General Dynamics Corp.
(14) General Instruments
(15) Honeywell, Inc.
(16) Magnavox Co.
(17) RCA Corp.
(18) Sandia National Labs.

A sponsoring organization may have several sponsoring sites. There are approximately 75 sponsoring sites at present.

In the remainder of this paper, I shall provide an overview of the NTU master's program in Computer Science. This overview is not intended to serve as a substitute for the NTU Bulletin [1]. Persons interested in knowing the exact admission and graduation reuirements should read this bulletin carefully.

2. ADMISSION REQUIREMENTS

To be admitted to the NTU master's degree in Computer Science program, the applicant must have successfully completed a Bachelor of Science Degree in Computer Science or a related field. All applicants are also required to perform satisfactorily in the aptitude test of the Graduate Record Examination (GRE). In addition, applicants may be granted provisional admission to enable them to make-up deficiencies prior to obtaining regular graduate admission.

3. THE COMPUTER SCIENCE CURRICULUM

The Master of Science Degree Program in Computer Science consists of 30 semester credits (or the equivalent quarter credits). These must be appropriately distributed over the three broad categories of courses: Core, Depth, and Breadth. In addition, participation in a seminar is required.

CORE COURSES

The general categories for the core courses are:

(1) Algorithms and data structures
(2) Software systems
(3) Computer architecture
(4) Mathematics and theory of computation
(5) Artificial intelligence

DEPTH COURSES

The categories for the depth courses are listed below. Together with each such category, a sampling of some of the topics included in the category is provided.

(1) **Computer Software**
- Structure of higher level languages
- Translators
- Operating systems
- Database systems
- Software engineering
- Programming and algorithms for supercomputers
- Computer networks
- Computer graphics
- Security and protection mechanisms

(2) **Computer Architecture**
- Computer architecture operating systems
- Distributed computer systems
- I/O and memory systems architecture
- Supercomputer architecture
- CAD tools for VLSI design

(3) **Mathematics & Theory of Computing**
- Numerical analysis
- Methods for supercomputing
- Design & Analysis of algorithms
- Modeling and performance evaluation
- Automata theory
- Formal languages
- Complexity theory

(4) **Artificial Intelligence**

- General methods for artificial intelligence
- Knowledge based systems
- Knowledge representation
- Natural language processing
- Computational epistomology
- Logic programming
- Robotics
- Computer vision
- Speech recognition
- Pattern recognition

BREADTH COURSES

The general categories and a sampling of example topics within these categories are summarized below:

(1) **Operations Research**

- Linear Programming
- Integer Programming
- Nonlinear Programming
- Queueing Theory
- Dynamic Programming
- Stochastic Methods
- Combinatorial Optimization

(2) **Electrical Engineering**

- VLSI Technology & Design
- Coding & Information Theory
- Computer Hardware Design
- Computer Communications

(3) **Business Applications**

- Management Information Systems
- Computer Methods In Management

(4) **Mathematics**

- Combinatorics
- Graph Theory
- Statistics
- Probability
- Recursion Function Theory
- Logic

NTU is able to provide a very rich selection of courses in each of the above categories. This stems from the fact that NTU gets its courses from its participating universities. These universites together have a combined engineering faculty in excess of 2,800. The number of different computer science and related courses taught at these universities together is far larger than the number of such courses taught at any one of these universities. In fact, it is safe to say that NTU's course offering, in computer science, is richer than that of any single university in the country.

4. CREDIT DISTRIBUTION REQUIREMENT

The required 30 NTU credits should satisfy the following distribution:

(1) At least one course from each of the five core categories.

(2) At least three courses from any one of the depth depth categories.

(3) At least one course from a breadth category.

To meet the needs of students whose Bachelor's degree is not in Computer Science, NTU offers three bridging courses:

(1) Computer Programming

(2) Discrete Structures

(3) Data Structures and Algorithms

Credits earned for bridging courses cannot be applied towards the 30 credits required for a master's degree.

5. 1985-86 ENROLLMENT FIGURES

While NTU first started offering courses in Fall semester 1984, the Computer Science program became available only in Fall 1985. The enrollment figures for the 85/86 academic year are summarized in Table 1. The entries in this table are total course enrollment counts. Thus the sum of the number of students enrolled for credit in each course in the Fall semester was 232. The actual number of students taking courses for credit in this semester may be slightly less as it is possible for one student to take several courses in a given semester. The number of different courses made available during the academic year exceeded 130. A little over 40 of these were actually subscribed to by NTU students.

	Fall	Winter & Spring	Total
Credit	232	200	432
Audit	92	105	197
Total	324	305	629

Table 1 1985/86 enrollment figures

In addition, 16 courses were made available for the summer 1986 session. Enrollment figures for this session were not available at the time this paper was written. As is evident, the Computer Science program is off to an excellent start. Enrollments are expected to climb significantly in the next few years.

6. MEDIA

NTU is committed to the use of state of the art technology to provide the best delivery of its courses. Many of the courses are broadcast live over satellite. The satellite link prvides for a color transmission of the video. A two way audio channel is also used. This permits live interaction with remote students. The remaining courses are viewed with a time delay. These get to the viewing sites either via satellite transmission during off peak hours or via video tapes express mailed to the viewing sites. Live tutorial sessions are organized for courses that are not broadcast live. This gives students an opportunity for live interaction with the instructor and/or the teaching assistants.

The lectures may be viewed by students at a time convenient to them. This is true even in the case of live broadcasts as viewing sites have video taping facilities and taping authorization. This flexibility is essential to the success of the NTU program as all its students are full time employees. Their primary responsibility is is to their employers. With NTU, students need not organize their work schedules around their class activities. Rather, the class activities are made to fit around the work schedule.

Interaction with the instructor and teaching assistants may take the form of telephone conversations or communication via AT&T mail or the US postal service. Initial data indicates that only about 10% of the students are currently using AT&T mail. The use of this powerful electronic communications system needs to be encouraged as a convenient way to ask and answer questions that are of interest to all students enrolled in a given course. Further, this could provide a fast inexpensive mechanism to get assigments to and from remote sites. The delay currently involved in doing this poses a serious problem. NTU is currently exploring the possibility of adding an analog signal to the end of its video signals. This analog signal will encode classroom handouts. Thus, these will become available at the same time as the lectures.

7. SUMMARY

NTU has begun a new era of educational delivery. It promises to bring quality education leading to a graduate degree into the work place. By combining the educational resources of the country's leading institutions, NTU is able to provide curricula that is richer than found at any one of these institutions. In fact, the services of NTU could also be benificially used by participating (as well as nonparticipating) universities to enrich their own offerings.

It is anticipated that by the end of this decade, NTU will become one of the top producers of M.S. degrees in engineering.

8. ACKNOWLEDGEMENTS

I am grateful to Dr Lionel Baldwin, President, NTU for providing some of the data used in this paper and also for authorizing the use of material from the NTU Bulletin [1].

WORKSTATIONS AT CARNEGIE MELLON

Bruce Arne Sherwood

CDEC, Carnegie Mellon, Pittsburgh PA 15213

ABSTRACT

Carnegie Mellon University intends to deploy advanced-function workstations for students, faculty, and staff. The basic goals and the organizational structures created to attain those goals are described. Several hundred workstations are currently deployed. There is an overview of the Andrew and CMU Tutor software environments.

In 1982 Carnegie Mellon University (CMU) established the goal of giving all students ready access to the wealth of information made possible by personal computers, and providing the kind of computational environment that would enhance learning. At the same time, faculty would use these computers for research and teaching, and the university itself would benefit, both in improved administrative functions and more rapid communications.

Some other universities have adopted the goal of providing every student with a personal computer, but CMU's plan is unusual in emphasizing advanced "workstations" which are much more powerful than typical personal or home computers[1]. While these workstations are rather expensive today, the rapid pace of computer evolution insures that these tools will be inexpensive and widely available in the late eighties. Because it takes significant lead time to integrate any computer system into university life, Carnegie Mellon started early to deploy and exploit machines which will constitute the next generation of personal computers.

Another important component of the Carnegie Mellon plan is to link these workstations together, giving students, faculty, and staff immediate access to up-to-the-minute programs and data. Fiber-optics links between all major campus buildings already exist. By the fall of 1986, IBM token-ring networks will be installed inside the buildings to distribute information to offices, classrooms, and to student residences.

ORGANIZATIONAL STRUCTURE

When the project was conceived, a contract between Carnegie Mellon and IBM established the Information Technology Center (ITC) to develop system software to support large-scale deployment of workstations. ITC, led by its director and computer scientist James Morris, has focused on two major aspects of the challenge: (1) a file system to support several thousand networked workstations, and (2) a friendly, graphics-oriented operating framework for users of workstations. Representatives from IBM work closely with professional system designers, CMU graduate students, and consultants from the Department of Computer Science, doing the basic research and development necessary to create this large-scale system. While much remains to be done, the system is already operational and heavily used. The various system-software components built by ITC are collectively called the Andrew system[2,3], honoring Andrew Carnegie and Andrew Mellon.

The university also set up the Center for Design of Educational Computing (CDEC) to help create educational applications. The cognitive psychologist Jill Larkin was the first director of CDEC, and the new director is the philosopher Preston Covey. CDEC consults with faculty, provides seed money for educational projects, develops software tools to assist educational programming, and runs a seminar series and newsletter. CDEC serves as a liaison between faculty and ITC, helping both groups define and refine the computing environment necessary for education.

The environment for developing educational computer applications is enhanced by CMU's strong Department of Psychology with its special strength in cognitive psychology, the study of thinking. The expertise on learning from the Department of Psychology, combined with the technical expertise of members of the Department of Computer Science, promises to provide exceptional new opportunities for students to learn and for faculty to explore new ways to teach. Already, unusual "artificially intelligent" tutoring programs exist which will be increasingly useful as Carnegie Mellon installs workstations capable of handling these complex programs.

The nature of the new generation of powerful, sophisticated computers has made it possible for ITC to develop system software which operates on a variety of different computers. This will greatly reduce the current severe problems of obsolesence and of incompatibility which plague educational computing. To encourage the kind of sharing that is so important in an undertaking of

CH2345-7/86/0000/0015$01.00 © 1986 IEEE

this size, CDEC works closely with the Inter-University Consortium for Educational Computing (ICEC), headed by Ken Friend, who is stationed at Carnegie Mellon. The Consortium includes major universities which are strong in the computing field, such as Brown, Cornell, Michigan, MIT, and Stanford. For balance of viewpoints and needs, ICEC also includes some smaller schools such as Vassar and Mills. Through collaboration among these universities and colleges, the Consortium hopes to convince computer vendors that it is worthwhile to develop compatible systems. If exceptional educational software developed at one institution could be readily adapted to the needs of others, the total equipment market would be much larger than it is now.

Older organizations are playing new roles. The user services section of the university computing center now offers short courses on how to use and program the workstations. The university library in association with CDEC has created a software library with acquisition and cataloging functions.

All of these organizations report to William Arms, vice president for academic services. John P. Crecine, senior vice president for academic affairs, has played a central role in formulating policies and plans concerning the workstation project.

DEPLOYMENT HISTORY

In January 1985 fifty workstations were placed around the campus to give faculty an early look at the system and to start developing educational applications. In January 1986 the first public cluster of advanced workstations was made available for shared student use. This cluster contained twenty-four IBM RT PC's. By fall 1986 there are expected to be several hundred workstations on campus, with about a hundred of them in public clusters. At present, even with quantity educational discounts workstations cost close to ten thousand dollars, which precludes individual student ownership. However, by the late eighties prices should drop considerably, enabling students to buy any of several brands of compatible advanced workstations in the campus computer store.

Although some students were involved as programmers from the beginning of the project, other kinds of student use were limited due to lack of public machines. In the spring of 1986 other students could begin to take advantage of the new resources[4]. For example, undergraduate architecture students used a powerful structural design package to synthesize and visualize buildings, and students in a graduate physics course on non-linear dynamics used a sophisticated function plotter.

THE SOFTWARE ENVIRONMENT

The machines deployed at CMU (currently including IBM RT PC's, DEC Vaxstation 2's, and Sun workstations) all use the Berkeley Unix 4.2 operating system, which is a key to compatibility of applications. The Andrew file system software (called Vice) intercepts Unix file references and converts these references into calls to file servers to which the workstations are attached. Each file server handles about thirty workstations, and the file servers are connected to each other by a high-speed backbone link. As a result, a user can log in to any workstation anywhere on campus and file access is completely transparent. Whole files are transferred over the network and cached on a local hard disk. The workstation receives a message from a file server if the server has a newer version of a previously cached file. While there exist many implementations of networked personal computers, Vice is unusual in being designed from the beginning to be expandable to several thousand workstations while providing good security for data.

The Andrew programmer and user interfaces (called Virtue) consist of a window manager, a text-processing subroutine library, a database subroutine library, and applications such as editors, mail, and bulletin boards. The Andrew window manager will soon be replaced by the X window manager built by MIT, in order to enhance compatibility above that provided by the underlying Unix. The text-processing subroutine library, called the Base Editor, provides powerful display and manipulation of text, including italics and centering, scroll bars, and real-time justification within a rectangle. Because it is a subroutine library, not a text editor, it is easy to invoke a sophisticated text editor inside one's own program. It also has a marker facility which will keep track of a part of a file and inform the surrounding program when a marked section has been changed. The Base Editor library will soon be replaced by a new "Multi-Object Environment" which has the important enhancement of permitting "insets" to be contained in documents. These insets can be equations, graphs, tables, etc. Cutting and pasting text containing these non-text items will be as easy as current text operations.

CMU TUTOR

While the system software is written in C, this language is not well suited for applications programming by non-expert programmers. To give such people the ability to create complex interactive graphics programs which exploit the rich capabilities of the workstation environment, Bruce and Judith Sherwood have created a programming environment called CMU Tutor[5,6,7,8]. While patterned on the MicroTutor language developed in the PLATO project at the University of Illinois, CMU Tutor has enhancements for the workstation environment, including pop-up menus, variable window size, mouse support, etc. Thanks to the Base Editor keeping track of which routines have been changed and therefore need recompilation, CMU Tutor operates as an incremental compiler, which combines the revision speed of an interpreted language with the execution speed of a compiled language. A tightly integrated graphics editor generates source code from a display created using the mouse. An on-line help facility not only describes the language features in detail but provides sample routines which can be run immediately thanks to the multi-window and incremental-compiler environment.

During the summer of 1986, the Carnegie Foundation of New York funded four one-week workshops on advanced-function workstations and CMU Tutor for faculty and support staff at universities in the Interuniversity Consortium for Educational Computing. The workshops were held at Carnegie Mellon, and in less than one week many workshop participants created significant interactive graphics programs written in CMU Tutor. IBM funded an additional week of workshops for people from some non-ICEC universities.

Work is underway to be able to execute CMU Tutor programs on popular micros, including the IBM PC and the Macintosh. A limited authoring capability will also be available, although the workstation environment is a more productive one for the creation of new materials.

INTELLIGENT TUTORING SYSTEMS FOR PROFESSIONALS

ALAN M. LESGOLD

Learning Research and Development Center
University of Pittsburgh
Pittsburgh, Pennsylvania 15260

Abstract

Tools are becoming available for developing intelligent tutoring systems to teach professional and technical jobs. One basic tool is a method for analyzing jobs that involve considerable problem solving, such as electronics troubleshooting. A second tool is a combined device simulation and hypertext design capability. Combined with recent developments in cognitive instructional science and artificial intelligence, these tools promise affordable and efficient computer-based tutors that can speed up on-the-job learning.

Introduction

So far, most of the intelligent tutoring systems that have been built have aimed at relatively simple educational goals. However, it is now possible to build systems that can address the very job-specific, complex tasks that professional and technical workers face in our rapidly changing society. While many approaches seem worthy of investigation, I favor job-situated, coached practice as the basic approach.

In such an approach, a series of problem forms are developed that afford opportunities to exercise the various bits of knowledge one wants to teach. Trainees work through these problems in a cognitively real simulation environment, receiving coaching as necessary. Decisions about which variants of which problems to present and how to coach are made intelligently on the basis of aspects of the trainee's performance. This means that the following capabilities, among others, are needed to build such a tutoring system: (a) a curriculum goal structure to motivate the choice of problem forms and variants; (b) a cognitively-real simulation of the work environment, within which problems can be posed; (c) adequate knowledge about how people at different levels of skill think and act as they attempt to solve the problems that will be posed. In the sections that follow, two tools are described that contribute to developing these components. A task analysis methodology is described that can drive the development of the curriculum, as is a tool for building the simulated work environment.

Effective Problem Space Descriptions: A Tool for Cognitive Task Analysis

In order to decide what to teach, it is necessary to do task analyses of the jobs that trained professionals are asked to perform. Because the jobs a professional does are largely thinking jobs, cognitive task analyses are required — we need to know how professionals think their way through problems. In our own work, we have found it useful to begin by identifying an expert who has to contend with the problems produced by inadequate training. Such a person can be helpful in identifying classes of problems that the target group of professionals should be able to solve but often are not. We then work with the expert to develop an effective problem space for each such problem. That is, we ask the expert to describe how he would solve the problem and then probe deeply for alternative solution methods that either other experts or trainees might conceivably take.

We then use a differential empirical strategy to verify the expert's analyses. We take other experts, new professionals who are doing well, and new professionals who are having difficulties and ask them all to solve the problems for which we have preliminary effective problem spaces developed. The general differences between fast-track and slower new professionals are used to develop a set of goals for the tutor, its curriculum. The specific differences in problem solution paths are used as a basis for the part of the tutor that coaches problem solving performance. So, a trainee is constantly solving problems that are known to separate faster and slower newcomers to the profession, and the tutor is prepared to coach, assist, and demonstrate the steps that newcomers are likely to find difficult.

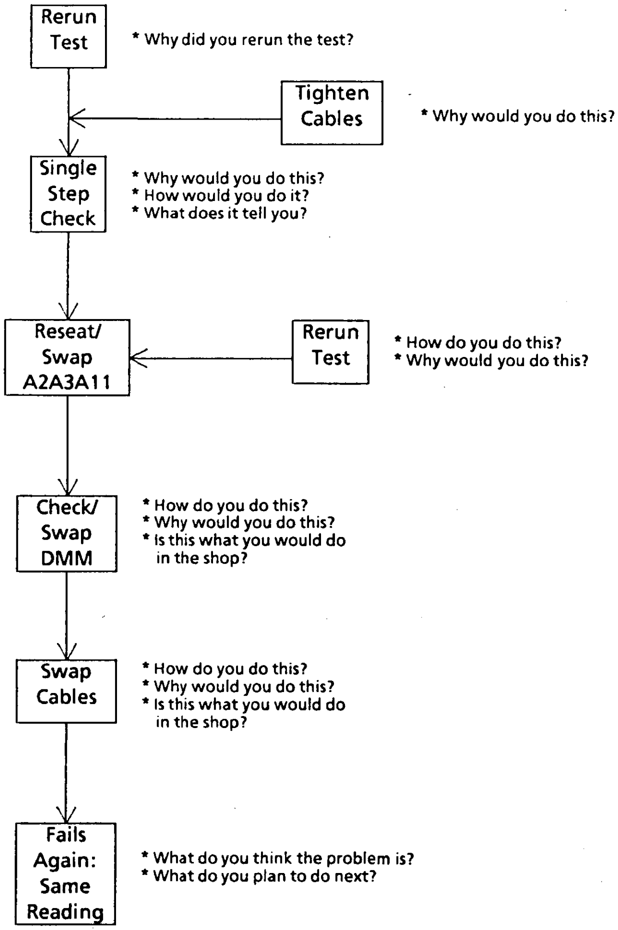
A few specifics

The approach my colleagues and I have used can be made clearer by looking at an example. One of our projects is to develop a tutor for a particular Air force specialty in which manual (non-automated) test equipment is used to diagnose and repair faults in navigational equipment for a particular airplane, the F-15. To carry out this project, we needed to find out what was difficult about this job, which involves massive amounts of electronic circuitry. Our breakthrough came not so much from our psychological expertise but rather from interactions of three of us (the author, Debra Logan, and Susanne Lajoie) who had substantial cognitive psychological training with an electronics expert (Gary Eggan) who had extensive experience watching novice troubleshooting performances. He pointed out that it was quite possible to specify the entire effective problem space, even for very complex troubleshooting problems. That is, he could almost completely specify all of the steps that an expert would take as well as all of the steps that any novice was at all likely to take in solving even very complex troubleshooting problems. In this case, the task was to find the source of a failure in a test station that contained perhaps 40 cubic feet of printed circuit boards, cables, and connectors, but various specific aspects of the job situation constrained the task sufficiently so that the effective problem space could be mapped out.

This then created the possibility that we could specify in advance a set of probe questions that would get us the information we wanted about technicians' planning and other metacognitive activity in the troubleshooting task. For what is probably the most complex troubleshooting task we have ever seen, there are perhaps 55 to 60 different nodes in the problem space, and we have specific metacognitive probe questions for perhaps 45. Figure 1 provides an example of a small piece of the problem space and the questions we have developed for it.

An examination of the questions in the Figure reveals that some are aimed at very specific knowledge (e.g., *How would you do this?*), while others help elaborate the trainee's plan for troubleshooting (consider *Why would you do this?* or *What do you plan to do next?*). Combined with information about the order in which the trainee worked in different parts of the problem space, this probe information permits reconstruction of the trainee's plan for finding the fault in the circuit and even provides some information about the points along the way at which different aspects of the planning occurred. In fact, we went a step further and also asked a number of specific questions about how critical components work and what their purpose is. Finally, when a trainee was headed well away from a reasonable solution path, we would, at preplanned points, redirect his efforts back to more fertile ground.

Figure 1
Examples of Problem Space Probes



After reviewing the records of performance in our tasks, we developed six scales on which we scored each airman. Each of these scales could be further subdivided into subscales to permit more detailed and task-specific issues to be addressed. The six scales were titled *plans, hypotheses, device and system understanding, errors, methods and skills,* and *systematicity.* Table 1 gives two examples for each scale of the items for which points could be earned (in the error scale, more points means more errors and thus is a lower score).

Table 1
Examples of Items Counted in each Subscale

Plans
- Extend and test a card.
- Trace through the schematic of an individual card.

Hypotheses

- There is a short caused by a broken wire or a bad connection.
- The ground is missing from the relay.

Device and system understanding

- Understanding and use of the external control panel.
- Understanding of grounds and voltage levels in the test station.

Errors

- Misinterpreting/misreading the program code, called FAPA, for a test that the test station carries out under computer control.
- Getting pin numbers for a test wrong.

Methods and skills

- Schematic understanding: Ability to interpret diagrams of relays, contacts, coils.
- Ability to run confidence check programs.

Systematicity

- The subject returns to a point where he knew what was going on when a dead end is encountered.
- The path from the power source is checked.

Plans was a count of the number of plans mentioned by the subject during his problem solving efforts. Any time that the subject entered a new part of the problem space, we prompted for a plan, but the lower skill subjects, especially, often did not have one. That is, they more or less randomly acted until a plan or hypothesis came to mind. A count was kept of the number of hypotheses offered by subjects at various points in their work. Again, subjects were prompted for hypotheses at the predetermined boundary points between regions of the problem space. The high-skill newcomers entertained more hypotheses, which is what we would expect given that even they are at intermediate skill levels. True experts were be expected to have a more constrained set of probable hypotheses.

The *device and system understanding* scale was based upon specific questions that were put to the subjects after they had performed the troubleshooting tasks. We asked a fixed set of questions about each of the components of the test station that played a role in the problems we had posed. These questions probed for knowledge about how the component worked, what role it played in the test station, what its general purpose in electronic systems was, and what it looked like.

The *errors* scale was simply a count of the number of incorrect steps taken by the airman in trying to troubleshoot the system.

The *methods and skills* measure tallied which of the procedures needed to carry out the troubleshooting of the test station were successfully demonstrated by the subject.

Finally, the *systematicity* measure consisted of a set of relatively broad criteria gauging the extent to which troubleshooting proceeded in a systematic manner rather than haphazardly or without a sense of goal structure.

This, then, provided a first, relatively global view of the skills that separated high and low skill first-term airmen. We found out quite a bit from these analyses. High skill airmen differed on most of the measures, except for *Plans*. Looking a bit more closely, the higher-skill airmen seemed not to be less inclined to engage in metacognitive activity; rather, their planning was more general, less conditioned to the specific point in a specific problem solution at which they found themselves. This suggested to us that it might be necessary for us to teach very much in the context of the skill domain. It wasn't that the high-expectation airmen were more likely to use general planning strategies. Rather, they were only better at concrete, domain-specific variants of those planning methods. The missing knowledge to be taught to less-promising airmen was domain-specific planning, plus some specific skill components, such as tracing schematics and using meters for active-circuit measurement. Thus, we had a basis for specifying our curriculum.

However, the knowledge coming from the six scales, or even from slightly more specific tallies, was insufficient to drive the specification of our problem types. To do that, we needed to be able to look at additional qualitative aspects of job-domain performance. An impressive example of how to do this was provided by Christopher Roth, an LRDC student working at HumRRO in Alexandria, Virginia. He took our methods and applied them to a slight variant of the domain we studied. He also used the same domain expert (Gary Eggan). However, he spent more of the total effort comparing the specific problem-space paths of experts and novices. The next few figures illustrate the yield of this work.

Roth worked with Eggan to develop a collection of diagnosis problems that were characteristic of real problems faced in the work environment and that were likely to be solved correctly by the best technicians and not by many of the less-skilled first-term airmen. People with experience in handling the tasks on which many airmen have difficulty tend to have a good sense of the kinds of problems that are in this class (problems that are representative of the domain, solvable by the better technicians, and not solvable by a substantial number of workers), and Eggan's advice has proven itself empirically. Figure 2 illustrates the effective problem space that Eggan helped Roth construct for the problem. It was felt that the bulk of problem solving activity would fall within this space, for both experts and less-skilled

workers.

Roth and Eggan then proceeded to run subjects on this task. The problem was posed verbally to airmen who had access to the full set of Technical Orders (documentation for the devices involved). Technicians were encouraged to offer their hypotheses, state their plans, and announce specific steps they would take in attacking the problem. Whenever an overt step was stated by a technician, he was immediately informed of the outcome of that step.

Figure 3 shows the basic results that Roth obtained. The experts, whose performance is outlined with a solid line, used a subset of the effective problem space, avoiding some of the steps that were less likely to be productive. The novices, whose empirical problem space is outlined in heavy dashes, failed to make some of the expert moves and did make some moves that experts would not make, such as swapping a disc pack (see bottom left of Figure 3. Further, their empirical problem space was discontinuous, a set of islands.

To better understand what knowledge separated the experts from the novices, Roth and Eggan then tried to determine the specific knowledge that experts used at critical points in the problem space. Knowledge involved in making a move that experts make and novices do not is a clear candidate for inclusion in the curriculum. At the individual problem tutoring level, a wrong choice at a decision point in the effective problem space then becomes a mandate for specific instruction on the knowledge that could have led to correct performance.

Several things became clear from this work. First, there will be a lot of variability from one trainee to the next, so that the coaching for this sort of problem solving performance cannot be prespecified completely. Rather, some online intelligence will be required. Second, the summary measures of planning, systematicity, etc., do not provide the detail on which instructional design and specific coaching must be based. Third, the validity of any conclusion about what a trainee is doing during an effort to solve one of our problems must rest on a pattern of logical relationships among the observed details of performance, the expert knowledge of the domain, and the cognitive psychology of expertise. That is, it is reasonably easy for an electronics wizard and a cognitive psychologist to get a good picture of what knowledge a novice has or does not have, through cognitive extensions of rational task analysis approaches. This is a form of diagnosis more like what a physician does in an individual case than like what a testing expert does. Fourth, the scientist can reasonably ask what empirical support there is for this approach. Several successful analyses of technical jobs have taken place, in three different laboratories, but continued work is needed.

Simulating the Work Environment

I turn now to a totally different kind of tool, a software tool. Given the goal of building a problem-based tutor, we need to be able to simulate the job world in which the problem solving takes place. Here, I also have an interesting discovery to report. Like a number of laboratories, ours has been working on tools for simulating devices. By a device, I mean a network of objects that pass information between themselves. for example, a resistor circuit can be thought of as a set of objects, batteries and resistors perhaps, that pass information about current and voltage along paths that correspond to wires. To simulate a resistor circuit, we need to specify a method for each object that permits it to demonstrate its behavior. For example, a resistor is an object that, given modifications in its resistance, changes the current it will pass at a given voltage, according to Ohm's Law.

Of course, a device simulation must also model the behavior of the device as a whole, and that overall behavior is constrained by properties of its components, too. Further, simulated of response to changes must be instructive, which may require a departure from reality at times, but that is not the issue I want to address in this paper. What is critical for the present purposes is that a device model must be prepared to illustrate both local component behavior and overall system behavior.

It rapidly occurred to my colleagues Jeffrey Bonar and John Corbett that this loca/global distinction can be applied recursively. A computer has as components a number of subdevices; they in turn are composed of boards; the boards are composed of chips; many of the chips are arrays of logic gates. Thus, what we really have to be able to simulate is an entity that has an overall functional description and also a description in terms of the behaviors of its individual components. Corbett has built a system that can do this, called Flowchips. It is still evolving, but we already know that it is a very powerful tool, both for providing an environment in which problem solving activity can take place and also for providing explanatory simulations of complex objects.

The next step in the story represents a stroke of genius, for which Bonar and Corbett, not I, deserve the full credit. They realized one day that hierarchical displays of devices are no different from hierarchical displays of texts. Indeed, texts can be included as components of devices, too. They are special components, perhaps, that don't necessarily change; or they are labels; or they are function descriptions that changed as parameter thresholds are crossed, as in labels on a capacitor that might say *charging* or *discharging* or *saturated*. They can also be terse statements of function that can be "opened up" to reveal more detailed statements of function, just as a chip might be opened up to reveal its logic-gates contents.

In the limit, then, a device model is more or less like a hypertext system. Information is presented at multiple levels of detail in multiple media (for us, currently, line drawings and text). However, it also has some special properties. The entities of which it is composed are not passive. They propagate changes in themselves throughout the simulation system; they respond to the student or trainee not only by elaboration, but also by demonstration, by explanation, and most importantly by affording opportunities for manipulation.

In an idea processor, the user can change an entry, but the change is passive. In the Flowchips system now under development by Corbett and Bonar at the Learning Research and Development Center, the user can make changes that affect the entire system and can then open up the system to examine those changes. For example, changing a few switch settings might totally change which parts of a complex circuit are active and also change the texts that explain what different parts of the circuit are currently doing. It is this level of device simulation that we believe is crucial.

One final viewpoint on such change propagations is worthy of note. If a change that has to do with a parameter being simulated, such as voltage, can be propagated through the system then it should also be possible to propagate changes having to do with pedagogy, such as advice that a particular student reads poorly, has trouble interpreting graphics, speaks only a particular language, is a computer scientist, not an electrical engineer, etc. Hopefully, we can move beyond our current efforts, which are much more mundane, and consider adding directly to the device simulation two other component objects, a student model and a teacher of sorts.

In a real device, certain changes in parameter values can be catastrophic. For example, pouring cold water into a very hot steam plant can be deadly. In the kinds of device simulations that now appear to be possible, whether the simulation explicitly makes a big fuss about such an act should be mediated by an intelligent system that decides whether focusing attention on the catastrophic implications of the last step taken will be useful in teaching the student. Similarly, while there are many aspects of a circuit to which an expert should attend, an active simulation might elide over some components and concentrate on others to which a novice should be particularly attentive or which relate to an active instructional goal.

AN APPROACH TO TYPE SAFETY IN A TRAITS SYSTEM

Gael Curry

Sequent Computer Systems

Abstract

This paper extends some of the multiple inheritance subclassing ideas developed for use in early versions of the Xerox Star workstation. It first shows how to capture the class hierarchy in compiler-visible form. Next it shows how to attribute a useful notion of "type" to instances. Then it shows how a compiler and a programmer relate to this approach.

1. Introduction

This paper describes an approach to supporting type-safe multiple-inheritance object-oriented programming. It is the outgrowth of experience with traits as supported in the Mesa language for Xerox Star.

For completeness, the paper will first describe what traits are, how they were used in Star, and what the problems were.

Then, it will describe how to embed a multiple-inheritance class hierarchy in compiler-visible structures, and discuss the meaning of type-safety in these terms.

2. Traits

This section reviews the central ideas behind traits and compares them to similar facilities in other environments.

2.1. Basic Concepts

A "trait" is a property that an object may have which allows clients to interact with the object in a certain way. To a client, a trait appears as a set of operations, any of which may be applied to any object carrying the trait. For example, the trait "stores_integer" may have two associated operations: put_integer and get_integer.

A trait does not capture the essence of an object. It captures the essence of a property of an object. In this respect it is different from an "abstract data type". Traits are, however, similar to abstract data types in the sense that they are information-hiding encapsulations of (properties of) objects.

Traits can be mixed rather freely in objects. Often primitive traits are independent of other primitive traits, such as "stores_integer" and "has_name". Under these circumstances, it is quite natural for objects to carry several traits.

Several traits can also be combined into more complex traits. For example, "is_integer_variable" could be considered to be the combination of "stores_integer" and "has_name". These compound traits can then be carried by objects.

A "class" (for a given trait) is something which generates instances whose only property is the trait, and, by implication, its subtraits.

Traits are described in greater detail in [Curry81] and [Curry83].

2.2. Similarities to Other Environments

The idea of primitive abstractions which can be combined into more complex ones has been used elsewhere.

In Smalltalk [Goldberg83], the rough analog to trait is "abstract class", a class without instances. The "carries" relation on traits corresponds to the "superclass" relation on classes. See [Borning82] for a description.

In KEE, the rough analog to traits are "units". See [Intelli83].

CH2345-7/86/0000/0025$01.00 © 1986 IEEE

In various versions of LISP, "flavors" are the analog to "traits" [Weinreb80]. The LOOPS extension to Interlisp also has corresponding concepts [Bobrow83], [Stefik85].

A comprehensive comparison of the various approaches can be found in [Carnese84].

2.3. Differences from Other Environments

While conceptually similar to the various other mechanisms previously mentioned, traits were motivated by different types of concerns. The approach arose out of the need to control the complexity in the Star implementation by increasing the reusability and sharability of common program fragments. Subclassing first, and multiple-inheritance second, helped to accomplished this.

There was another point of departure. It was vital that the implementation of multiple-inheritance be lightweight. For this reason, message-passing approaches to supporting multiple-inheritance were rejected. Message-passing is an expensive way of implementing inheritance in cases where the very dynamic binding permitted by message-passing is not required.

Since it was acceptable to hold the class structure constant for a particular build of Star, it became possible to precompute (at load-time or earlier) all of the values inherited by a class.

A more subtle difference between traits and more dynamic systems also exists. The central traits notion is that of an abstract specification of a property of an object; the semantic specifications of trait operations are the constants. Other schemes seem to focus more on message passing; message names are the constants. At issue is whether alternate methods selected by a given message need to meet a given specification.

3. Traits in Star

This section discusses the use of traits in Star: the programming conventions, binding times, and type-safety. The casual reader can skip this section.

Traits were used extensively to build the early versions of Star. Versions of Star released in 1983 included some 260 different traits.

The Star programmer dealt with traits as a pattern of programming conventions over the Mesa language.

3.1. Mesa

Mesa was the systems implementation language for Star. It is a strongly-typed, modular language [Geschke77], [Mitchell79]. "Definitions modules" represent the abstract interface to "program modules," which implement the interface.

The strong-typing of Mesa had a deep influence on the Star programmer. Because Star was such a large piece of software - on the order of a thousand program modules - any support for maintaining and making comprehensible large software systems was welcome. The Mesa compiler's support for strong-typing was invaluable; breaches of the type system (which traits seemed to require) were frowned upon. The desire for a type-safe way of supporting traits led to the thoughts behind this paper.

3.2. Trait Client Programming Pattern

A trait appeared to its client as a Mesa definitions module. The module would contain a set of procedural interfaces for trait operations. The first parameter of each procedure was the handle to the object (allegedly) carrying the trait. It might be declared as:

```
     "Op: PROC[oH:Handle, t:T]".
and would be invoked as:
     "Trait.Op[oH, t];"
```

It was the client's responsibility to ensure that, before applying a trait operation to an object, that the object did in fact carry the trait. In general, there were no compile-time or run-time guarantees that it did. It was a serious error when a trait operation was applied to an object not carrying the trait.

3.3. Trait Implementer Programming Pattern

Implementing a trait was more involved than simply using one as described above. The implementer of a trait had to obey certain programming conventions since traits were not supported directly by the language.

Each instance reserved storage for all the traits that it carried. The conventions required that each trait declare how much storage it needed in instances which would carry it. For example, the trait "stores_integer" would require enough storage for one integer in every object that carried it.

In addition, each class reserved storage for all the traits that it carried. This storage was used exclusively for storing procedure values reflecting the inherited "methods" of the class. The conventions required that each trait declare how many overridable operations it had.

A "trait manager" (TM) existed which represented compile-time and run-time knowledge of global aspects of the trait hierarchy.

Each trait declared certain things about itself to TM (e.g., amount of trait storage required in each instance carrying the trait, amount of trait storage required in each class carrying the trait, whether the trait would generate instances, which (sub) traits it carried). Each trait registered this information with TM at load-time. Logically, this could have all happened at compile time.

The TM used this information to determine the locations of trait data in instance storage, and of trait data in class storage. Traits could query TM to determine where their data was in instances and classes. For accessing its data, a trait would ask TM to help it open a scope onto its data in the instance:

```
     put_integer(oH: Handle, i:int]
          p = TM.Data[oH, me];
          p.storage = i;
```

In addition, where carrying traits (subclasses) were able to override this trait's methods with their own, the trait implementer needed to provide a "switch". The pattern was similar; a trait would ask TM to help it open a scope onto its data in the class:

```
     put_integer(oH: Handle, i:int]
          p = TM.Ops[oH, me];
          p.put_integer[oH, i];
```

Initialization of instances and classes was done by explicit bottom-up traversal of the traits hierarchy by each individual trait. That scheme was fine in the single inheritance world (where there was only one immediately carried trait, or "superclass"), but broke down completely for multiple-inheritance. A better approach would have been for TM to drive the static initialization of instances and classes, rather than conversely.

The pattern was too involved to be satisfactory. The whole scheme could have been supported much more cleanly by a compiler (if the information known to the Star traits manager were only available at compile-time).

3.4. Pre-calculated inheritance

The class information massaged by TM was in fact static. All method overriding was performed at boot-time, and recorded in the class structure. It could as well have been specified at compile-time (this is not necessary for type safety as described below).

3.5. Pre-calculated initial instances

Similarly, statically initialized instances for each class could have been calculated at compile-time.

3.6. Optimized instance, class layout

When a trait accesses its data in instances or in classes, it does so via TM. It actually has no idea where its data is with respect to the class or instance. It is the association of trait storage with instances that is important, not the location of the storage. In many cases, it is possible to arrange that, for all classes, trait data is in the same object-relative location (class-independent positioning). This can be used to generate optimal accesses to trait data.

For single-inheritance systems, class-independent positioning is always possible. For multiple-inheritance systems, it is easy to show that it is sometimes impossible if no "holes" are permitted in instance storage. In general, class-independent positioning of trait data in class and instance storage is excessively expensive.

The Star trait manager originally calculated a globally optimized layout for trait data in instances and classes. A recompilation of Star with this globally optimized layout made trait data access even faster.

3.7. Type-safety

There were many places where the Mesa type system was breached by the traits programming convention. We were unable to find a safe pattern which still retained the information-hiding benefits.

4. Problems with Traits in Star

While traits worked well enough to get the job of building Star done, they had certain drawbacks.

This section describes the major problems encountered which using traits in Star.

4.1. Traits were unsupported

The most basic problem was simply that that style of programming was unfamiliar. As a language feature it was unsupported by the production tools

4.2. Runtime support was required

One of the more interesting aspects of multiple-inheritance is that runtime support seems to be required to locate trait data in instance storage (and class storage), at least when no gaps are permitted in instance storage. For single-inheritance systems, the convention of placing superclass data closest to the base of instance storage provides class-independent positioning for all traits. For multiple-inheritance systems, there is no convention which assures class-independent positioning for all traits. There will always be a trait whose data (in an instance) can only be located by accessing a runtime which can only be constructed after all traits' implementations are compiled.

If gaps are permitted in instance storage, a compile-time database of trait data locations can eliminate the need for runtime access.

4.3. Global optimization was performed

The Star traits mechanism went one step beyond providing a runtime. It tried to minimize access to the runtime by doing an analysis of the entire traits hierarchy in order to achieve class-independent positioning as often as possible. From a development standpoint, the optimization was not a good idea, since addition of a single new trait could require recompiling all trait implementations.

4.4. Traits breached Mesa type system

Perhaps the most serious problem with traits in Star was the fact that its use fostered systematic breaching of the Mesa type system.

For the trait client the danger lay in invoking a trait operation on an object which did not carry the trait. Eventually, a run-time check was added; the object's "create type", the highest level trait it carried, had to carry the trait introducing the operation.

For the trait implementer, the problem lay in the way a scope was opened on trait data in class and instance storage; a (generic) TM function was used, returning a pointer which was then coerced into a trait-specific type.

In practice, surprisingly, these breaches did not cause problems very often. Their existence was disturbing, however.

In addition, the only checks which could be implemented were run-time checks. This deferred detection of what was basically a type breach to late in the development cycle.

5. Elements of a Solution

Static typing is always a compromise. In exchange for compiler support for the more static aspects of a program, the programmer gives up some dynamic control.

The most important element of type-safe multiple-inheritance traits programming is to embed the trait hierarchy in structures which are identifiable by a compiler. At the very least, trait "names" and the "carries" relation should be visible; the compiler needs to be able to determine whether one trait carries another or not. For type-safety, only this is necessary. It is also useful if method inheritance can be precalculated at compile-time; cases of inconsistent inheritance can be resolved by the compiler. It is more efficient to calculate the value of statically-initialized instances at compile-time also.

The second necessary element for type-safe trait programming is a change of viewpoint about what "type" is.

Conventionally, variables which hold values of a given type are tagged with the "create type" of the variable, reflecting total knowledge of the characteristics of the value. For example a variable which holds an object of the (earlier-described) type "is_integer_variable" would be tagged with "is_integer_variable". This notion of type does not help with type-safe traits programming.

An alternate approach is to tag variables holding values of a specific type with (sub) traits carried by that type, reflecting partial knowledge of the characteristics of the value. In the case above, a variable holding an object of type "is_integer_variable" might be tagged with "has_name". This tagging allows the programmer to apply the operation "get_name" (for example) to the object. Even though the operation "get_integer" makes sense, it may not be invocable.

Syntactically, one might write:

```
     <var>: Handle CARRYING <trait>
```

to declare <var> to hold handle values for objects known to carry <trait>. A more general approach allows the programmer to express partial knowledge that an object carries a set of traits:

```
     <var>: Handle CARRYING <traitlist>.
```

"Type-safety" for trait clients means that it is not possible to apply a trait operation to an object which does not carry the trait.

6. A Static Trait Hierarchy

This section describes how trait information can be embedded in compiler-visible structures - trait interfaces. A trait interface is the means by which trait clients know the types and operations introduced by the trait. In Mesa, a trait interface would be represented as a "definitions module".

A trait interface contains a single "trait declaration". A trait declaration includes a "trait id" and a list of carried traits (we exclude referential circularity). Note that a trait interface may be shared indirectly via different paths. The importance of the trait declaration is that it embeds a description of the traits graph (i.e., carries relation) in the set of trait interfaces, in a form which can be understood by the compiler.

A trait interface contains a number of operations introduced by the trait and which can be applied to objects carrying the trait. These are called "trait operations". Every trait operation has a distinguished parameter, which identifies the object to which the operation is to be applied. This parameter must be of type

```
    Handle CARRYING <trait>,
```

where <trait> is the trait being declared.

In a trait interface, each trait operation is described. For each operation, the name, input and output parameters and their types are listed. The semantics of each trait operation are described. As is usual with interfaces, the "implementations" of trait operations are usually not specified.

A trait interface specifies whether each trait operation is rebindable and if so, a preference for that operation. A syntax such as:

```
      t: TRAIT[ ... ];
      THandle: TYPE = Handle CARRYING t;
      Op: TRAIT PROC[oH: THandle, ...]
            PREFER OpDefault;
```

could be used. Preferences are not permanent bindings. That is, invoking a rebindable trait operation bound with PREFER cannot be guaranteed to invoke the preference. For example, if the trait operation is being applied to an object carrying a higher level trait which overrides the preference expressed here with its own, then the preference of the higher-level trait will be invoked instead.

Each trait interface specifies preferences for its rebindable operations. Higher level traits must be able to override preferences of traits they carry. A variant of the PREFER verb can be used. For example, if the declared trait carries a trait declared in another trait interface "T", and "Op" is a rebindable operation declared in "T", we could use:

```
    T.Op:  PREFER OpOverride.
```

This means that the trait defined here is "overriding" the earlier preferences with its own.

This ability of higher-level traits to override preferences of lower level traits is the basis for much of the power of traits. In more dynamic subclassing systems the same purpose is accomplished by intercepting messages and executing alternate "methods". In a traits system, this "message-passing" overhead would be incurred at compile time instead of run time.

The traits hierarchy implicitly expressed in the set of trait interfaces defines operation inheritance paths. It a higher level trait "Th" carries a lower level trait "Tl", then operations of Tl can be applied to objects carrying Th.

Notice that from the perspective of a given trait interface, everything about the trait hierarchy below it is known. The trait operations for this and all carried traits are known, and preferences for rebindable operations for this and all carried traits can be calculated. If the trait is a class, the inherited methods for the class can be calculated and conflicts resolved.

7. Client Perspective

From a trait client perspective, things are straightforward. References to objects are maintained as handles carrying the needed traits. For example, a "page" object could be composed of "heading", "footing" and "body" objects. "page" trait data could be declared as:

```
     RECORD[
          head: Handle CARRYING heading,
          body: Handle CARRYING body,
          foot: Handle CARRYING footing
     ].
```

An Object whose handle is stored in page.body may be a good deal more elaborate than "body", but for the purposes of "page", it does not matter. The "page" object will only deal with the object at the level of "body" or below.

If a client wishes to apply an operation introduced by a lower level trait to an object, the compiler can validate and perform the necessary coercion, since it sees the entire traits hierarchy. For example:

```
    Object.Print[page.body].
```

In this case, page.body carries the "body" trait, which we assume carries the "object" trait. The compiler notices that the programmer is attempting to apply an operation introduced by "object" (namely Print) to an object known to carry the "body" trait. This is valid exactly when "body" carries "object", a simple reachability check on the traits graph.

On those occasions when a programmer "knows" than an object carries a higher level trait than the source guarantees, he may coerce it explicitly. A runtime check that the object really does carry the trait can be performed to maintain safety.

8. Applications

The real value of traits is reusability. Traits offer a way of capturing essential abstractions more easily than single-inheritance subclassing schemes. In order to be truly useful this way, traits should be implemented over some widely used programming language. In addition to being based on a widely-used language, an extensive library of abstractions is desirable.

The approach taken by the language C++ [Stroust86] is perhaps the best way to deal with the need. In this case a preprocessor "virtually" extends a standard, widely-used language.

Mesa, Modula, and ADA are perhaps the languages best suited for these extensions, since they provide strong-typing support already, and support for interface modules.

With some work, however, the approach may be applied to FORTRAN as well.

9. Conclusion

This paper has indicated how to extend a strongly-typed language to support traits-based programming. There are two key ideas. First, embed the trait hierarchy in a set of statically defined interfaces. This potentially eliminates message-passing as a means of implementing inheritance (since the compiler can now manage inheritance and type checking). Second, rely for type-safety on a notion of "type" which reflects static knowledge that an object carries a given trait, rather than the notion of "create type". The compiler can then assist in automatic coercion and type-checking, based on its understanding of the (statically-specified) trait hierarchy.

Object-Oriented Programming for Macintosh Applications

Larry Rosenstein Ken Doyle Scott Wallace

Apple Computer, Inc.

Abstract

One of the attractions of the Apple® Macintosh™ is the uniform user interface across applications. Users judge a Macintosh program not only by its functionality, but also by its adherence to the user interface guidelines. Implementing the standard user interface is tedious, however, because of the many details that each developer must program.

This paper describes an object-oriented system, called MacApp,™ that is designed to improve both programmer productivity and user interface consistency. MacApp consists of a set of object types that implement the standard Macintosh user interface. Programmers customize MacApp not by editing its source code, but by defining new object types that override methods in MacApp.

Introduction

Apple's Macintosh computer is noted for the consistent user interface across applications. Users judge Macintosh programs not only by their functionality but also by their adherence to the established user interface guidelines. For example, they expect applications to use windows and pull-down menus, to transfer data from one program to another, and to provide an undo operation for every command.

User interface consistency is encouraged by the *Macintosh Toolbox*,[1] which is a set of several hundred procedures and functions built into read-only memory. The Toolbox provides the low-level implementation of the standard user interface, including windows, menus, and scroll bars.

The Toolbox does not provide an overall structure for an application; it is up to each developer to call the correct Toolbox routines in response to user actions. Most of the source code needed to implement the standard user interface is identical in all applications. In addition, some of it can be tedious to write and debug. The time a programmer spends implementing the user interface could be better spent working on the specific features that make the application unique.

The typical approach to assisting programmers has been to provide a series of sample programs that they can modify to suit their needs. We have taken a different approach by implementing a generic Macintosh application, called MacApp. MacApp automatically handles the common user interface details such as moving, resizing, and scrolling windows. It is structured so that programmers can easily override the standard program behavior and add application-specific behavior.

MacApp is written using object-oriented programming techniques. It consists of a set of object types, each of which corresponds to an aspect of the Macintosh user interface, such as a document or window. An object type defines the behavior of instances of that type in terms of: (1) the state information stored in every instance and (2) the methods that act upon the state information. The Document type in MacApp, for example, includes the name of a disk file as part of its state and methods for opening the file, reading the document from disk, and closing the file.

Developers use MacApp by defining descendants of the basic MacApp object types, which automatically inherit the standard behavior of MacApp. They customize MacApp, not by editing its source code, but by overriding the methods they wish to change. In the example above, the programmer would define a descendant of the standard Document object type and override the method that reads the disk file with one that can interpret a particular file format. The methods that open and close the disk file, however, would be inherited from MacApp.

MacApp is similar in purpose to the Model, View, Controller classes of Smalltalk-80;[2, 3] both provide a standard framework within which to implement applications. The design of MacApp was also influenced by the Lisa® Toolkit,[4, 5] which was an earlier object-oriented system developed at Apple for the Lisa operating system.

Why Object-Oriented Programming?

There are two basic reasons for using object-oriented programming in MacApp.

First, object-oriented programming generally promotes better programming style.[5, 7] Programs are easier to maintain, because the interactions between objects are through well-defined method interfaces. Also, code can be more easily reused and extended through subclassing and inheritance.

The second reason involves the structure of a Macintosh application. All applications follow the same basic structure, at the heart of which is an event loop. The event loop reads an event from a queue, classifies it, and then processes it. Pressing the mouse button, for example, could be interpreted as choosing a menu command, moving a window, or selecting an icon, depending on where the user was pointing at the time.

Since the event loop is common to every application, it should be implemented once in MacApp and used by every application. This is a radical change from the typical application because the primary control loop of the application resides in MacApp, and is not implemented by the programmer.

Although MacApp can handle generic actions such as moving a window, it cannot handle application-specific actions such as choosing an icon. For the latter kind of actions, MacApp must make calls to procedures written by the programmer. This is inconvenient to do in a conventional programming language, because a procedure call must specify at compile time which piece of code to execute.

Object-oriented programming is ideal for this situation. Sending a message to an object corresponds to calling a procedure. The difference is that the method to be executed is determined at run time, based on the type of the object. Although the same effect can be achieved with pointers to procedures, the resulting programs are more readable and easier to maintain if they use object-oriented constructs.

Object Pascal

MacApp was developed using Object Pascal,[7] which is an object-oriented extension of Pascal. Object Pascal provides language constructs for defining object types, similar to the facilities of Simula or Smalltalk-80.[2, 3] Object Pascal is descended from Clascal,[4, 5] which is an earlier language designed for the Lisa computer. Two important design goals of Object Pascal were: (1) to make it as simple as possible to learn and use, and (2) to integrate the object-oriented extensions with the rest of Pascal.

An object type definition is written much like a record type definition. For example, the following defines a Shape object type:

```
Type Shape = Object
     bounds:    Rect;
     color:     Integer;

     Function   Shape.Area: Integer;
     Procedure  Shape.Draw;
     Procedure  Shape.MoveBy(dh, dv: Integer);

     End;
```

The main difference between a record definition and an object definition is that the latter can contain declarations of procedures and functions, which are the methods of the object type.

Another difference is that an object definition can contain an optional ancestor type designation. For example, the following two object types have Shape as their immediate ancestor object type:

```
Type Circle = Object(Shape)
     Function   Circle.Area: Integer; Override;
     Procedure  Circle.Draw; Override;
     Procedure  Circle.SetRadius(radius: Integer);
     End;

Type Triangle = Object(Shape)
     vertices:  Array[1..3] of Point;

     Function   Triangle.Area: Integer; Override;
     Procedure  Triangle.Draw; Override;
     Procedure  Triangle.MoveBy( dh, dv: Integer);
                                            Override;
     Procedure  Triangle.SetVertices(v1, v2, v3: Point);
     End;
```

The descendent object type inherits all the fields and methods of its ancestors, and can add new fields and methods. In the definition above, Circle inherits the bounds and color fields and the MoveBy method from Shape, and adds the new method SetRadius. An object type can also override methods defined by its ancestor; for example, Circle overrides the Area and Draw methods.

In this example, Shape is an abstract object type. There would not be any instances of Shape itself, only of descendants such as Circle and Triangle. The reason for defining a Shape object is to establish a standard interface that all kinds of shapes can share. As we will see below, it is possible to refer to generic Shape objects without knowing until run time if they will actually be Circle or Triangle objects.

When a programmer declares a variable of a particular object type, the variable is a reference to an instance of that type. In the current Object Pascal implementation, an object reference is a pointer to a pointer to the actual object data. (In the Macintosh terminology, a pointer to a pointer to a data block is called a handle.)

Fields of an object can be referenced much like fields of a record. For example:

```
Var   aCircle:   Circle;
      aShape:    Shape;

aCircle.bounds := aRect;
oldColor := aShape.color;
```

Methods are invoked using the same syntax:

```
aCircle.MoveBy(10, 20);
aShape.Draw;
```

Since Circle and Triangle objects inherit all the properties of Shape objects, they can be used in any situation where a Shape is required. In particular, the object reference 'aShape' could refer to a Circle, or a Triangle. Because aShape is declared as a Shape reference, the Object Pascal compiler restricts accesses to aShape to those that are defined in the Shape object type. For example, the compiler would flag the statement 'aShape.SetRadius(r);' as a syntax error, since Shape objects do not define a SetRadius method. This is different from Smalltalk, where the error would not be caught until the statement was evaluated.

The determination of which method implementation is called for a particular method call is made at run time. To illustrate this, consider the following procedure:

```
Procedure  MoveTinyShapes(aShape: Shape);
Begin
    If aShape.Area < medianArea Then
        aShape.MoveBy(100, 0);
    aShape.Draw;
End;
```

When the Object Pascal compiler compiles this procedure it has no way of knowing whether a Circle object or a Triangle object (or for that matter an instance of an entirely new Shape subclass) will be passed to MoveTinyShapes. Method calls such as aShape.Draw do not directly call a particular method. Rather, they call a special method dispatch routine that examines the object to determine its type and then refers to memory-resident method tables to determine which method to call.

MacApp

MacApp is a generic Macintosh application. By itself, it can be compiled into a runnable program that would have many features of the Macintosh user interface. For example, it would support multiple windows that can be resized and scrolled. The windows would be blank, however, since MacApp does not specify what should appear in the windows.

There are six basic object types that MacApp programmers use:

Application	Document	Window
Frame	View	Command

Each of these object types correspond directly to an aspect of the Macintosh user interface.

There is one Application object during the execution of a program. The Application object receives events such as mouse presses and distributes them to other objects. It also handles desk accessories and any commands that apply to the application as a whole, such as opening a new document.

Document objects contain the data that the program uses; for example, formatted text or a spreadsheet model. In addition to providing methods for manipulating data in memory, it also provides methods for saving the data onto the disk and later reading it back into memory. There can be more than one type of Document object in a MacApp program: an integrated application might define both word processing and spreadsheet Document types.

The Window, Frame, and View object types all deal with displaying information on the screen. Window objects represent Macintosh windows that can be resized and moved. Frames are used to partition a window into independent pieces, each of which contains a View object. For example, MacDraw™ windows contain a tools palette as well as a drawing area.

View objects translate between the Document's data structures and an image within a Frame. The main function of the View object is to draw the data when its Draw method is called. Before MacApp calls the Draw method, it sets up the graphics clipping and translation so that only the desired portion of the image is drawn. MacApp calls the same Draw method when printing each page of the document; in this case, the graphics state is set up so that the image appears on the printer rather than on the screen.

The last object type that MacApp programmers commonly use is the Command. Command objects provide a convenient framework for implementing the Undo command, an important part of any Macintosh application. Command objects encapsulate information about how to execute, as well as undo, an operation.

When the user selects a command from a menu, the application does not immediately carry out the operation. Instead, it creates a Command object and returns that object to MacApp. MacApp will then send a DoIt message to the Command. The DoIt method is responsible for carrying out the user's command and updating the image on the screen. It also must remember enough information so that the operation can be undone if necessary.

If the user selects Undo from the menu, MacApp sends an UndoIt message to the same Command object. The object restores the previous state of the Document and again updates the screen image. If the user selects undo again, MacApp sends the message RedoIt to the Command object.

A MacApp programmer will define a subclass of Command for each kind of operation that can be performed. For example, the Copy and Paste menu commands would be handled by different Command types. Often it is possible for one Command type to handle several menu commands; the Cut, Copy, and Clear commands are usually similar enough to each other that a single type of Command object can be written to handle all three.

In addition to the six basic object types described above, MacApp also contains support for other important application features; such as: creating and using dialog boxes, sending and receiving data over the AppleTalk network, and recovering from I/O and out-of-memory errors

Experiences with MacApp

Programmers, both inside and outside of Apple, have been using pre-release versions of MacApp since April, 1985. Of the approximately 200 people who have received MacApp, we have received comments from about 20 developers who have been actively using it in serious Macintosh applications. Three of these applications have reached "beta" test stage; one is a boat navigation program (which took six months to develop), another is a recording studio management program (nine months), and the third is a stuctured program editor and run time system (twelve months).

Before MacApp was developed, Macintosh programmers would spend several weeks reading *Inside Macintosh*[1] and example programs, in order to understand the structure of an application. Programmers who begin to use MacApp still spend several weeks reading the MacApp documentation. The important difference between the two approaches is that with the same investment of learning time, they end up with a much more functional application. By writing about three pages of source code, they can have a working application that has multiple scrolling windows, that reads and writes documents, and that prints.

Much of the difficulty in learning MacApp comes from its use of object-oriented programming. It takes time for a programmer who is not familiar with object-oriented systems to understand method calls and inheritance. In addition, MacApp requires thinking about an application in a different way, since most of the application control structure is contained in MacApp itself. Once developers overcome these obstacles, however, they are able to produce applications more quickly with MacApp than when using conventional programming techniques.

Programs written using MacApp follow the user interface guidelines more closely than most Macintosh applications. In addition, they are structured in a way that makes them easy to maintain and enhance. While developing MacApp, we talked to many Macintosh developers and incorporated their ideas and techniques into the final system.

There is a space and performance penalty for using Object Pascal. Each method call requires the same space as a regular procedure or function call; Object Pascal programs, however, also require memory space for method tables (about 3,000 to 5,000 bytes for a complete application). Method calls are also slower than regular procedure calls; the extra time required can range from 50 to 200 microseconds per method call.

The penalties for using MacApp in a serious applciation are much less, however, because most of a MacApp program is written in standard Pascal. We estimate that there is a 10 to 15% increase in application size and a 5 to 15% performance degradation, compared to a program written in standard Pascal. In most cases, these disadvantages are outweighed by the reduced development time and maintenance costs.

At the time this paper was written, we were beginning to look at ways to reduce the size of MacApp applications and improve their performance. Most of this involves standard code tuning that any application requires before being released. In addition, we are implementing an approach that will speed up method calls by analyzing the object type hierarchy.

Summary

We have developed an object-oriented system called MacApp that is intended to help programmers develop Macintosh applications. MacApp automatically implements the standard features of the Macintosh user interface and provides a convenient way for programmers to implement specific applications. Instead of editing the MacApp source code, programmers define new object types that override methods in MacApp, and inherit the standard behavior.

MacApp is implemented using Object Pascal, a version of Pascal that includes extensions for object-oriented programming. The object-oriented extensions were integrated with standard Pascal, so that programmers who already know Pascal could easily learn the language.

Applications written using MacApp follow the user interface guidelines more closely than most applications. In addition, MacApp encourages a program structure that makes applications easier to maintain and extend.

CLASSES VERSUS PROTOTYPES IN OBJECT-ORIENTED LANGUAGES

A.H. BORNING*

* Department of Computer Science, FR-35, University of Washington, Seattle, Washington 98195

Abstract

Smalltalk uses classes to describe the common properties of related objects. Unfortunately, the use of classes and metaclasses is the source of a number of complications. This paper discusses prototypes as an alternative to classes and metaclasses. In a prototype-based language, copying rather than instantiation is the mechanism provided to the user for making new objects. Inheritance constraints are proposed as a way of representing object hierarchies and supporting the automatic updating of related objects when edits are made.

1. Introduction

The Smalltalk-80 language[1], as well as a number of other object-oriented languages, uses *classes* to describe the common properties of related objects. Unfortunately, classes and the class-instance relation are the source of a number of complications. First, for an object to have a distinct message protocol, a separate class must be created for it. If, as in Smalltalk, classes themselves are objects, then to allow different classes to understand different initialization messages, each class must itself be an instance of a different class (called a metaclass in Smalltalk). Metaclasses add to the complexity of the language; a recent study[2] on difficulties encountered in teaching and learning about Smalltalk indicates that metaclasses are uniformly regarded as the single worst barrier to learnability by both teachers and students. Second, the emphasis on classes in the programmer's interface is .at odds with the goal of interacting with the computer in a concrete way. When designing a new object, one must first move to the abstract level of the class, write a class definition, then instantiate it and test it, rather than remaining at one level, incrementally building an object. This problem is most apparent in systems for graphical or visual programming.

The alternative suggested in this paper is the organization of the programming environment around *prototypes* rather than classes. A prototype is a standard example instance; new objects are produced by copying and modifying prototypes, rather than by instantiating classes.

The remainder of the paper is organized as follows. The following subsections list some sources of complexity in the current Smalltalk metaclass-class-instance mechanism, and then describe a small gedanken experiment in language design, in which prototypes are used instead of classes. This very simple language has several limitations, and a more realistic design is presented in Section 2. Following this is an enumeration of the advantages and disadvantages of the proposal. The final section provides comparisons and references to related work.

1.1. Some Sources of Complexity

One source of the complexity surrounding classes in Smalltalk is the interaction of message lookup with the role of classes as the generators of new objects, which gives rise to the need for metaclasses. Another source is the use of classes for several different functions.

In Smalltalk, when an object receives a message, the interpreter goes to the object's class and looks in its method dictionary for a method for receiving that message. If a method isn't found, the interpreter looks in the class's superclass, and so on up the class hierarchy. Classes are themselves objects, and to make new objects, one sends appropriate messages to classes. In general these messages will vary from class to class. For example, to make new points, one wants to send an *x:y:* message to the class Point, so that the *x* and *y* coordinates for the new instance can be passed as arguments. Given the way message lookup is done, this requires that the class Point be an instance of a different class from (say) class Rectangle, which should not understand the *x:y:* message, but rather a different initialization message specific to rectangles. This pragmatic need for class-specific initialization methods was satisfied by the introduction of metaclasses: each class is an instance of a separate metaclass. However, as noted above, this design decision has had unfortunate consequences for the teachability and learnability of the language.

In regard to the use of classes for several different functions, some of the roles that classes play in Smalltalk are as follows:

- generators of new objects
- descriptions of the representation of their instances
- descriptions of the message protocol of their instances
- elements in the description of the object taxonomy
- a means for implementing differential programming (this new object is like some other one, with the following differences ...)

CH2345-7/86/0000/0036$01.00 © 1986 IEEE

- repositories for methods for receiving messages
- devices for dynamically updating many objects when a change is made to a method
- sets of all instances of those classes (via the *allInstances* message)

While some of the above items are related, it is clear that classes in Smalltalk are playing multiple roles.

1.2. A Gedanken Experiment in Language Design

To help unravel the complexity, let's do a small gedanken experiment in language design. Considerations of space and time efficiency are to be ignored for the moment, to avoid needlessly intertwining semantic and implementation considerations.

Suppose that objects are completely self-contained, so that an object consists of *state* and *behavior*. One can send messages to an object asking it for information, asking it to change its state, or asking it to change its behavior. The only way to make a new object is to make a complete copy of an existing object, copying both state and behavior. Once the copy is made, there is no further relation between the original and the copy. (Creating new objects by copying eliminates the need for metaclasses, since creation and modification messages are sent to prototypes or other individuals rather than to classes.)

This is a clean model, and would be easy to teach about. It handles object creation, modification, and representation. What is missing? First, there is no notion of classification of kinds of objects, either by message protocol or by representation. Second, there is no way to update a whole group of objects in a similar manner at one time (the equivalent of such actions as adding new methods to a class in Smalltalk). These are both important, and so the model needs to be augmented to support classification and updating.

2. A Proposal for a Prototype-Based Language

In this section a proposal for a more realistic language is presented, in which the simple model described above is augmented to support object classification and updating. Many of the ideas used here have arisen from the author's work on constraint-oriented languages and systems[3, 4, 5], where a constraint describes a relation that must hold. In this proposal, constraints are used to express inheritance relations among objects. However, the set of inheritance constraints used here is limited and straightforward to maintain, and a general-purpose constraint representation and satisfaction mechanism is not required.

In this proposed language (as in the language described in the gedanken experiment), an object has state and behavior. The state of an object is represented by a set of named *fields*. We will on occasion be interested in an object's field names, and this list of names can be accessed separately from the contents of the fields. There are two components of an object's behavior. The first component is a *method dictionary*, which is similar to that in Smalltalk, except that there may be several methods for receiving a given message. (The way in which one method is chosen, or several are combined, is discussed in Section 3.2.) The second component is a *protocol* that describes the set of messages the object declares that it can understand, the protocols required of the arguments to the messages, and the protocols of the results returned by the messages.

New objects are produced by copying other objects. Thus, to make a new point, one would make a copy of the prototypical point, with new values substituted for the *x* and *y* fields. Once a prototype has been copied, there would be no hidden relation between the prototype and the copy; any further relations that were desired would be explicitly represented using constraints.

2.1. Inheritance Constraints

The proposed language does not include a general constraint mechanism. Rather, there is a fixed set of *inheritance constraints*–constraints on an object's field names, methods, and protocol–built into the language. These are as follows:

- *inherits-field-names(x,y).* This constraint holds if every field name of *y* is also a field name of *x*.
- *inherits-behavior(x,y).* This constraint holds if all of the methods in *y*'s method dictionary are also in *x*'s method dictionary.
- *inherits-protocol(x,y).* This constraint holds if the protocol of *y* is a subset of the protocol of *x*, i.e., if every message that *y* can understand is also understood by *x*, and if each object returned by *x* in response to one of these messages also obeys the corresponding protocol declared in *y*.

In general these three constraints are independent. For example, an object *x* might inherit the protocol of *y* but not its methods (*x* would implement the necessary methods in completely different ways). If an object *y* does not use all of its fields, then *x* can inherit the behavior of *y* but not all its field names. Of course, the constraints are not totally independent–for example, if *x* inherits behavior from *y*, all of the field names used by *y* must also be field names of *x*.

Nevertheless, it will often be the case that these three constraints will be applied together, and so a *descendant* constraint is defined as follows:

$$\text{descendant}(x,y) \equiv \text{inherits-field-names}(x,y) \wedge \text{inherits-behavior}(x,y) \wedge \text{inherits-protocol}(x,y)$$

2.2. Object Creation Messages

There are two messages available for creating new objects: *copy* and *descendant*. The *copy* method makes a complete copy of the receiver and returns it. There is no further relation between the receiver and the copy. The *descendant* method makes a copy, and also sets up a one-way descendant constraint between the original and the copy.

2.3. Examples of Use

In place of the class Point would be a prototype point. The prototype point would have *x* and *y* fields, each initialized to 0. (Alternatively they could be left as *nil*). It would understand messages such as *+*, *printOn:*, and so forth. To make a new point, one would evaluate

```
point x: 4 y: 6
```

which would make a descendant of the prototype point, and then set its fields to 4 and 6. The code for *point x:y:* is as follows:

```
x: newx y: newy
  ↑ point descendant setx: newx sety: newy
```

The message *setx:sety:* is defined as in Smalltalk:

```
setx: newx sety: newy
  x ← newx.
  y ← newy.
```

The following messages would build a new kind of object, *threepoint*, and define an addition method for it.

```
threePoint ← object descendant.
threePoint hasFields: 'x y z'.
threePoint hasMethod: '+ p
     ↑ threePoint  x: x + p x  y: y + p y  z: z + p z'
...
```

Naturally, there would be user interface support for the creation and modification of prototypes. This could be done using a browser, which could have much the same appearance and functionality as the browser in the current Smalltalk system.

3. Implementation

The *descendant* method should be implemented as a primitive, and the primitives for *new* and *new:* eliminated. It might also be useful to implement *copy* as a primitive. To make new variable-length objects, one would make a copy or descendant of an appropriate prototype, and then grow or shrink the copy as needed. It might be useful to combine copying and growing in *descendant:* and *copy:* methods.

To test the scheme, it could be implemented using the present Smalltalk bytecode set by simulating the new primitives. Classes would be given an additional field named *prototypes* that points to the collection of prototypes for that class. (Usually, a class would have a single prototype, but multiple prototypes are possible.) Below is the Smalltalk code for simulating *Object copy* and *Object descendant*, along with some auxiliary methods.

```
copy
  "if I am a prototype, need to copy my class;
   otherwise just make a simple copy"
  self isPrototype ifTrue: [↑ self class copy prototype]
                  ifFalse: [↑ self simpleCopy]

descendant
  self beProtoype. "make sure that I'm a prototype"
  ↑ self simpleCopy

simpleCopy
  "return a complete copy of me, taking account of
   shared substructure. IdentityDictionary is a
   dictionary in which == is used for key comparison"
  ↑ self copyWithDict: IdentityDictionary new

copyWithDict: dict
    | copy f |
  (dict includesKey: self) ifTrue: [↑ dict at: self]
  "make the shell of the new copy, then fill it in"
  copy ← self class new.
  dict at: self put: copy.
  1 to: self class instSize do:
      [:i | f ← (self instVarAt: i) copyWithDict: dict.
          copy instVarAt: i put: f].
  ↑ copy

bePrototype
  "make me into a prototype, if I'm not already"
    | newSelf |
  self isPrototype ifTrue: [↑ self].
  newSelf ← self class newSubclass prototype.
  1 to: self class instSize do:
    [:i | newSelf instVarAt: i put: (self instVarAt: i)].
  self become: newSelf.

isPrototype
  ↑ self class prototypes includes: self
```

These general methods would be overridden for classes, and for primitive objects such as numbers.

3.1. Classes

For objects such as points and rectangles, the field names, method dictionary, and protocol will be the same for many objects. In an implementation, then, it is reasonable to group these together into a class. Further, rather than having multiple methods in a given dictionary, the methods could be partitioned among sub- and superclasses, as in Smalltalk. Thus, there would be classes as well as prototypes. However, classes in general won't have global names, there won't be any metaclasses, and the user will usually interact with a prototype rather than a class.

3.2. Multiple Inheritance

An object can have *descendant* constraints that relate it to several parents, i.e. multiple inheritance is supported. Each of the three constraints that compose the *descendant* constraint (*inherits-field-names*, *inherits-behavior*, and *inherits-protocol*) establishes the correct relation when multiple inheritance is used. The only difficult question is which method (or methods) to execute in response to a given message, if there are several conflicting inherited methods. However, this problem arises equally in class-based systems, and the same sorts of choices are applicable. For simplicity, for the present the rules described in the Smalltalk multiple inheritance implementation[6] are to be used.

4. Evaluation

In this section, a (doubtless biased) listing of the benefits and drawbacks of the proposed scheme as opposed to that in the standard Smalltalk-80 language is presented.

4.1. Benefits

Some benefits of this scheme over the current one are:

- The initial explanation of the language is much simpler. One can just talk about objects as having state and behavior.

- Even at a deeper level, there are fewer concepts–metaclasses are no longer needed. It is simpler to explain how message lookup occurs when teaching about the language.

- Fields are automatically given default values in newly created objects (by copying the contents of the corresponding field in the prototype).

- A prototype-based language would provide better support for concrete, visual programming systems.

- Any object can be given individualized behavior. This could be useful for example in debugging, when one might want to set a halt in the method for one particular object, and not for all instances of a class.

- The semantics of inheritance are described in terms of constraints; sharing is regarded as simply an implementation technique. This distinction might be useful when building distributed systems, systems that run on multiprocessors without shared memory, object servers, or the like. In such systems, sharing would *not* be the only technique used to implement inheritance.

4.2. Drawbacks

- The use of prototypes seems natural for things like windows, but unnatural for such basic objects as integers. What is the prototypical integer? The decision here is that *all* integers are prototypes, that is, that a change to the methods of any integer affects all integers. Alternate possibilities are that 0 or 1 is the prototypical integer, or else that the prototype is a special integer whose value is undefined. None of these possibilities seems completely natural.

- A related drawback is that the concreteness of prototypes may be inappropriate for describing such standard data structures as stacks or queues. Rather than talking about a prototype stack, one wants to talk about stacks in general.

- There is a danger of inadvertently modifying a prototype. One can of course inadvertently modify a class in Smalltalk, but this seems less likely since it has a different message protocol from its instances.

- There is an efficiency problem in regard to making new objects by copying. For example, when building a new rectangle the system will make a copy of the prototype rectangle, probably only to replace its *origin* and *corner* fields immediately with new values.

The first drawback listed above applies to the extreme situations in the language. This seems to be analogous to the situation in Smalltalk itself. Objects and messages are a great idea most places, but they seem bizarre for things like integers ("3 + 4 means sending the message + 4 to the object 3??"). However, the benefits of uniformity are such that making 3 be an object that understands messages is the right choice in Smalltalk.

Regarding stacks and similar data structures, the explicit existence of classes in this scheme may a help, since one can still talk about classes if one wants.

Regarding inadvertently modifying a prototype, I believe that the solution to this is not to introduce a different message protocol for prototypes, but to introduce some form of protection. For example, one might make prototypes read-only except in particular environments. One should also be able to designate some messages (e.g. *setx:sety:* for points) as being private, and allow this message to be sent only by *self*.

Regarding the efficiency problem, an obvious step is to code the *descendant* primitive efficiently. Beyond that, it appears that code sequences like *point descendant setx: newx sety: newy* will occur frequently. Therefore, in addition to the *descendant* primitive, for each object the system might automatically compile a method for e.g. *descendantWithx:y:*, which would accomplish the same thing, but more efficiently. This would call a new primitive that makes a clone of the receiver and then sets all of the instance fields in the clone. (Since this message exposes the object's representation, it is best regarded as a private initialization message.)

5. Related Work

The idea of prototypes is not new, and discussions of prototypes from a variety of perspectives appear in the literature. (However, the idea of using constraints to establish and maintain inheritance relations does appear to be new.)

One sort of system in which prototypes have often been used is systems for visual or concrete programming. In such applications, prototypes are more useful than classes, since it is more straightforward to display them for viewing and manipulation by the user; their concreteness also makes them valuable for less experienced users. Examples of systems of this sort that have been built in Smalltalk include ThingLab[3, 4], Programming by Rehearsal[7], the Alternate Reality Kit[8], and Animus[9, 10].

Languages in the Actor family are general-purpose programming languages that use prototypes. Rather than inheritance, the Actor languages use a more general concept of *delegation*, in which any object may be delegated to handle a message for another; Lieberman[11] provides a useful and readable discussion of both prototypes and delegation. LaLonde[12] describes an exemplar-based Smalltalk (an exemplar is the same as a prototype); this language allows a given class to have multiple exemplars, an idea that has been borrowed and used in the design described here. In Biggertalk[13], an object-oriented language implemented in Prolog, instances are like classes in all respects, except that they cannot be further refined. Finally, prototypes are often used in artificial intelligence representation languages[14] to store default or typical information.

The language proposed in Section 2 does not include type declarations. However, if type declarations were to be added, protocols would be the logical entity to use in the declaration and checking of type. An object-oriented language that does have strong typing, along with a separation of protocol and implementation, is Trellis/Owl[15].

Why Properties are Objects or Some Refinements of "is-a"

Stanley B. Zdonik

Department of Computer Science
Providence, RI 02912

Abstract

This paper contains several examples that illustrate some problems with the is-a relationship as defined by many object-oriented programming languages. These problems relate to two distinct areas: 1. the confusion between the inheritance of behavior and the inheritance of representation and 2. the lack of any requirement for semantic relationships between a named operation on a type and a replacement operation with the same name on a subtype.

We indicate how these problems can be improved by making some useful distinctions. We then show how these distinctions can be built into the system easily by treating properties as first-class objects and using the basic specialization techniques of the language to express the differences.

1. The Data Model

We have been developing an object-oriented database system that provides a data model that strongly resembles some of the type systems in many popular object-oriented programming languages. As a database system, however, all objects, including the types and operations, persist beyond the current session and are sharable between users and user processes. Our system is also strongly influenced by work in the area of semantic database models [ADP, Ch, Co, GAL, HM, MBW, S, SS].

Our model centers around the notion of a type. A type is a behavioral template for its instances. The behavior of a type T is expressed by a set of operations O(T), a set of properties P(T), and a set of constraints C(T). The type type defines an operation called Instances that can be applied to any type. It returns a set containing all instances of that type that are currently in the database. The functions legal-operations and legal-properties return the set of all operations that can be applied to its argument and the set of all legal properties that are defined for it argument repsectively. The following condition is always met by a type definition T:

$$
\begin{array}{l}
(x \in \text{Instances } (T)) \\
(o \in O(T)) \; (p \in P(T)) \; (c \in C(T)) \\
\quad o \in \text{legal-operations } (x) \text{ and} \\
\quad p \in \text{legal-properties } (x) \text{ and} \\
\quad c(x)
\end{array}
$$

Properties, operations, and constraints are all objects in their own right. That is to say, there exists a type called Property that defines the general behavior of a property, a type called Operation that defines the general behavior of an operation, and a type called Constraint that defines the general operational characteristics of a constraint. A type is also an object and as such is an instance of a type called Type that describes the behavior of all types. Since type Type is a type, it is an instance of itself.

An operation is an active element in our database. It is essentially a piece of code. All operations support the operation *invoke* which takes an operation and a set of arguments as parameters and invokes the given operation on the set of parameters. Since operations are code (written in a language like C), in order to use them, the system must link any symbols used in this code to the library routines and other code objects to which they refer. This requires a dynamic linking loader.

A property can be conceptualized as a piece of string which binds together two objects. For example, Cars can have owners. Therefore, we define a property type that can link a Car to a Person. An instance of this property type will link an individual car (e.g., my car) to an individual owner (e.g., me). All properties support the operation *get-value* which, given a property, returns the value of that property. Get-value (my-car) returns me.

Constraints are predicates. They are defined on types and take an instance of the type as an argument. All instances of a type must always satisfy that type's constraints.

A type in our model is an abstract data type [LSAS] in the sense that it defines a private representation that is not visible to any code other than the operations that are defined on that type. The representation (rep) is an object of some other abstract type. As we shall see later, the rep is not even available to other subtypes. The type is, therefore, the unit of modularity.

Inheritance is provided in our system by a special property that is defined to hold between instances of the type Type. This property is called is-a and if there is an is-a property between types A and B such that B is-a A, then all instances of B are also instances of A. All behavior (operations, properties, and constraints) that is defined on A is also defined on B. We say in this case that B is a subtype of A and A is a supertype of B. It is possible for a type to have several supertypes from which it inherits behavior. We call this phenomenon multiple inheritance. Circularity in the type lattice is not allowed. It is important in the example that is presented later to remember that is-a is just another property.

Object-oriented databases [CM, DGM, MS, MSOP, Zd1, ZW] differ from their programming language counterparts in the following fundamental ways.

1. persistence
2. unique naming
3. sharing
4. transactions

Objects that are created by a process persist beyond the lifetime of that process. The database system assigns all objects a unique identifier that is guaranteed to remain unique even across multiple processes. Any number of applications can share the objects that reside in this persistent memory space. In the process of using these objects a given process can define the boundaries of transactions that are guaranteed to be atomic and resilient and that preserve some set of correctness criteria. If we adopt a strong world view, these criteria might encompass serializability, however, they may also be defined to be weaker [SZR].

2. The Role of Properties

One of the strengths of the object-oriented approach is the ability to create new types by specializing the behavior of old types. In our object-oriented database [ZW1, ZW2], we treat properties as objects, thus providing the ability to specialize the behavior of properties by defining new subtypes of the type Property. This paper describes this technique and discusses a few interesting property subtypes as an illustration of this approach. This example further illustrates how we might fix what we consider to be a common defect that occurs in some object-oriented systems. This defect arises from the confusion between the inheritance of specification and the inheritance of implementation. The example illustrates how these concepts might be separated.

It is, of course, possible to get the behavior of simple properties by defining a set of operations on the type of the object to which the property applies. These operations would get and set the value of the property. For example, suppose that the type Person has a property mother-of that relates a person to his or her mother. We could achieve same behavior by defining a get-mother-of and a set-mother-of operation on the type Person.

In our view, properties are objects which implies that as such they can partake in all behavior that objects in general have. This means that it is possible to define properties on properties since all object types have the ability to define properties. This allows us to model some situations more precisely. Suppose that John loves Mary. This could be modeled as two instances of type person with a loves property between them. If we wanted to assert that the intensity of this relationship is 8, placing the intensity on either John or Mary would be somewhat inaccurate. The intensity does not assert anything about John or Mary by themselves, but rather, it describes the loves property.

More importantly, by making properties be objects, we can refine their behavior by defining subtypes for them. Although there seem to be operations that do not apply to properties, yet are influenced by their definitions, a closer inspection reveals that these operations are really more complex composites that make use of the operations of the property types. For example, all objects are defined to have a get-property-value operation. This operation takes an object x and a property name p as arguments and returns the value of p if the type of x is defined to support properties of the type of p. This is an operation on x that appears not to use the property object. In reality, the get-property-value operation is implemented as follows:

```
get-property-value (x, p) =
        get-value (get-property (x, p))
```

A useful modeling tool is that of a derived property. A derived property is one whose value is dependent on other information that is contained in the state of the object. For example, employees might have a Salary property which is stored with each employee. They might also have a FICA-payment property that is not stored at all. Instead its value is computed as a function of the employee's salary.

It is possible to add the notion of a derived property to our model by noticing that derived properties are just like regular properties except that it is not possible to set their values. The derivation function is embodied in the get-value operation for the property. We define type property to have a get-value operation, but no set-value operation. We define a subtype of the type Property called Setable-property that adds the set-value property. We then add another subtype of Property that adds a property to Derived-properties called the derivation-expression. The get-value operation for derived properties evaluates this expression.

3. Some Important Distinctions

We begin our extended example by pointing out again that in our system a type exports an interface that is the only way that other code can manipulate objects of this type. This is also true for subtypes and supertypes of a given type. For example, suppose that the type Toyota is a subtype of the type Car. The create operation on the type Toyota has a side effect of invoking the create operation on the type Car and all types between Car and type Entity (the root of the hierarchy). Each of these create operations may allocate additional storage to store the state of its instance. Type Car has a move operation defined on it. In defining a drive operation for Toyota, if we want to change the position of the car, we must call the move operation defined at the Car level. The code for Toyota cannot manipulate the state of the Car variables directly.

This choice was made to incorporate in our system the benefits of data abstraction to the fullest possible extent. It now becomes possible to change the code for any type without having to modify the code for any other type (including subtypes and supertypes) as long as the interface remains unchanged. If the code for type Car changes but its operations and properties remain fixed, the operations on type Toyota will still work since they can only rely on the interface to Car. Of course, if the code for Car changes, any instances of Car that are already in the database might be affected. The problem of coping with this problem has been discussed in [SZ, Zd2].

In some systems such as Smalltalk [G,GR], it is possible for a subtype to directly access the instance variables of its supertypes. By saying that B is-a A, type B inherits the specification and the implementation from type A. B acquires all the operations defined on A as well as all of the storage level representation that is used to implement type A.

3.1. Behaves-like

We recognize that there are cases in which our strong view of data abstraction may sometimes interfere with what the programmer really needs to accomplish. For these somewhat rare cases we make a few distinctions about the is-a property. These distinctions will attempt to separate the inheritance of behavior from the inheritance of representation.

Our first example of this is a subtype of type Property called Behaves-like. The is-a property that we have already described is a subtype of Behaves-like. Behaves-like makes a guarantee about the specification of the two types that it relates. If B behaves-like A, B must have at least the behavior of A. B may add additional behavior (properties, operations, and constraints), but all of the behavior of A must be supported on B.

Unlike is-a, behaves-like has no side effect of creating instances of the higher-level types. This extra behavior is added in the definition of the is-a property. As a result, when B behaves-like A, no additional storage is allocated for the supertype A if an instance of B is created.

For example, this might be useful if we wanted to define two types Stack and Small-stack. Stacks in general might be represented by a list since that is most flexible for things that can grow without bound, while Small-stacks might be represented by an array since we can require that a small-stack not grow beyond a certain limit. We would then specify:

Small-stack behaves-like Stack

A create operation on the type Small-stack would have the effect of allocating space for the array and not allocating any space for the list that is the representation at the Stack level. Small stack must reimplement all of the behavior of the Stack. That's what it means for it to behave like a Stack. The system does not check this requirement. We assume that the type definer is a good citizen.

It is worth pointing out that the same effect could be achieved by rearranging the type lattice such that a third type called Generic-stack becomes the supertype of both Stack and Small-stack. Generic stack would have a null representation and be non-instantiable. That is to say that there is no create operation defined on the Generic-stack type. Generic stack could specify the standard stack operations (i.e., push, pop, empty) and the two subtypes could redefine these operations to work with their respective storage structures.

Although this change works, suppose that a definition for Stack already existed. Further suppose that the definition of Small-stack is added at some point' after many instances of Stack have already been created. This is common since we are concerned with a database system with persistent objects. Once a type has been created, we can assume that there will be many instances of it in our persistent store. Changing the type hierarchy, is therefore a very difficult and error-prone activity since the changed type structure might not fully suport the old instances. Although work is being done to ease some of these difficulties [SZ, Zd2], we would like to minimize the number of times that type changes occur. The behaves-like property allows us to retain the old structure, while achieving the behavior that we want.

3.2. Subsumes

There is another distinction that we often want to make. This is exemplified by the is-a relationship in Smalltalk. Here we would like a subtype to have access to the representation of its supertypes. We define another subtype of behaves-like called subsumes that accomplishes this.

Subsumes also guarantees that a subtype have at least the specifications of its supertypes, but it adds the ability for the subtype to access any state that is available in the supertype instance. One way of thinking about the subsumes property is that if B subsumes A, then A exports it get-rep operation to the B type module. The get-rep operation takes an object of an abstract type and returns an object of the concrete type (i.e., representation type). It is similar to the CLU [LABMSSS] down operation.

Although this variation of the behaves-like is potentially dangerous, we will give an example of where this kind of capability is necessary. Suppose that we have a type called Set. The representation of the Set type is an array. The set type has no operations that can observe or exploit the fact that an array is an intrinsically ordered type. Further, suppose that we wish to define a subtype of Set that is called Ordered-set. If we used strict data abstraction, we would have to store something like ordered pairs in the unordered set. The first element of the pair might be the set element and the second element of the pair might be its position or index. Because of information hiding, we have been forced to reinvent the ordering that is already available in the array data type. This is very inefficient.

Instead, by saying that Ordered-set subsumes Set, we can allow the code for Ordered-set to access the array directly. Now this code has the ability to exploit the natural ordering for the array. Of course the code for Ordered-set must maintain any rep invariant that is specified in the Set module. The Ordered-set module can add additional state of its own if this is deemed necessary. A create on the type Ordered-set would then allocate storage for both the Set and the ordered-set. The difference here is in what is accessible.

We have distinguished three different types of behavior related to the notion of is-a. We can define these property types in terms of each other as shown in Figure 1. Each of the arrows in this picture are behaves-like properties.

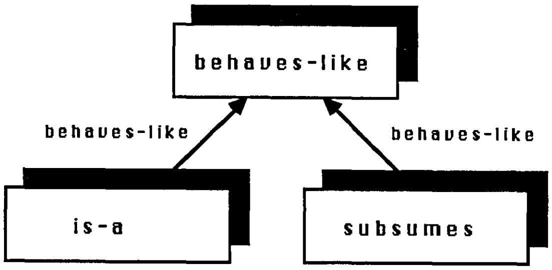

Figure 1: Distinguished versions of is-a

4. Operation subtyping

Another problem with many object-oriented systems is that the notion of operation refinement is not based on any semantic properties of the operations involved. In a language like Smalltalk, one may define an operation Op on a type B that has the same name as an operation Op that has been previously defined on type A, a supertype of B. If x is an instance of B, Op(x) will invoke the definition of Op that is attached to the subtype. This definition will block the definition that is provided by the supertype. Here, the paradigm is operation replacement, not operation refinement. There is no requirement that the two operations named Op bear any semantic relationship to each other. The only semantic tie is that they share the same name.

The problem with this undisciplined use of names is that if we insist that a type hierachy ought to induce a subset relationship among the sets of all instances of the types, we are left with a situation in which some instances of a type may have wildly different behavior from other instances of the same type. If Orange is-a Food-stuff, both types might define a squeeze operation. Squeezing a food stuff is defined to return a firmness coefficient that is useful for determining how fresh that item is, while squeezing an orange might have a side-effect which is to produce a refreshing citrus drink. Although all Food-stuffs support squeezing, some support it with very different results than others.

We prefer to use a somewhat different technique for operation (and property) refinement. Our technique is based on the use of operations and properties that are subtypes of each other as refinements. Therefore, our solution to this problem is another example of why it is useful to treat properties as objects having a type.

We will allow an operation Op2 on a subtype B to refine an operation Opl on a supertype if and only if Op2 behaves-like Opl. Notice here that there is no need to define the two operations as having the same name. In fact, if an operation Op on B is defined with the same name as an existing operation Op on A and the two operation types are not related by a behaves-like property, the system flags this as an error.

In order for the above definitions to make sense, we must explore the meaning of operation and property subtypes a little more closely. What does it mean for an operation type to be a subtype of another operation type? What conditions must hold?

Let us suppose that the type Car has a paint operation defined on it. Paint takes two arguments: a car and a color. Suppose that there is a subtype of car called Model-T that defines an operation called Mpaint. Mpaint takes a Model-T and the color black as arguments and paints the model-T black. We can now ask what the relationship between Paint and Mpaint is?

Cardelli [Ca] holds that, in general, an instance of a subtype should be usable anywhere an instance of the supertype is usable. By this definition, we would say that Paint is a subtype of Mpaint to see this consider the following piece of code:

```
procedure decorate-fleet (p:paint, c:car)
          . . .
          p (c, "black");
           end;

mt: Model-T:
decorate-fleet (Mpaint, mt);
```

Since Mpaint will work very well as the value of p in the decorate-fleet procedure with a Model-T and "black" as arguments, Paint will work just as well in the same context. This leads us to say that Paint will work wherever Mpaint works. Paint is, therefore, a subtype of Mpaint. This is backwards from what intuition would tell us.

Instead we will adopt a point of view in which Mpaint is a subtype of Paint. This is the case because all of the constraints on Paint are met by Mpaint but the opposite is not true. These constraints include the pre-conditions on the argument list and the post-conditions on the return value. In this way we can say that the operation subtype inherits all pre-conditions, post-conditions, and exceptions from the operation supertype.

We can now give a more precise definition of operation refinement. Assume that B behaves-like A. We will say that an operation Op2 on B refines an operation Opl on A if and only if Op2 behaves-like Opl. B inherits all operations O defined on A such that O is not refined by an operation defined on B.

A type is represented as a 5-tuple (N, O, P, C, S) where N is its name, O is a set of operations, P is a set of properties, C is a set of constraints, and S is a set of supertypes. If $T_1 = (N_1, O_1, P_1, C_1, S_1)$ and $T_2 = (N_2, O_2, P_2, C_2, S_2)$, then

$(op \in O_1)$ and $\neg (op \in O_2)$
iff ($op' \in O_2$) such that (op' behaves-like op)

In order for an operation type to be a subtype of another operation type, it too must obey the rule that it have at least the behavior of its supertype. That is, the subtype must inherit all operations, properties, and constraints (pre-conditions and post-conditions) from the supertype.

5. Operation Refinement

We would like to define the behavior of new subtypes such that changes in the semantics of operations (and properties) will not have serious effects on old programs. It would be desirable to have a method that would allow old programs to function properly in the face of a changing type lattice.

There is a tradeoff between the amount of information that we can rely on at compile-time and the ability for programs to adapt at compile time. The more assumptions that we build into compiled code, the more brittle that code will be. In order to allow programs to adapt at compile time, we are forced to defer certain decisions until runtime. This often introduces additional overhead because of the additional runtime checking. Often this checking can be minimized if our compiler is intelligent enough to introduce it only where necessary.

We introduce another subtype of the behaves-like property type called refines. This property is used to relate operation types. It is like behaves-like for operations except that it introduces an additional piece of functionality. If B behaves-like A and an operation Op2 on B refines an operation Opl on A (i.e., Op2 refines Opl), then an invocation of Opl with an instance of B as an argument will cause Op2 to be invoked if all other preconditions match. The preconditions include the decalred types of the arguments to Op2. Opl may only be refined once on a given subtype of A.

An example of this is given below in Figure 2. Here Porsche behaves-like Car. Wash and Wash-gently are defined on Car and Porsche respectively. Wash-gently refines Wash. Suppose that we had the following code:

```
Procedure spring-cleaning (c:car)
     . . .
     wash (c, "ivory")
     . . .
     end;
p: porsche;
spring-cleaning (p);
```

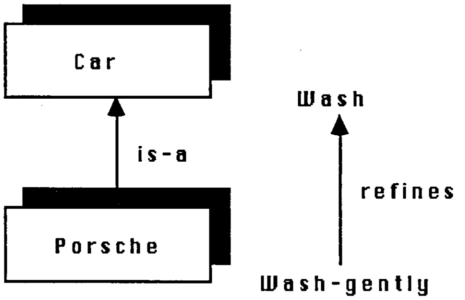

Figure 2: Example of Operation Refinement

Spring-cleaning is called with a porsche which gets passed to the procedure wash along with a second argument of ivory. Since both arguments match the preconditions for wash-gently, a refinement of wash, the wash-gently code is used instead. This is the behavior that you might want in the best of all worlds since you have met all the requirements and would be very dismayed if your porsche were scratched from the use of conventional brushes.

Notice that if in the previous example we had not used ivory soap or if the wash-gently operation had not been defined to be a refinment (perhaps it was only defined to behave-like wash), none of this dispatching would have occurred. It is available only through the use of the refines property and only in cases where the environment is right.

6. Property refinement

All of the above discussion about operation subtyping is applicable to properties. Rather than going through all of that detail again for properties, we will give an example of how property refinement would work.

Suppose that we have two types Person and Porsche-owner with Porsche-owner as a subtype of Person. Type person defines an Age property with a constraint that ages must be integers between 0 and 110. Porsche-owner refines this age property by tightening the constraint to be integers between 35 and 45.

Consider the following piece of code:

```
p: Person;
po: Porsche-owner;

p := po;
p.age := 60;
```

Although the last line is legal, since it is possible to set the age of some people to 60, in the example, p will be assigned a Porsche-owner. The interpretation of p.age will get the age property that is defined on Porsche-owner not the one defined on Person. This property is constrained such that 60 is an illegal value and the assignment will not succeed.

Property refinement is accomplished by refining the get-value and the set-value operations on the property subtype. In the example, the set-value operation for age of Porsche-owner refines the set-value operation for age of Person such that set-value on age of Porsche-owner raises an exception if it is given a value that is not between 35 and 45.

7. Summary

We have presented some examples of the ways in which distinctions ought to be made in the treatment of the is-a hierarchy. We have shown that by treating properties as objects, it is possible to incorporate the desired behavior into our system in a clean and homogeneous manner. We have also assumed that is-a is not a special system-defined resource, but rather that it is simply another property type that relates objects of type type.

It should also be emphasized that this work has been done in the context of an object-oriented database system. In this paper, we have concentrated on some of the linguistic characteristics of the data definition and manipulation languages.

One of the strengths of the object-oriented paradigm is the uniformity with which it treats information. Here, we have extended the uniformity argument by stating that properties or relationships should be treated as objects as well as the more conventional examples. Other systems have made a similar observation, most notably the entity-relationship model [Ch] and several knowledge representation systems [Brl, Br2]. In these systems as in ours relationships or links are denotable. The principle difference here is that we have added this facility to a system that has a very strong notion of type. We have incorporated this view into a paradigm in which a type supports the notion of data abstraction and information hiding. It gives us a modular way to modify the behavior of a property. We do this by using the inheritance mechanisms that are available on the subtree of the type hierarchy that is rooted at the type Property. This approach increases the expressive power of our data modeling language, although it does not provide additional computational facility.

A Systolic Parsing Algorithm for A Visual Programming Language

A. W. Bojanczyk and T. D. Kimura

Department of Computer Science
Washington University
St. Louis, MO 63130

ABSTRACT

In this paper we consider a problem of parsing a two dimensional visual programming language Shaw and Tell on a two dimensional array of processors.

A program in Show and Tell is a bit mapped two dimensional pattern satisfying a certain set of grammatical rules. The pattern consists of a partially ordered set of rectilinear boxes and arrows distributed over the space of nxn pixel area. The corresponding directed graph, the box graph, where boxes are nodes and arrows are directed edges, may not have a cycle in a Show and Tell program. The cycle detection is the most computationally intensive stage of the parsing section of a Show and Tell program.

We propose to exploit the concept of systolic array in parsing of Show and Tell programming language. A given bit pattern is mapped onto nxn array of mesh connected processors with one pixel assigned to one processing element. We show an algorithm for cycle detection which runs in time proportional to the size of a box graph. The complexity of any individual processor is independent on n, the parameter describing the size of the array.

1. Introduction

Thanks to the recent advancement of VLSI technology, high resolution graphics capabilities have become a dominant computer interfacing mechanism for end users. Efficient man-machine communication can be achieved through a graphic interface because of its high bandwidth. Visual programming[1] is a new concept in software engineering that takes advantage of such high bandwidth for designing better software environments. In a visual programming language, a two-dimensional pattern (or an icon) is used to represent various programming concepts, such as iteration, concurrency, recursion, and so forth. One key problem in visual programming language design is to find a formal syntax of such a two-dimensional language and a parsing algorithm based on the formalism.

A systolic array[2] is a collection of identical processing elements (PE, a CPU with local memory), mesh-connected in a two dimensional form. Each PE communicates with its neighbors by passing messages through a thin-wire. There is no shared memory among the PE's. The concept of systolic array was proposed to take advantage of the reduced hardware cost due to the VLSI technology advancement. Many systolic algorithms are designed for numeric, database, and textual applications.

We propose in this paper another application area; a parsing of two dimensional graphic programming language. A program in a such a language is a bit-mapped two-dimensional pattern satisfying a certain set of grammatical rules. The systolic parsing problem is to construct a systolic array such that when a visual program is mapped onto the array with one PE assigned to one pixel, the array can decide whether the pattern satisfies the grammatical rules or not. It is desirable for the array to make the decision in linear time to the size of the pattern. It is also desirable that the complexity of each PE is independent of the size of the array.

Show and Tell™ Language[3] (STL) is a visual programming language designed for novice computer users such as school children and implemented on the Apple® Macintosh™ personal computer. A STL program is entered through mouse clicking and it consists of a partially ordered set of boxes and arrows. Arrows and boxes may not form a cycle in a STL program. The cycle detection is algorithmically the most complex component of the parsing section of the STL system.

As a part of our efforts to find formal specification methods for visual programming languages (syntax and semantics), we are investigating possible systolic parsing algorithms for STL. In this paper we will present a design of a systolic array that can detect a cycle in a 'box graph' in linear time to the size of the graph, where box graph is an abstraction of a STL program capturing features relevant to the detection of cycles.

In the next section we will briefly introduce STL to provide the background for the problem. Section 3 will define the problem in terms of a formal definition of box graph and systolic array. Section 4 and 5 will describe the results, i.e., the design of a finite state machine that can detect a cycle in linear time to the size of the box graph. Section 6 will conclude with possible extensions of the results.

2. Show and Tell Language

Keyboardless programming is one of the main goals of the STL design. A STL program can be created by using a mouse only. A keyboard is needed only for entering texual or numeric data. STL is designed for computer users who are not familiar with keyboarding.

An STL program consists of nested boxes connected by arrows. Loops and cycles are not allowed. A box may be empty or may contain a data value, an icon which is a name of a system or user-defined operation, or another STL program. Arrows allow data to flow from one box to another. An

CH2345-7/86/0000/0048$01.00 © 1986 IEEE

operation in a box will be executed when and only when all incoming values have arrived at the box. Except for this data dependency there is no inherent sequencing mechanism in STL. The semantic model of STL is based on the concept of dataflow. However, since there is no loop in an STL program, once an operation is executed and the result is registered in an empty box, the value will never change. There are no side effects. Thus, STL is a functional parallel programming language.

An empty box can be filled with a data object. Some empty boxes are used for communication with the environment of the program. They are called the *base boxes* of the program and are depicted by a thicker box frame. They correspond to formal parameters of a subroutine in traditional programming languages. The STL interpreter executes a STL program by filling the base boxes with appropriate solution values.

An STL program can be named by a user defined icon. Any Macpaint™ picture can be used as a name. When a box containing a user defined icon is evaluated by the STL interpreter, the named program will be evaluated, after the incoming data values are moved into the base boxes of the called program. An icon in STL is a subroutine name. Recursive definition of a program is also allowed.

An example of STL program is given in Figure 1. The program defines the factorial function recursively. Note that the program has one input and one output parameter. It consists of four boxes one of which contains five boxes. The inconsistent box, which is defined as any box that contains *conflicting information* such as "5 flowing into 0", is shaded by the interpreter. The data flows from the top to the bottom of the graph. The name of the program is given on the upper left corner of the editing window. The leftmost column provides the editing tools for program construction. Any box that overlaps with other boxes or forms a cycle will be rejected by the editing program of the STL system.

The language is implemented on the Apple® Macintosh™ personal computer. Using the editing tools provided by the STL system, a user constructs a program on the editing window through a sequence of mouse clicking and dragging. In order to draw a box, for example, the user drags the mouse from the upper-left corner of the box, causing a mouse-down event, to the lower-right corner, causing a mouse-up event. The editing program in the STL system recognizes these two mouse events and constructs an internal data structure representing the box, provided that the box is acceptable, i.e., the box does not overlap with other boxes nor forms a cycle with the existing arrows.

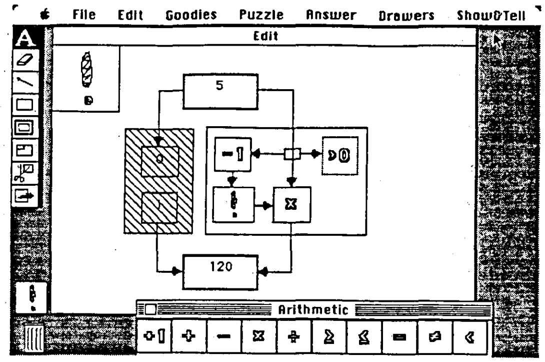

Figure 1: A Recursive STL Puzzle (Factorial Function)

The current STL system does not have capability of parsing a bit mapped image as a STL program. For example, if the factorial program of Figure1 is constructed by MacPaint™, and the resulting MacPaint file is pasted onto the editing window of the STL system, the current STL editor program will interprete the image as a background (comment) image of some other program, and will not be able to parse the bit image as a STL program. Thus, *programming in MacPaint* is not possible with the current STL system.

In this paper we try to solve the problem of finding a parsing algorithm for two-dimensional representation of STL programs. One approach is to find a formal syntax for STL and to construct a parsing algorithm based on the formalism. Our efforts in this direction is reported in a separate paper[4]. Another approach is to construct an algorithm which can accept all and only images that represents a legal STL program. We will take the second approach in this paper.

3. Problem Definition

In this section we will define the problem. Our solution to the problem will be given in the next section. First we will define the concept of *box graph* as a syntactic abstraction of STL program. Then, we will define the concept of *systolic array* as a model of parallel computer architecture. Finally we will define the problem of detecting a cycle in a box graph by an systolic array in linear time to the size of the box graph.

3.1 Box Graph

A box graph is a collection of boxes and arrows geometrically distributed over the space of n x n pixel area. No two boxes overlap with each other. No box contains another box. Every arrow starts from the boundary of one box and ends on the boundary of another box. Arrows may intersect with one another, but they don't branch out. No two arrows intersect with a box at the same location. There must be no loops or cycles in a box graph, i.e., there is no sequence of arrows that connects a box to itself. Boxes and arrows are composed of horizontal and vertical line segments. No diagonal lines exist in a box graph. An example of box graph is given in Figure 2. Note that a box graph is an abstraction of a STL program in hiding the type and the content of each box. Thus, in a box graph no nesting of boxes exist. There is no semantics associated with a box graph.

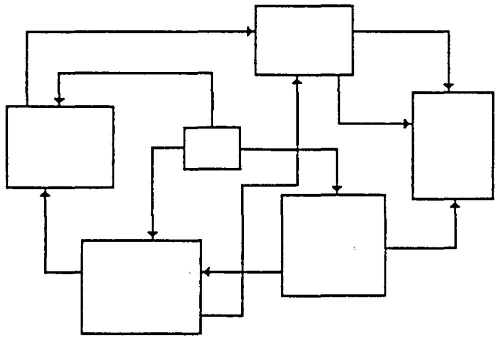

Figure 2: An Example of a Box Graph

The exact definition of a well formed box graph as a bit image will be given in the section 3.3.

3.2 Systolic Array

A systolic array is a collection of n x n processing elements (PE: a CPU with local memory), mesh-connected in a two dimensional form. See Figure 3. Each processor is a simple finite state machine with local memory registers. The memory size of a single processor is independent on n, the parameter describing the size of the array. The processors communicate only with their four nearest neighbors, i.e., north, east, south and west neighbors. Knowing what operations the processors must perform in order to solve a problem, we define a *time unit* to be the maximal time that is necessary for a processor to perform the most time consuming operation together with loading and unloading its registers. Like the memory size, the duration of the time unit is independent on n. A synchronization mechanism allows processors to exchange data at time instants separated by integer multiples of a time unit. We assume that processors are microprogammable. This allows us to change the set of operations performed by each processor when necessary. This approach is similar to one adopted in the PSC project[5].

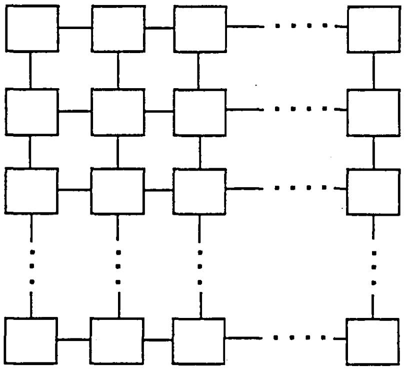

Figure 3: A Systolic Array

3.3 Problem

To design a systolic array of size n x n that can decide whether a given bit pattern is a well formed box graph or not, in $O(n^2)$ steps with constant memory requirement for each PE, where the bit pattern is mapped onto the array with one pixel assigned to one PE.

A well formed box graph is defined as follows:
(1) A box and an arrow consists of line segments. A line segment is one pixel wide. A line segment may be horizontal or vertical, but never diagonal. Two parallel line segments must be separated by at least one pixel. An arrow does not start at a corner of a box.

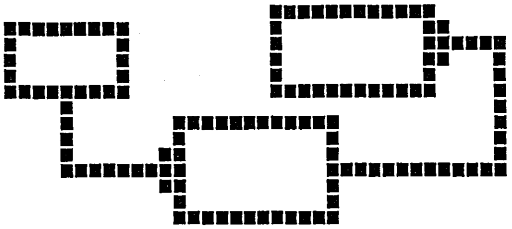

Figure 4: A legal box graph

The following configurations are not allowed.

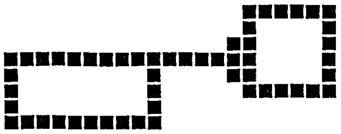

Figure 5: Illegal Box Arrow Combination

(2) A box is a rectangle enclosed by line segments. A box contains nothing and it has at least one empty pixel inside the enclosure.

Figure 6: The Smallest Box

(3) An arrow head is represented by extra two pixels as follows:

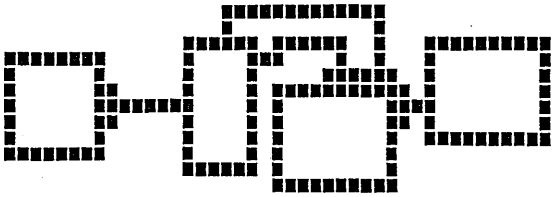

Figure 7: Legal Arrow Heads

The following configurations are not allowed:

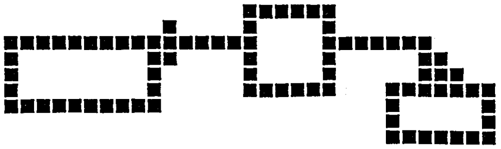

Figure 8: Illegal Arrow Heads

(4) There must be no cycle. The following is an example of cycle:

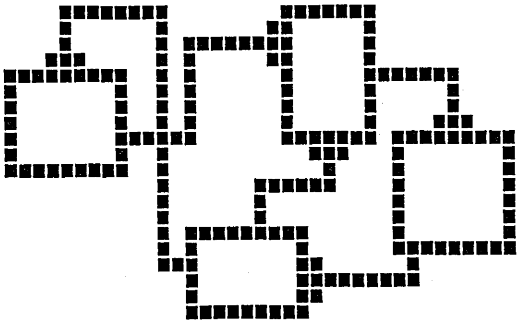

Figure 9: An Example of a Cycle in a Box Graph

3.4 Representation of the Box Graph

A box graph is made up of boxes and arrows (connecting directed lines). Arrows and boxes in turn are made up of pixels, single points of rectilinear grid. Although as individuals the points are indistinguishable, they represent different elements of boxes and arrows, i.e., corners, T-junctions (which are arrow tails), cross junctions, straight line segments and arrow heads. These elements form *basic building blocks* for any box or connecting arrow.

Decision of what a given non-empty pixel represents can be made locally by examining its neighbourhood. The neighbourhood about a pixel consists of all the pixels in a 3x3 window whose center is the given pixel. The pattern of the neighbourhood determines the role played by each non-empty central pixel. Figure 10 illustrates possible representation of basic buildings blocks where 1's denote non-empty pixels, 0's empty or background pixels and X's either of these two. There is also unique pattern code associated with each pattern.

Note that all fifteen patterns are mutually exclusive.

There is a restriction that no arrow can start from a box corner. This restriction excludes the possibility that a T-junction could represent a box corner and a tail of an arrow starting from that corner, or that a cross could represent a box corner and tails of two arrows starting from that corner. See Figure 11 for illustration.

```

not allowed T-junction           not allowed cross
```

Figure 11: Illegal Patterns

The representation of the arrow head involves two additional non-empty pixels which are superfluous, they simply help to identify the arrow-head. This is not the only possible identification. There are many other but all, including the one considered here, have some drawbacks.

4. Recognition of the Box Graph

This section describes the procedure for recognizing a box graph which is initially defined by a set of non-empty pixels distributed over a square nxn grid.

The grid is mapped onto the square array of processors with one grid point assigned to one processor. Each processor has a *pixel register* where non-empty pixel is represented by 1 and background pixel by 0.

The recognition of the box graph proceeds in two stages. In the first stage processors recognize the basic building blocks by comparing the patterns of the neighborhoods with the predefined patterns of the basic building blocks. Note however, that basic building blocks still do not uniquely determine elemments of rectangles or arrows. A corner may be the box corner or turning point of an arrow. A line may be a part of an arrow or a side of a box. Basic building blocks together with specification whether they belong to rectangles or arrows form *box graph building blocks.* In the second stageof box graph recognition, the processors uniquely determine the box graph building blocks.

4.1 Identification of Basic Building Blocks

All fifteen patterns defining the basic building blocks (see Figure 10) are stored in local memories of all processors. Processors which correspond to non-empty pixels have to examine their neighborhood in order to determine what building blocks they represent. Succesive shift operations bring pixels from the neighborhood to the center processor. The pattern of the neighborhood is compared to each of the fifteen basic patterns. If there is a match to any predefined pattern, the pattern code is stored in the pattern code register (LPCR) of the center processor and the center processor is marked as initially recognized. However, for some non-empty pixels the pattern of the neighborhood do not match the pattern of any basic building block. This is a side effect of the representation of the arrow-head. Only the pixels that serve as identifiers of arrow-heads may find themselves in such position.

The resulting ambiguity can be solved in the following way. The processors which were identified as arrow-heads transmit that information to those neighbors which served as markers of the arrow-heads. Because all arrow-heads were found, the markers are not needed any longer and can be erased. The erasing removes ambiguity. Now, by repeating the matching process for all "undecided" processors the identification of basic building blocks is complete, all non-empty pixels know exactly what they represent.

Note that the identification of the basic building blocks takes constant time, independent on n, the array size or even the graph size.

4.2 Identification of the Graph

Once basic building blocks are identified, the array is set to recognize the box graph. Processors have to decide whether they constitute a part of an arrow or a box. In order to make that decision processors must receive enough information possibly coming from the distant regions.

Prior to the computation all processors are in the initial states. In the course of the computation the processors change their states until the final states are assumed. The initial state corresponds to the starting information possessed by a processor which, in case of non-empty pixel, is the pattern code of the basic building block, while for empty pixels the pattern code is zero. The final state means that a processor recognized what element of the box graph it represents. The processor stores the pattern code of the graph building block, which is the code of the basic building block together with the indication whether the building block is a part of an arrow or a box.

For some processors the initial state is also the final state. This is the case with the processors corresponding to the background pixels. Similarly, the processors representing arrow-tails (which are T-junctions), arrow-heads and arrow crossings are in the final state to begin with. All other processors need some additional information before they are able to recognize what element of the box graph they represent.

All decisions (or state changes) are made based on states of some processors, *bounding processors*, lying in the same vertical and horizontal line as the processor making a decision. A bounding processor is such that contains information which may influance states of processors in the same horizontal or vertical line. First of all, any non-empty processor which is in the final state is a bounding processors. Corners, T-junctions, arrow heads and crossings are bounding for a processor which is connected to any of them by a straight line of non-empty processors. Any non-empty processor is bounding for another non-empty processor which is separated from it by a straight line of empty processors. In Figure 12 a possible situation is illustrated. Numbers are codes of basic building blocks. The top, the bottom, the leftmost and the rightmost processors are the bounding processors for the central processor.

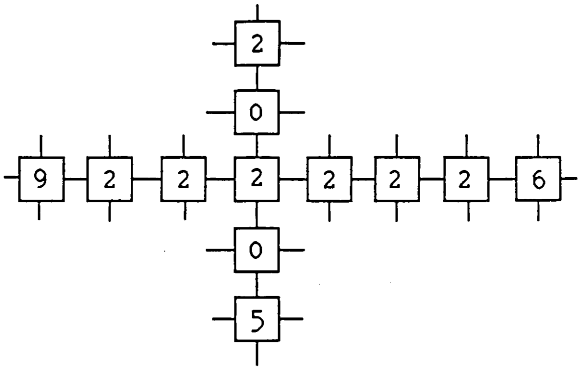

Figure 12: Bounding Processor

The array operates in the synchronous mode. Triggered by the outside control the processors start executing their individual programs. The program to be executed depends on the current state of the processor. All processors pass the data about their current knowledge to the north, east, south and west neighbours. Simultaneously, processors receive similar data from the neighbors. Based on the local data and the data received from the neighbours the processors update their states and also prepare data to be sent to the neighbours in the next cycle.

Each processor has four special registers NR,SR,WR and ER monitoring the states of the bounding processors above, below, to the left and to the right of it. Figure 13 shows some registers which are used for graph building blocks recognition.

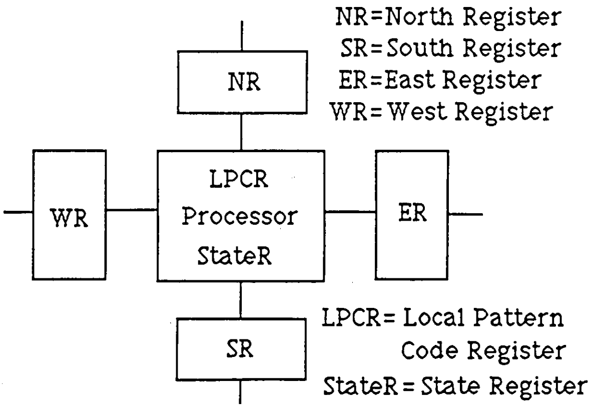

Figure 13: Processor Registers

The StateR register describes the state of the processor. When the processor is not in the final state, the content of StateR is 0. The content is A,B,E,H or T if the processor repretents arrow, box, empty processor, arrow-head or arrow-tail respectively.

The data which is sent by a processor to its neighbors is a concatenation of LPCR and StateR registers of either the processor itself or those of the bounding processors. All incoming messages are evaluated against the information possessed by the processor. A decision is made locally whether the incoming data has higher priority than the information evaluated by the processor. In the case when the incoming data has higher priority it is transmitted further in the same direction it came from. Otherwise, the processor transmits the locally evaluated data.

The data representing empty pixels have the lowest priority. The corresponding processors do not perform any computation but simply shift the incoming data along vertical and horizontal connections. The data representing non-empty pixels which are in the final state have the highest priority. The corresponding processors also do not perform any computation. They ignore the incoming data but keep sending the information what (final) part of the box graph they represent to the immediate neighbors. If both incoming data and local data represent the final states then, as the incoming data is ignored, the local data has precedence. In the case when the incoming data have the same code as the code of the local data, the local data have the higher priority. The data representing line have lower priority than the data representing any other building block. The local data representing any building block other than line have higher priority than any incoming data except when the incoming data represents the final non-empty state and the receiving processor is not in the final state.

4.3 Arrow Identification

If a processor is not in the final state but one of its non- empty neighbors is in the final state, then the final state of the neighbor uniquely determines the final state of the processor. That is if any of the nearest neighbors (north, south, west or east neighbor) represents an arrow then the processor must be a part of that arrow. Similarly, if a neighbor represents a box then the processor is also a part of that box. Recall that arrow-heads, arrow-tails or crossings are in the final state from the very begining of the computation. As a consequence, any non-empty processor which is connected to an arrow-head, arrow-tail or crossing will assume the final state A or B on completion of the first unit of time . Next, one by one, succesive non-empty processors connected to arrow-heads, arrow-tails or crossings by a chain of non-empty processors, will be able to determine their final states.

In particular, as the maximal length of any straight, horizontal or vertical, line is n, then any non-empty processor connected to an arrow-head, arrow-tail or crossing by a straight line of non-empty processors will assume the final state in at most n units of time.

When a processor is a corner connected by a straight (non-empty) line to another corner of opposite orientation then both corners must belong to an arrow. (Two corners connected by a line have the *same orientation* when traversing the line either only right or only left turns are encountered, otherwise the corners have the *opposite orientation*). Similarly, for a processor representing a line, if both end of the straight part of the line are corners of oposite direction then the line must be a part of an arrow. Both cases are easily recognized by one of the processors lying on the line that joins the two corners. The processor will receive the information that the opposite bounding processors are corners of opposite orientation and recognize that it is a part of an arrow. Next the message will spread along the line and eventually will reach the corners.

The recognition of a segment of an arrow between two corners of opposite orientation takes no more than 2n units of time.

The constant two comes from the fact that the information about two corners is combined in one of the processors lying in between and next propagated back to the corners.

The only hard situation is when following a line only corners of the same orientation are met. This can happen with a box or a *spiral*, see Figures 14a and 14b below.

Figure 14b: Box.

A box has the property that its interior is "empty". Spiral on the other hand has one or more *coils* inside. This makes all but the innermost coils of a spiral easy to recognize. However, the innermost coil must end in a box so it is easy to recognize anyway. The procedure is the following.

As we mentioned before, any non-empty processor which lies on a line connecting two corners of the same orientation is either a part of a box or an arrow. However, if there is a coil inside then any corner of the inner coil will betray that.

Consider a processor which is the part of the outer coil and which lies on the same vertical or horizontal line as the corner of the inner coil. After at most n units of time (which is the maximal distance in vertical and horizontal direction in the array), the processor will have the information that two of its bounding opposite processors represent corners of the same orientation, i.e., the processor represents either a part of a box or a spiral. However, the processor will also receive the message that there is a corner inside. Hence, the processor must represent a part of a spiral. This is conclusive, the processor assumes the final state. That final state is communicated along vertical and horizontal lines. Passing through all nonempty processors the information eventually reaches the two bounding corners which in turn can now decide that they are parts of an arrow. The procedure is simultaneously executed for all four sides of all outer coils.

Any spiral can be recognized in no more than 4n units of time. All outer coils can be recognized in time at most 2n. This is because at most n units of time are necessary to propagate data from all three corners to the processor which makes the final decision. Additional n units of time are needed to propagate the message back to the corners. The innermost coil has the length at most 4n and its end must be an arrow-head or an arrow tail. As the end of the innermost coil is in the final state from the begining of the computation this fact will propagate along the innermost coil in time equal to the length of the coil which is at most 4n.

4.4 Box Identification

It remains to find a way for recognizing boxes. Without loss of generality, consider processors forming upper and left side of a box. These two sides are bounded by corners of the same orientation with the upper-left corner being the only common point. Note that a box is convex and "empty" inside. Thus all processors lying on the upper and left sides have their *counterparts* on the lower and the right sides, only empty processors separate the opposite sides.

Now consider any north-west corner. This processor initiates search for a box. A signal is sent from the north-west corner to all processors forming upper and left sides (including bounding corners) to check on their counterparts. The signal propagates along both sides until it reaches the corners.

If any of the two corners has the opposite orientation than the north-west corner, that corner immediatelly concludes that the line is a part of an arrow. The corner assumes the final state, terminates the search and propagates the information back to the north-west corner. All processors in between, one by one, assume the final states. Next, the north-west corner assumes the final state and transmits this information to its neighbors. Now, the information spreads along the second side, changing the states of all processors on that side which are not in the final states into the final states.

On the other hand, if the corner has the same orientation that the north-west corner, the search continues. The corner which received the signal from the north-west corner (and has the same orientation as the north-west corner) replies by sending boolean value true back to the north-west corner. This boolean value stops at each processor it passes. Each processor which the boolean value visits holds it until the check on the processor counterpart is finished. If the result of the check indicates that the counterpart may belong to the same box as the processor, i.e., for the north/west side the south/east bounding processor represents a line, the boolean value is passed along the line, towards the north-west corner, unchanged. Negative check, i.e., for the north side the south bounding processor is not a line, indicates that the processor is a part of an arrow. This is the final decision overruling other actions the processor may contemplate to take. The search is aborted. The information is sent to the neighbors and transmited further in succesive units of time. Eventually all processor on both sides starting from the north-west corner are informed.

In case when all checks are positive, the north-west corner will receive the boolean value true. The search along one side is positive. If also the search along the second side is positive this means that the interior of the structure is empty. As only a box has this property, the structure must a box. The north-west corner assumes the final state marking the corner as the box corner. The information is transmited to the neighbors which will propagate it further until all processors forming the box are reached. The recognition of the box is now completed.

The recognition of a box takes no more than 4n units of time. This follows from the fact that the message from the north-west corner must travel to the south-east corner and back to the north-west corner, which takes at most 4n units of time.

The results of this section can be summed up in the following theorem.

Theorem 1: A well defined box-graph given as a colection of basic building blocks can be recognized in at most 4n units of time on an nxn array of processors. The size of the local memory of any processor is independent on n.

5. Cycle Search

Let b be any box in the box graph G. By indeg(b) we denote the number of arrows pointing at the box b and by outdeg(b) the number of arrows originating at the box b.

The algorithm for establishing whether a box graph is acyclic is based on the simple observation that removal of all boxes, together with arrows originating at or pointing to them, for which indeg(b)*outdeg(b)=0 will leave the subraph cyclic if the graph is cyclic. If a graph is acyclic the procedure will render the subgraph empty.

The cycle search is initiated by boxes north-west corners. For every box the computation consits of two local phases, checking phase, which may be repeated number of times for the box, and erasing phase, which when entered is executed only once for that box.

In the erasing phase each north-west corner propagates two control bits, *head* and *tail*, along the box perimeter. The initial values for these bits are zeros. The value of tail is changed to one when at least one arrow-tail is found on the perimeter. Similarly, the value of head is changed to one when at least one arrow-head is found on the perimeter.

After at most 4n units of time (the maximal perimetr length of any box), the north-west corner receives both control bits. The next action depends on the value of the bits. When both are ones this indicates that indeg(b)*outdeg(b)>0, i.e., there is at least one arrow pointing to the box and at least one arrow leaving the box. The north-west corner sets both bits to zero and the checking cycle repeats.

In the case when indeg(b)*outdeg(b)=0 the north-west corner initiates erasing phase. A single control bit *erase* is propagated along the perimeter and further along all arrows leaving or pointing to the box up to the point where another box is met. When a processor receives the control bit 'erase' it marks itself as erased and transmits the 'erase' bit to all non-empty and not erased neighbors. When the 'erase' bit is received by a processor belonging to another box, which must be an arrow-head or arrow-tail, the processor replaces the content of LPCR register, which is the code of an arrow-head or an arrow-tail, by the code of a line having the same direction as the direction of the side the processor represented originally. This operation removes one arrow-head or arrow-tail from the second box, possibly changing the product of indeg and outdeg for that box. The (local) erasing phase terminates at this point, however a new (local) erasing may start at the second box.

It is clear that if the original box-graph is acyclic, the cycle search procedure will terminate leaving all non-empty processors marked as erased. The execution time is proportional to the total number of marked processors. We now prove this assertion. To do that we will use the standard graph terminology. In addition, let card(b) and card((b1,b2)) denote the number of processors forming the box b and the number of processors forming the arrow (b1,b2), respectively. Finally, let card(G) denote the total number of non-empty pixels forming the graph G. We are ready to prove the main result of the paper.

Theorem 2:
If a box-graph is acyclic then the cycle serch procedure terminates in time at most 3*card(G).

Proof: Without loss of generality we can assume that G is connected.

As G is acyclic there is at least one box s, a source box, such that indeg(s)=0 and outdeg(s)>0. Similarly, there is at least one box t, a terminal box, such that outdeg(t)=0 and indeg(t)>0.

Consider all source boxes b(1,1),b(1,2),..,b(1,i_1), and all arrows starting at these boxes. The arrows point at boxes b(2,1),b(2,2),...,b(2,i_2). Choose the source box b for which the sum of card(b) and card((b,c)) of the longest arrow staritng at that box is maximal. Let it be the box b(1,1) and the arrow (b(1,1),b(2,1)). From the description of the cycle search procedure it follows that after

2 * card(b(1,1)) + card((b(1,1),b(2,1)))

units of time all boxes b(1,1),b(1,2),..,b(1,i_1) and all arrows which started at these boxes are erased. (We take card(b(1,1)) twice as there are two traverses along the box perimeter, in the first travers the product of outdeg and indeg is calculated, and in the second, the erasing phase is processed).

Some of the boxes b(2,1),b(2,2),..,b(2,i_2) in the resulting subgraph may now become the source boxes for that subgraph and some may have been partially or fully erased. Again, consider all source boxes b(3,1),b(3,2),..,b(3,i_3) and all arrows originating at these boxes in the current subgraph. Note that the intersection of the sets {b(2,1),b(2,2),..,b(2,i_2)} and {b(3,1),b(3,2),..,b(3,i_3)} may be empty. Nevertheless, in the current subgraph there is at least one source box. Otherwise the subgraph would have been cyclis which is impossible as the graph itself is acyclic. Choose the box b and the arrow (b,c) starting at that box for which sum of card(b) and card((b,c)) is maximal. Let it be the box b(3,1) and the arrow (b(3,1),b(4,1)). After

3 * card(b(3,1)) + card((b(3,1),b(4,1)))

units of time all boxes b(3,1),b(3,2),.., b(3,i_3) and all arrows which started at these boxes are erased. (We count card(b(3,1)) three times as now there may be up to three trverses along the box perimeter. In the first travers the check for the product of outdeg and indeg may still be negative. In the second travers the fact that indeg=0 is discovered, and finally in the third travers the erasing phase is processed).

As there are no cycles in the graph, the procedure must terminate on one of the terminal boxes. This happens after

M=[2*card(b(1,1))+card((b(1,1),b(2,1)))]+...+
[3*card(b(2*m-1,1))+card((b(2*m-1,1),b(2*m,1)))]

units of time. But M<3*card(G) which completes the proof.
QED

In the worst case the procedure takes order of n**2 units of time. The reason for this is that the longest "non-empty" path cannot exceed the overall number of processor, which is exactly n**2.

If there is a cycle in the graph, the procedure will not terminate without the intervention of the outside control. However, we know that after at most 3*n**2 units of time the acyclic graph would have been erased. Thus after that time, if there are still not erased processors in the array, the graph must have cycles.

6. Conclusions

We introduced a concept of a box graph and proposed a systolic algorithm for an nxn array of processors which dedects cycles in a well defined box graph. The algorithm is synchronous and its behavior in the worst case is proportional to n**2. The memory requierement is constant per each processor. When a graph is acyclic the algorithm can recognize that fact in time proportional to the cardinality of the graph. However, it cannot discover a cycle until "full time" n**2 is reached. It is an open question whether it is possible to detect cycle in time, say, proportional to the cardinality of a box graph. This question is related to the another one. We assumed that the array is synchronous. It is not known to the authors whether the cycle search procedure could terminate if the array operated in asynchronous manner.

In our considerations we assumed that the initial box graph does not have flaws and that no arrow starts or ends at box corners. The question is whether these assumption can be relaxed while maintaining the execution time proportional to cardinality of the graph.

ABSTRACT

Although there are many programming languages, there are few alternatives in terms of presentation mode. This paper describes the programming language FPL, a graphic representation of classical programming. The premise behind the design of FPL is that some novice learners would benefit more from a visual presentation of conceptual programming structures rather than from the traditional textual representation. FPL's interactive, graphic programming environment, which supports the learner throughout the programming process is discussed. This environment provides a rich research environment for the study of novice programmers and the effect of this graphic programming language. Preliminary research on FPL suggests that this programming environment has a positive effect on the programs written by novices.

INTRODUCTION

Despite the number of languages available, the learner of programming has few alternatives. Though there are many detailed differences encompassed by the range of most programming languages available today, in one pedagogical sense they afford no variety whatever: all rely exclusively on text for representing the program. For those teaching programming this is unfortunate. It means there is no graphic alternative for the student who is more visually than textually oriented.

This paper describes work addressing this problem. It involves FPL, a visually represented programming language, and the interactive FPL environment used by novices for learning computer programming.

The paper proceeds by successively describing:

1. the contextual background;
2. the FPL language;
3. the interactive environment in which FPL is used;
4. FPL-based research on the learning of programming;
5. concluding observations.

CONTEXTUAL BACKGROUND: GRAPHICS AND ALTERNATIVES FOR LEARNING TO PROGRAM

The work reported here assumes that a visual approach to programming is an important alternative for many learners, and discusses some appropriate development work and research based on that assumption. This first section discusses the foundation for such an assumption.

Classical Programming

Classical programming refers to well-structured programming as done in a number of now well-established, structurally similar languages such as Algol, Basic, Cobol, Fortran, Pascal or Pl/1. A casual glance at programs written in these languages makes one thing immediately obvious: all are shaped by their adoption of our natural language. All use words, punctuation, special characters and narrative sequence to represent programs. In particular, all use key words to designate specific programming structures and to indicate a program's flow of control.

Classical programming is widely taught in educational settings. However, it is not clear that the exclusively textual representation characteristic of all the classical languages can meet the needs of all types of learners equally well. Although the sequential, linear nature of language may match the computer's organization (linear, sequential and rule-governed), it does not necessarily match the way many people think about problems and problem solving, either on or off the computer.

Graphics vs. Text

Although little is known about how graphics influence learning, intuition seems to suggest that the use of graphic materials makes learning easier. "It is commonly acknowledged that the human mind is strongly visually oriented and that people acquire information at a significantly higher rate by discovering graphical relationships in complex pictures than by reading text"[1] (p. 12).

Educators have long realized that not all learners have identical learning styles and preferences. Supporting alternative learning styles by providing a variety of methods and materials is an important and worthy educational goal. Teachers and learners of computer programming have not had alternatives available to them, in one sense, at least. The textual focus of all of the commonly available languages severely limits the learner's options. A language that presents programming graphically would provide visually oriented learners with an appropriate alternative vehicle for learning about programming.

A Graphical Approach To Programming

FPL graphically represents programming through the set of 11 icons, each of which represents one programming construct. Two icons are textless, the other nine include text, in the form of variables and/or constants. Together, the icons eliminate the need for key or reserved words, so variable names and constants are the only textual elements in an FPL program. Each icon is directly translatable into corresponding text in a traditional classical language. For example, Figure 1 shows the icons and their Pascal translations.

In FPL the spatial arrangement of icons embodies the flow of control so an FPL program is drawn, not listed. Because they are entirely textual, traditional program listings visually suggest sequential action, regardless of the actual nature of the program flow. By contrast, an FPL drawing more immediately indicates the program's actual structure. Refer to Figure 2 for a representative FPL program and its textual Pascal equivalent.

Design Criteria

The design criteria were shaped by the underlying purpose for FPL: to provide novices with a simple, visually oriented alternative for learning classical programming. These criteria can best be summarized by the following goals:

1. To reduce classical programming constructs to a minimum set reflecting the underlying similarity of all languages in this classical group;
2. To graphically represent each such construct with a unique icon, and to represent the logic of programming through these icons and the manner of connecting and relating them;
3. To make each icon easy to draw and remember;
4. To implement the language in an easy to use environment that provides extensive explanatory help on demand and blocks any error with an immediate and precise explanation.

The resulting system provides an alternative programming vehicle for the student whose aptitude favors a visual rather than a purely textual approach to learning and remembering, in a supportive editing and testing environment. It also provides a rich environment for studying the programming process.

Readers who want a more complete description of the FPL language should consult Programming Primer[5], the FPL icon design criteria, should see Taylor's description[6], and those interested in the general visual programming context should see IEEE's Special Issue on Visual Programming[3].

Visual Programming

Early attempts to define an alternative mode for representing logic in programming gave rise to standard flowcharts. They became a widely used, popular vehicle for planning and debugging program logic and algorithms. Despite on-going debate over the usefulness of this particular tool, the value of graphical representation was recognized, and many more attempts have been made to design viable tools for graphically representing programming[2]. One limitation of many of these early visual representations is that they offer the programmer only a limited graphical representation; actual coding must still be done in standard textual form.

Recent efforts to expand the use of visualization in programming systems has given rise to the genre of "visual programming," defined by Grafton and Ichikawa[3] as encompassing three distinct areas of research: "graphic techniques that provide both static and dynamic multidimensional views of software, graphics-based very high-level programming languages, and animation of algorithms and software" (p. 7). The field of visual programming is a relatively new one, and much of the development has focused on systems for graphic display of the program flow and data values during execution and debugging. Such systems make visual the dynamic nature of a program. As Grafton and Ichikawa[3] point out, "...the ability to see data flow and control structures of algorithms and software as they execute will give software engineers and computer scientists an ability to understand and 'feel' the action of software or algorithms" (p. 8). Meyers[4] has carefully reviewed many of these systems and has devised a taxonomy for classification of the wide variety of languages, environments and systems which claim to be "visual" in one sense or another.

Systems employing any of the currently available visual techniques can certainly help both novice and expert programmers, but they often confine the use of graphic representation to a limited subset of the actions involved in the programming process. What is needed is an integrated system that provides a programmer with a graphic tool for program planning, an interactive, graphic, computer-based interface for program writing, and a program execution environment that permits examination of memory contents while seeing data flow and control structures. Such a system seems ideal for novices who are grappling with understanding programming language constructs at the same time as they are trying to understand how the computer actually acts on the written program. An integrated, graphically represented language would enhance understanding and simplify the cycle of program composition, comprehension and debugging. It ought to especially suit those novices who are more visually than textually oriented.

The growing interest in visual programming suggests that some developers, at least, believe graphic tools make it easier to understand the complex action of the computer. However, while intuition and anecdotally recorded observation may have persuaded many people of the viability of graphical systems, empirical research to confirm that viability is still missing.

A firm understanding of the programming process, the behavior of programmers, and the interaction of language, graphics and programming achievement can only follow the development of contrasting alternative environments and well-designed empirical research on their use. As a graphically represented programming language, FPL and its implementation constitute such an environment. The FPL-based research described in the fourth section of this paper is designed to illuminate specific aspects of the programming process and thus contribute to our general understanding of it.

THE FPL LANGUAGE: A VISUAL REPRESENTATION OF LOGIC

FPL (First Programming Language) reflects the structure common to the entire family of classical languages and is designed to facilitate learning that structure. However, though it shares the structure, it does not share the exclusively textual, keyword representation of that structure. Instead, FPL uses iconic representation. The first two figures illustrate the difference. Figure 1 presents the eleven FPL icons and their equivalent in Pascal, a representative classical language. Figure 2 broadens the comparison by presenting parallel versions of the same program.

THE FPL ENVIRONMENT: STUDIO CREATION AND LAB TESTING

In one respect, FPL goes beyond the scope of many other attempts at visual programming: the FPL environment supports the user from the initial problem solving and computer representation stage through debugging, refinement and execution. The FPL environment runs on the IBM PC/XT/AT family of microcomputers and has two parts, a Studio and a Lab. In the Studio the program is created and refined. Figures 3, 4, and 5 (discussed further below) illustrate scenes of work in the Studio. In the Lab, the program is executed and its execution monitored, via an animated representation of the program, its I/O, and the dynamic display of the value of user selected variables. Figure 6 (also discussed further below) illustrates with a scene from the Lab. The Studio is discussed first and the Lab, which is still in prototype, second.

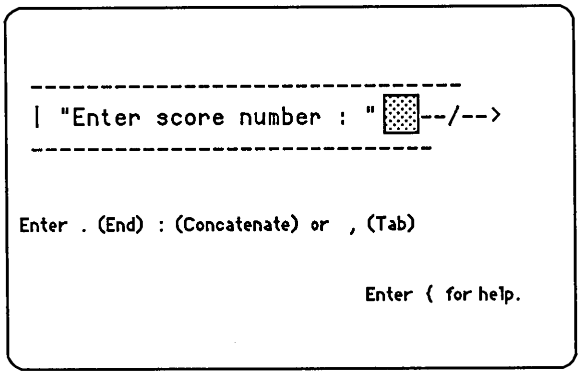
FIGURE 6: FPL LAB screen layout

The Graphic Studio: Program Creation and Editing

A student working in FPL is encouraged to sketch a program first on paper, planning how to solve the problem. When ready to enter or edit a version of his/her program, the student invokes the FPL Studio.

From the studio, the user can create or refine his/her program by adding new icons or by deleting, replacing or modifying existing ones. When creating or refining, the user focuses on a single icon, and the displayed context reflects this. Figure 4, for example, illustrates a scene from a user's entry of an "I" or Internal Assignment icon; figure 7, entry of an "X" or External Assignment icon. Though the user can easily move in and out of broader visual contexts (see next section, Program Viewing and Drawing), the immediate one is that of the single icon. In that context, the user is graphically prompted for each component of the entry (again, see figures 4 and 7 for examples), in a set order, based on the icon type. The user can freely intermix work on any icon with access to and browsing within the help system (see section below, System Support Features). The user can exit from work on any icon via this help system, or following system detection of any syntax error in the icon entry.



```
-------------------------------
| "Enter score number : " ▒--/-->
------------------------------

Enter . (End) : (Concatenate) or , (Tab)

                              Enter { for help.
```

FIGURE 7: External Assignment icon prompt

While entering icons, the user is always returned to the main entry prompt line (see figure 3) once entry of a specific icon is completed. When refining generally, the user is returned to a broader prompt to determine if he or she wishes to edit further, and if so, where. In deciding where to edit, seeing more context than a single icon is essential. For this, the user must be able to scan all or part of his/her program.

Program Viewing and Drawing. There are two different perspectives from which one can view the program under construction: immediate and global. In the first, the user can see the icons in the trunk currently being worked on. In the second, the user can view any part of the program whatever. Thus, though while working on a specific icon the programmer sees only that one icon, more of the current program can be viewed on demand.

Immediate viewing (Figure 5) shows one vertical line, or trunk, at a time, either the one being worked on, or any other trunk the user chooses. If this doesn't provide sufficient context, once the user has finished entering any logically complete version of his/her program, the system can create a complete drawing of the program to date. At that point, without leaving the Studio, the user can display the program on screen (see Figure 8) or stop and print out a drawing of the program on paper.

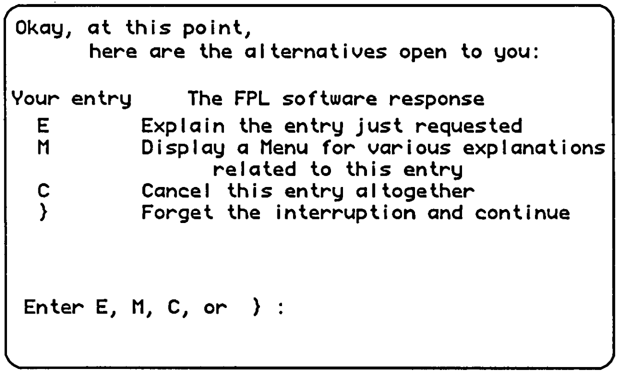
FIGURE 8: On-screen drawing

Program Preservation. When the programmer finishes working on a program, it is saved on disk in an intermediate representation form. At any later time, the programmer can reenter the Studio, access that program, and work on it further.

System Support Features. The FPL Studio offers comprehensive support to the programmer throughout the programming process by means of several special features which are similar in many ways to features employed by other programming language environments (*e.g.*, Macintosh Pascal[7] and Support[8]).

1. Tailoring by the user. To better reflect the learning styles and stages of different learners, the system can be moderately tailored by the user, to control how often he or she will be prompted to accept or cancel an entry. The user can select any of three frequency levels of such verification prompting :
   a. Beginning user : user verification required upon entry of each icon component and upon completion of each entire icon;
   b. Familiar user : user verification required only at the completion of each entire icon;
   c. Competent user : no verification required; assumes user can edit if required.

   The last enables the experienced user to work quickly; the first and second allow less experienced users to proceed more cautiously, at either of two lesser speeds.
2. On-line help. The Studio includes a comprehensive on-line help facility. At any point, the user can get help by means of a character reserved for this purpose. The system's response allows the user to either see an explanation specific to the immediate context, (see figures 9 and 10 for examples) or by going through a hierarchical menu structure, to access help on virtually any aspect of FPL (see figure 11). Following the invocation of the help system, the user may either continue from the point of interruption or cancel the entry or edit attempt which raised the need for help.

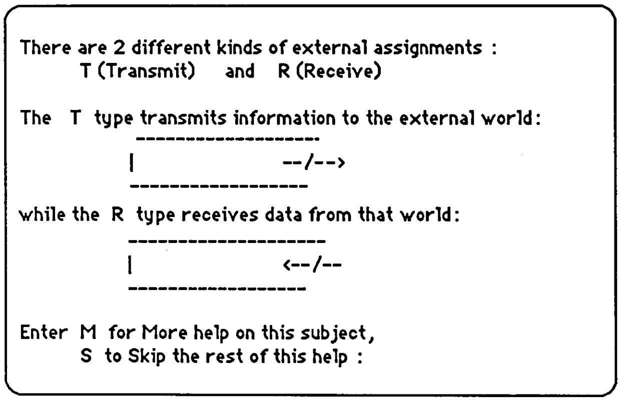


```
Okay, at this point,
     here are the alternatives open to you:

Your entry     The FPL software response
  E        Explain the entry just requested
  M        Display a Menu for various explanations
                related to this entry
  C        Cancel this entry altogether
  )        Forget the interruption and continue

 Enter E, M, C, or  ) :
```

FIGURE 9 : Help System main prompt

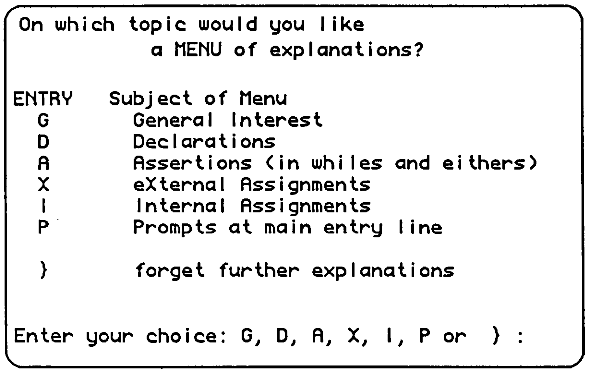


```
There are 2 different kinds of external assignments :
      T (Transmit)    and   R (Receive)

The  T  type transmits information to the external world:
              -------------------
              |              --/-->
              ------------------
while the  R  type receives data from that world:
              --------------------
              |              <--/--
              ------------------

Enter  M  for More help on this subject,
      S  to Skip the rest of this help :
```

FIGURE 10: Sample help message



```
On which topic would you like
           a MENU of explanations?

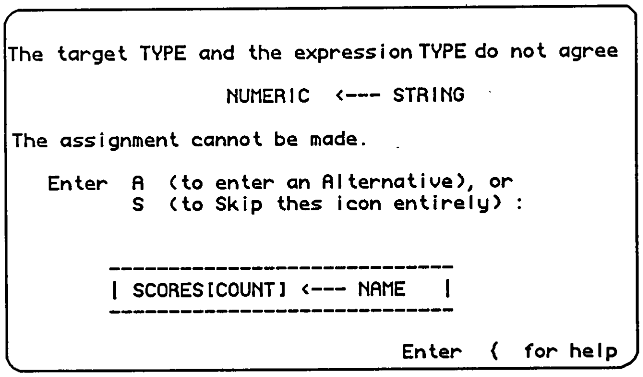
ENTRY   Subject of Menu
  G       General Interest
  D       Declarations
  A       Assertions (in whiles and eithers)
  X       eXternal Assignments
  I       Internal Assignments
  P       Prompts at main entry line

  )       forget further explanations

Enter your choice: G, D, A, X, I, P or  ) :
```

FIGURE 11: Help System sub-prompt

3. Context driven error messages. The FPL Studio also includes immediate, comprehensive syntax error detection, and follows the detection of any illegal entry with a message informing the user of the exact error, explaining why it is an error. It then prompts the user to either enter an appropriate choice or to cancel the entry altogether. An example appears in Figure 12. As a result, every completed FPL program is free of syntax errors and can be executed. This comprehensive error screening moves the novice programmer directly to the logical level of debugging without waylaying him/her in a swamp of indecipherable or misleading compiler messages.



```
The target TYPE and the expression TYPE do not agree

                    NUMERIC  <--- STRING

The assignment cannot be made.

   Enter  A  (to enter an Alternative), or
          S  (to Skip thes icon entirely) :

         -----------------------------
         | SCORES[COUNT] <--- NAME    |
         -----------------------------
                                  Enter  (  for help
```

FIGURE 12: Sample error message

<u>The FPL Lab: Executing and Monitoring the Program</u>

Since the FPL Studio always produces executable code, the learner can immediately execute his/her program upon leaving the Studio. However, simply executing it in traditional fashion may do little to help the novice understand the dynamics of any logical shortcomings. Given the aims of FPL and the support it provides for program development, such minimal execution support was inappropriate. Consequently, we began to develop the <u>FPL Lab</u>, as an interactive, animated environment for program execution. It completes FPL as a visual language, rounding out the planning - entry - execution - debugging - refinement cycle in a highly visual manner. The FPL Lab described below is a prototype for the system we are developing.

<u>Screen Design</u>. The FPL Lab divides the screen into four windows. See Figures 6 and 13 for typical screen scenes from the FPL Lab. Each window is dedicated to the presentation of one particular type of information. The windows are :

1. the user's FPL program drawing (in reduced size);
2. the precise icon being executed;
3. the contents of memory for one variable;
4. the normal I/O of the program.

The largest window, "FPL Program," displays a miniature version of the program drawing. (To conserve space, all icons there are reproduced without text, in outline only.) It reveals the path of program execution by moving a lighted "blip" about the miniature, from icon to icon, as each icon is actually executed. Because space is so limited, even in this miniature form most program drawings do not entirely fit in this window. To overcome this limitation, the system shifts the window's contents to show the executing portion of the program.

Since the Lab drawing of the program is textless, as each icon is executed, a full scale version of that icon, including any datanames and constants, is displayed in the "Program Icon" window.

The "Storage" window displays the data value in memory for any program variable the user selects, to help him/her realize how variables work, and to show where and when data values change.

<u>Dynamic Program Representation</u>. By comparing the currently displayed icon, the memory values in the storage window, and the textless program drawing, the user can clearly see where, why, and when values are getting changed. In short, the novice programmer "sees" the dynamics of execution, a prerequisite to developing a real understanding of what a computer program is.

Modes of operation. The FPL Lab has two modes of operation: Step Mode and Quick Mode. In Step Mode (see Figure 12), the program is executed one element (one icon) at a time at a rate under user control. All four windows are active to provide maximum visual feedback about all aspects of the program.

In Quick Mode (see figure 14), only two windows are active: "FPL Program" and "Program Execution". The user can watch the blip traverse the miniature program and can see the normal output and input through the "Program Execution" window. This mode does not display individual icons or storage values. It pauses only for the particular input entries required by the program, and between pauses it moves at a fixed and rapid pace.

RESEARCH: ASSESSING THE HELP FPL AFFORDS NOVICES

FPL was designed originally as a language for novices. We have continued to focus on that group, and have developed the FPL environment so that it can be used as a research laboratory for the study of the learning of programming.

Visual vs Textual Programming: Bug Studies

Two recently completed pilot studies have indicated that FPL may help novice programmers avoid some programming bugs commonly found in beginners' programs[9,10]. Both of these studies compared programs written in FPL with Pascal solutions to the same problem. The results of these studies suggest that FPL's graphic representation may help beginning programmers avoid some common programming pitfalls. Specifically, several types of syntax-related conceptual bugs evident in Pascal programs are eliminated in the FPL solutions. Also, bugs related to updating and initializations were considerably more common in Pascal solutions than in the FPL programs. There were some indications, however, that there are classes of bugs that appear to be language independent, and thus have less to do with the language of implementation than with the programmer's understanding of the flow of control of the program.

The results of these initial investigations were intriguing, and we plan to continue this line of research with an eye toward identification of ways of helping novices to avoid conceptual bugs and to develop methods of effective debugging. We think that development of a tool such as the FPL Lab may be an important step in this process of identification.

Study of On-Line Help and Errors

We have also recently completed a pilot study of FPL's on-line help system[11]. The study investigated the use of the help system by experienced and inexperienced computer users. The results indicated that although computer-experienced users seemed to use the help facility more than inexperienced users, by the end of several weeks of work using FPL, most users no longer asked for help at all.

For extended analysis of both the help and error sub-systems, the system records, by date and user identification number, all help requests and error messages generated. Analysis of this usage data pinpoints user difficulties with the system, and provide general insight into the process of learning programming. The resulting information is being used to inform instructors about difficulties they are having with introductory programming assignments.

Influence of Graphics on Learning

We continue to be intrigued by the influence of graphics on learning, particularly in relation to programming. To investigate the effect of the graphical interface of FPL, we are beginning to study how learners with different learning aptitudes use it. For example, we are investigating whether learners with high spatial aptitudes understand and learn programming more effectively when using this visual

Class (M/ath or A/rt):  A
```

FIGURE 14: FPL LAB / QUICK MODE

approach than when using a traditional textual approach. One study now in design will compare comprehension of FPL programs with comprehension of programs written in a textual language.

We are also in the process of developing a non-graphic version of FPL to be used in a full-scale study of novice programmers. It will preserve the interface design as much as possible, limiting the changes to replacement of the graphic icons by key words. This will facilitate a comparative study of a graphic and non-graphic language without the confounding effects introduced by comparing subjects using two entirely different editing and execution environments. Such a study will address the question of whether a graphic approach to programming is really more appropriate for some learners than is a traditional, textual approach. Through a group of such studies, we hope to prove that alternative ways of teaching and learning programming are important in light of the fact that learners are so different one from another.

SUMMARY

This paper describes the graphically represented programming language FPL, the environment in which the FPL user works, and some preliminary evaluative research. The premise for the development of this system is that for many learners, a language and environment that provides a consistent, graphical representation throughout the programming process is an appealing and effective alternative. We theorize that the consistent visual approach of FPL makes the abstract world of computer programming more concrete, and consequently, helps at least some novices to learn to program more easily and more effectively. Furthermore, because we believe that it can be empirically demonstrated, we have begun a series of studies aimed at testing our theory.

Although our preliminary research does not conclusively prove that FPL improves a novice's learning of programming, it certainly suggests that this alternative, graphic approach to improve the lot of the visually-apt, would-be programmer merits further exploration.

COMMAND LANGUAGE SUPPORT FOR APPLICATION PROGRAMS

Christine Genet

Grumman Data Systems Corporation
1000 Woodbury Road
Woodbury, New York 11797

ABSTRACT

Efficient data analysis programs must maximize the productivity of the data analyst/computer combination. To do this, the analysts must be able to use the program easily and efficiently. Thus, the human-computer interface is crucial to the design of an effective data analysis program. We develop an interpreter entitled KEYLAB that allows an application programmer to create programs driven by an English-like command language that is based on the functional decomposition of the applications requirements. We also develop a code generator named Keystone that creates the code necessary for the human-computer interface. The combination of these two programs allows a programmer to develop an application program with minimum effort and maximum uniform connection to functional requirements.

INTRODUCTION

Several types of human-computer interfaces exist in industry today. These include menu-driven systems, fill-in-the-blank systems, and parametric systems. Menu-driven systems are common in the microcomputer industry where users tend to be novice computer users. Parametric systems are used in applications such as airline reservation systems. Fill-in-the-blank systems are common in engineering environments since these applications require input of alphanumeric values, integers, and floating point values[1]. KEYLAB (the KEYword LAnguage Builder) is an interpreter that helps application program designers create a system that is controlled with keyword commands, yet has characteristics of a fill-in-the-blank system. The application program designer designs the command language so that the number of user type-ins is minimized, thus making the program easier to use. A programming aid entitled Keystone uses the command language design specification and generates the Fortran 77 code necessary to provide the specified command language. These programs have proven to be useful for our applications.

In a KEYLAB program, the user controls the program flow by entering a series of keywords and their associated arguments. The complete set of keywords for a given application program is called a command language. The KEYLAB parser detects syntax errors in the command string and immediately issues error messages to the user.

Command languages are based on the functional decomposition of the problem. When the program designer designs the command language, he takes human factors into account to try and make the command language more useable. Thus, the final command language is somewhat different from the original functional decomposition.

An example of a simple command language is given by the following structured list. The strings in quotations are short descriptions of the keyword functions.

```
ARTIST
  PICTURE      "Display the picture"
  SET          "Set variables"
    ROW        "Screen rows"
    HELPSET    "Display HELP"
    COLUMN     "Screen columns"
    BRUSH      "Drawing symbol"
    SCREEN     "Background symbol"
  STOP         "Terminate program"
  HELPART      "Display HELP"
  DISPLAY      "Display variables"
  DRAW         "Draw X1,Y1 to X2,Y2"
```

A code generator named Keystone reads this structured list and generates Fortran code with stub-subroutines at each leaf of the tree (e.g. ROW, COLUMN). The programmer then completes the Fortran code for each stub so that his program performs the desired function. If a keyword (ex. ROW) requires input, then the programmer adds a call to a KEYLAB subroutine to get this input. The programmer compiles the Keystone-generated code, and his own code and then links it to the KEYLAB library of subroutines to complete the application program. Using Keystone leads to more coherent software design since the application programmer concentrates primarily on coding the analytic sections of the code instead of on coding the human-computer interface.

Command languages have proven to be an effective human-computer interface for various data analysis programs at Grumman. TASKX, an advanced aircraft flutter analysis program [2] has used the KEYLAB prototype for three years and several new KEYLAB codes are being developed now. Both application programmers and program users are satisfied with the KEYLAB and Keystone programs.

KEYLAB - The KEYword LAnguage Builder

The application program users control KEYLAB program execution by typing keyword commands in response to prompts. The combination of a command language heirarchy and programmer-added syntax specify the valid sequences of commands. KEYLAB scans the input string from left to right without backtracking. KEYLAB terminates scanning and issues a message immediately when it finds a syntax error. KEYLAB also contains simple help facilities to help the user.

PROGRAM FLOW

The command language heirarchy can be thought of as a set of connected dictionaries of command keywords. Each dictionary in the command language is called a mode, and each mode contains keywords which either link to other modes, or cause execution of one of the program's analytical functions. The tree structure in Figure 1 depicts a command language heirarchy with seven dictionaries: COMMAND, INPUT, OUTPUT, TABULAR, GRAPHIC, INTERACTIVE, AND TAPE.

The user controls the branching through these modes by entering keywords. When the user types "OUTPUT GRAPHIC" from the command level, execution transfers to the GRAPHIC mode. If the user then wants to execute a command in the INTERACTIVE mode, he must enter a keyword which transfers execution to the COMMAND mode (e.g. INPUT). The user then enters the keywords to transfer program execution through the INPUT mode to the INTERACTIVE mode. KEYLAB provides no facility to transfer program execution from the GRAPHIC mode to the INTERACTIVE mode without first returning to the top of the command level tree structure. The command language designer takes this into account when he designs the command language heirarchy.

KEYLAB FEATURES

When users forget what keyword to type, they can type in a "?" at any point in the program execution to see the currently available keywords. Also, if they are not at the top of the functional decomposition, "??" shows the keywords that the user can type up to the top of the decomposition. For example, if the user is in the INPUT mode in Figure 1 and enters "?", he will see:

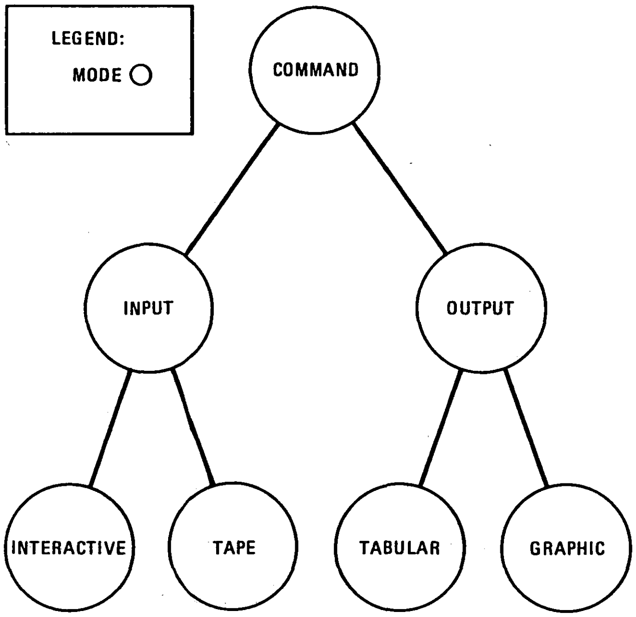

Figure 1. Example Command Language Design

```
THE CURRENTLY AVAILABLE KEYWORDS ARE:

INTERACTIVE       TAPE
```

If he enters "??" from the same point, he will remain in the current level and see keywords up to the top level.

```
THE CURRENTLY AVAILABLE KEYWORDS ARE:

INTERACTIVE       TAPE
INPUT             OUTPUT
```

They can also type in any keyword with the substring HELP to list out the keywords with a brief description. For the simple command language in the introduction, typing in HELPSET yields the following HELP screen:

```
ROW    - Number of rows in screen
COLUMN - Number of columns in screen
BRUSH  - Drawing symbol
SCREEN - Background
```

KEYLAB has a feature that allows the users to create their own procedures. Procedures specify a sequence of program functions to solve a specific problem. The users can create these procedures before they run the KEYLAB program by using the system editor. They can also create these procedures by using the KEYLAB procedure line editor named KEDIT. KEDIT lets the users edit procedures while they are running the application program. Thus, a user executes a procedure interactively by typing in the procedure name. He then examines the results, modifies the procedure with KEDIT and reruns the procedure. KEYLAB checks procedure as well as interactive type-in syntax.

KEYLAB stops parsing the input string when a syntactically incorrect token is encountered. For example, if the user types in "ROW 20 CO1", KEYLAB detects an error on the third token in the string. Since it is an undefined keyword, KEYLAB stops parsing the string, issues an error message, and reprompts the user. This ensures that the system is reliable regardless of a user error in keyword syntax [3].

The application program detects other errors such as range checking errors and syntax errors and directs KEYLAB to issue an error message. For example if the user types in "SET A 5.0" and the valid range for A is 10 < A < 20, then the application program tells KEYLAB to stop parsing the string. KEYLAB then issues the error message, and reprompts the user.

DESIGNING A COMMAND LANGUAGE

Previous sections mentioned that a command language for a program is based on the functional decomposition of the program, but is modified to account for usability. The command language design process is nontrivial and is essential for an effective application program design. This is a four step process.

The first step is to organize the requirements for the program on paper. The second step is to decompose the overall problem into a tree diagram and to assign keywords to each function on the tree diagram. The third step is to minimize the number of keywords that the user has to type in. The fourth step is to develop the command syntax requirements for the command language by imposing a logical order on the keyword type-ins. This section describes each step in the command language design process for an example program named Artist.

The method of organizing requirements for a given software system is chosen by the application program designer [4]. Here, we state the objective of the program and then describe the functions in the program that accomplish this objective. The Artist objective is:

> Artist allows the program user to
> draw lines on a terminal screen.

To do this, the program user must be able to do the following:

Choose the number of rows on screen
Choose the number of columns on screen
Choose a brush symbol
Choose a background symbol
Draw a line from X1,Y1 to X2,Y2
Display what was drawn
Display all variables that were chosen
Terminate the program

The second step in the command language design process is to organize these requirements into a functional decomposition. In our case, we will create a decomposition with four modes; SET, KEDIT, DISPLAY, and ARTIST. The ARTIST mode contains the keywords SET, STOP, KEDIT, HELPART, DISPLAY, and DRAW. The SET mode contains the keywords ROW, HELPSET, COLUMN, BRUSH, and SCREEN. The DISPLAY mode contains the keywords COLUMN, BRUSH, PICTURE, HELP, SCREEN, and ROW. The SET mode allows the user to set values for the desired variables. The DISPLAY mode allows the user to view what he has drawn and the variables that were set. The STOP keyword allows the user to terminate the application program. The KEDIT keyword allows the user to make use of the KEYLAB run-time editor. The HELP keywords display a list of the current keywords and their definitions. The DRAW keyword allows the user to specify a starting and ending point for a line. Figure 2 shows the entire functional decomposition for Artist.

The third step in command language design is to try to minimize the users type-ins by changing the decomposition. This is easily done by following two simple rules:

1. Decrease the depth of the decomposition by eliminating modes

2. Change the functionality of keywords to eliminate keywords.

If the user ran the program corresponding to the functional decomposition in Figure 2, he would have to type in the following command string to set all of the desired variables and display them.

```
SET ROW 10 COLUMN 20 BRUSH "*" SCREEN
"." DISPLAY ROW COLUMN BRUSH SCREEN
```

To draw a line on the screen, the user would type in the command string:

```
DRAW 1,1 5,5 DISPLAY PICTURE
```

To simplify this command string we can add a keyword to the ARTIST mode named PICTURE that displays the picture, and we can change the DISPLAY mode into a keyword that displays all of the variables that were set. This modified decomposition is shown in Figure 3.

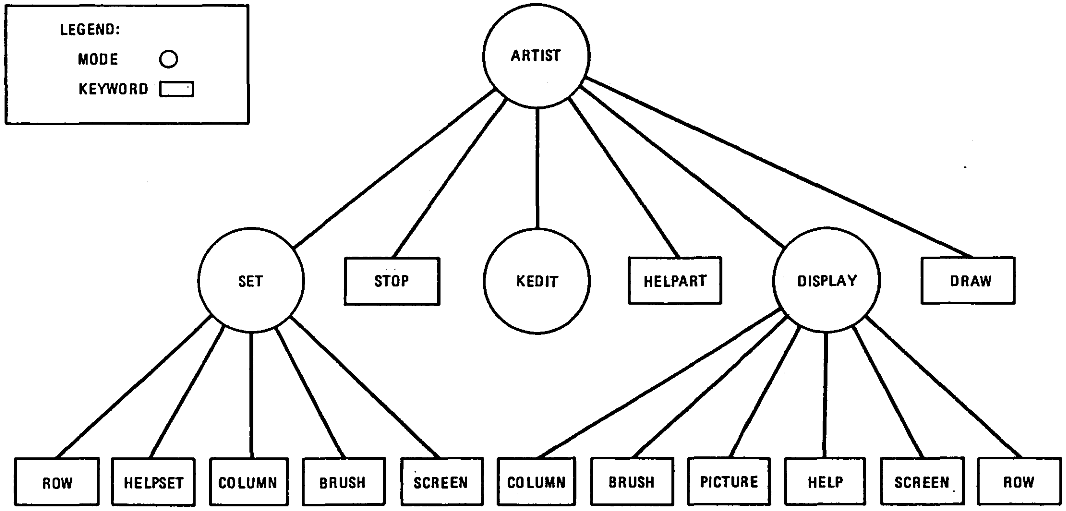

Figure 2. Artist Functional Decomposition

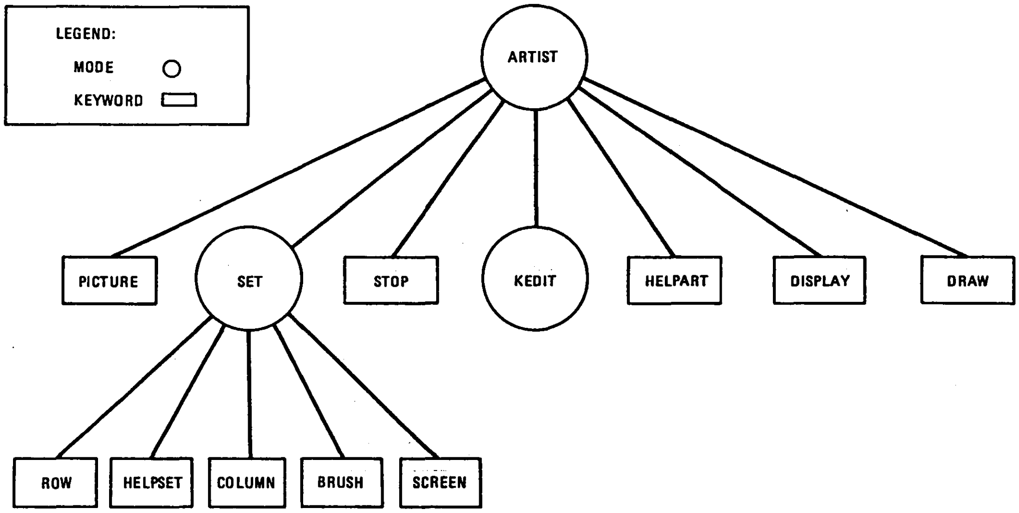

Figure 3. Command Language Design

The new command string to set and display all of the variables with four fewer tokens than before is:

```
SET ROW 10 COLUMN 20 BRUSH "*" SCREEN
"." DISPLAY
```

The new command string to draw the line is:

```
DRAW 1,1 5,5 PICTURE
```

With this acceptable sequence of type-ins, the program designer now adds rules to the command syntax so that the user is forced to type in keywords in the correct order. For example, the user should not draw until he has selected both brush and screen symbols. This means that the programmer doesn't let the user execute the DRAW command until BRUSH and SCREEN have been set. This syntax is known as Reverse Polish Notation [5] and helps to minimize the user type-ins. In our example, the syntax rules are:

1. Set BRUSH before DRAW.
2. Set SCREEN before DRAW.
3. Set ROW before DRAW.
4. Set COLUMN before DRAW.
5. DRAW before PICTURE.

This completes the Artist command language design. In Artist, we have only considered the case of one user input per keyword as in the case of ROW, or COLUMN. When more user inputs are desired per keyword, then the command language designer has to consider the possibility that the user may want to go back and change only one variable out of the entire string of inputs. Guidelines that we have found useful are:

1. When your program user is not likely to change one variable at a time (no mistakes), then you can program up to approximately seven inputs per keyword.

2. When your program user is likely to change one variable at a time (to change only one parameter in an analysis) then it is better to program only one input per keyword.

The following section describes how to take your final command language design, generate a code skeleton using Keystone, and then add the code necessary to complete the application program.

KEYSTONE

Keystone allows the application program designer to specify a command language and generate an executable program skeleton that runs with the specified keywords. The application program designer then adds the keyword functionality and syntax to complete the application program.

The programmer writes the command language design in the Keystone input file. Successive indentations in this file correspond to successive levels in the tree diagram. The input file for the example program Artist is shown in Figure 4.

```
ARTIST
  PICTURE
  SET
    ROW
    HELPSET
    COLUMN
    BRUSH
    SCREEN
  STOP
  KEDIT
  HELPART
  DISPLAY
  DRAW
```

Figure 4. Artist's Keystone Input File

Keystone reads this structured list and generates Fortran code with stub-subroutines corresponding to each keyword at each leaf of the tree (e.g. ROW, COLUMN, LINE, DISPLAY). The stub-subroutines contain print statements to which the programmer later replaces with the code for the keyword function. A stub subroutine looks like this:

```
SUBROUTINE row
Print (6,*) 'Code for ROW goes here'
RETURN
END
```

The programmer compiles this code and links it to the KEYLAB library. He then runs this skeleton via the command language that was specified in the functional decomposition. Thus, when the programmer runs the program corresponding to the decomposition in Figure 3 and types in the commands "SET ROW COLUMN DISPLAY", the program outputs the following lines:

```
The code for ROW goes here
The code for COLUMN goes here
The code for DISPLAY goes here
```

As the programmer develops analytical portions of the code, he substitutes them for the Keystone-generated Print statements. If the keyword requires input of a real, integer, or alpha- the programmer adds a call to a KEYLAB routine. This call tells KEYLAB what type of input (e.g. real input, alphanumeric input) to expect the user to enter at this point. To make sure that the program is reliable regardless of an error in the value of a number input, the application program must check that the number input by the user is within a certain range. The program then calls a KEYLAB subroutine that issues an error message such as "0 < ROW < 20".

The programmer also adds code so that the syntax specified in the command language design is present in the final application. For example, the program must check to make sure that the user SETs all variables such as SCREEN, ROW, COLUMN, and BRUSH before he attempts to DRAW a line. Thus, the user runs the application with the keywords specified by the program designer and the syntax imposed on the command language heirarchy.

EXPERIENCE WITH USE

In general, application program users, programmers, and managers have been satisfied with the capabilities of KEYLAB and Keystone as a method of human-computer interaction and as a code generation programming aid. These programs have been used successfully in data plotting application programs, aircraft trajectory estimation, flutter analysis, and others.

Program users find that it is easy to concentrate on their analysis while they are controlling the application program with keyword commands. They also like consistency of the human-computer interface across applications. Once they know KEYLAB features from learning one KEYLAB program, they can easily learn another KEYLAB program. Users like the procedure file capability since it allows them to set up a procedure with large groups of frequently executed commands and interactively enter any additional input that they need to complete the analysis. They can use these same procedures in either the interactive or batch mode.

The programmers' programming time is concentrated on the analytical sections of the code instead of on the human-computer interface details. Programmers also tend to produce easily maintainable code since the command language structure forces the programmers to write modular code. Also, programmers who write ANSI-standard Fortran 77 write portable code since the generated code is all portable.

From a manager's perspective, the Keystone input file provides a quick and simple way to verify that a given application program satisfies all of its functional requirements. This input file can be used to provide a working skeleton of the human-computer interface to the end-user before the programmer adds the functionality to the keywords. Thus, the user interface can be designed and tested separately from the analytical portions of the code.

The primary complaint with the existing system is that Keystone is initially frustrating to use because the input file structure is error-prone. Once a programmer has developed a successful template input structure, this problem is alleviated and Keystone users are generally satisfied with the ease with which they can subsequently modify their command language structure by adding or deleting modes and keywords.

The input file structure to Keystone could be changed to a less error-prone type of input file such as the Backus-Naur form (bnf) [6] . Currently, the Keystone code generator is adequate for even our largest (25,000 Fortran lines) stand-alone application programs so there is no reason to change the input file structure at this time.

It will probably be useful to incorporate some table-driven range-checking into KEYLAB so that the application programmer doesn't have to add code to check the range of user input. Thus, KEYLAB would then detect both type and range errors. This would place the burden of making sure the system is reliable regardless of user error on the KEYLAB interpreter instead of on the application programmer and would provide more consistent error messages to the user.

CONCLUSION

The KEYLAB interpreter provides a convenient and simple way to control a scientific application program. The command language design and the KEYLAB features add to the flexibility of the application program.

Command language designers go through a four-step process when they design a command language. First, they organize the requirements for the program on paper. Second, they organize the problem into a tree design and assign Keywords to each function. Third, they minimize the number of keywords. Finally, they impose rules on the command language structure to create a language syntax.

The Keystone program allows a program designer to quickly implement a language design into executable code. Once the command language is finalized, the programmer adds the analytical sections of code and the command syntax to the program. Also, if the command language design is changed later, the input file can easily be modified to account for these changes.

Both users and application programmers are satisfied with the KEYLAB interpreter and the Keystone code generator. In the future, however, the Keystone input file structure may be changed to make it less error-prone. KEYLAB may also be modified to detect out-of-range input errors.

SURVEY OF IMAGE QUALITY MEASUREMENTS

Ikram E. Abdou - Nicolas J. Dusaussoy

Department of Electrical Engineering
University of Delaware
Newark, DE 19716

ABSTRACT

Image quality is one of the most important factors in the evaluation of any imaging system. This measure can be used to compare the performance of the different systems and to select the appropriate processing algorithm for any given application. Image quality can be defined in general terms as an indicator of the relevance of the information presented by an image to the task we seek to accomplish using this image. Although there are many techniques developed to measure image quality, little has been done to unify the various concepts, or to test their relevance to specific applications. In this paper, we address the various issues related to image quality. We begin with a survey of the various factors that should determine the image quality measures. Then, we review and analyze the different analytical methods used in measuring the image quality for both image processing and image understanding applications. We survey experimental approaches to evaluate image quality in another section. Finally, we discuss some of the advantages of image quality measurements.

1. INTRODUCTION

The most important factors in the evaluation of any imaging system are the system cost, the processing speed, and the quality of the produced images. While the system cost and speed are dependent on many factors including the advancement in technology and the progress in hardware and software implementation, the image quality is a technology-independent measure, which can be used to compare the performance of the different systems and to select the appropriate processing algorithm for any given application. Image quality is determined by the relevance of the information presented by the image to the task we seek to accomplish using this image. Image quality can be divided into image fidelity, which measures the departure of a processed image from some standard image, and image intelligibility, which denotes the ability of man or machine to extract relevant information from an image.[1]

Image quality is calculated for various applications of imaging systems for which three different aspects of quality evaluation appear. First, quality evaluation techniques are necessary to measure the performance of an imaging device; the high performance of a system is usually indicated by the good quality of the final product. The second aspect is that quality evaluation techniques are the basis for the design of any image processing or understanding system as they form the framework for the optimization of the system. Finally, a very important aspect is assurance; quality assurance receives great attention because in many cases, it is necessary to ensure the presence or non-presence of features of interest in an image.

The techniques developed to measure image quality depend on the field of application. As we will see later, such applications are diverse and, therefore, there is no single standard procedure to measure image quality. However, there are some basic concepts that are reflected in the image quality measures. A summary of these ideas is given in [1, 2, and 3].

In this paper, we address the various issues related to image quality. We begin with a survey of the various factors that should be considered in determining image quality measures. Then, we review and discuss the different analytical methods used in measuring the image quality for both image processing and image understanding techniques. We survey experimental approaches to evaluate image quality, in another section. Finally, we discuss some of the advantages of image quality measurements.

2. FACTORS DETERMINING IMAGE QUALITY

In defining image quality, there are various factors reflecting the field of application, the end user, the parameters and characteristics of the system being evaluated.

2.1. The Field of Application

The field of application should affect the choice of an image quality measure because it determines the characteristics of the imaging task we would like to evaluate. These characteristics, specific to each field, are very well known in various applications including text reproduction that deals with binary images,[4,5] medical radiology,[6,7,8] industrial inspection,[9,10] and aerial photography.[3] Practical image quality measures must evaluate these characteristics and therefore, may vary according to the field of application. More general areas, where the evaluation of image quality is also of prime importance, such as image transmission,[11] general optical systems,[2,12] and electronic image display,[13] deal with several kinds of images. Quality measures should evaluate the overall performance of these systems. They are usually standard methods that can be used in most applications of these systems and they resume to rate image fidelity and image intelligibility.

2.2. The End User of the System

Another important factor in evaluating image quality of a system is the end user which can be a human observer or a computer. The measures we use should reflect this fact. If the end user is human, the quality measures should be based on a psychophysical model. However, because of the difficulties encountered in taking subjective measurements, many researchers worked on establishing relations between subjective evaluation and some quantitative figure of merit.[14,15] On the other hand, if the images are processed by a computer, the image quality can be based on the classification accuracy of the system. One example is the use of receiver operating characteristic to evaluate diagnostic systems.[16] We believe that it is much easier to develop quantitative models for automated analysis systems, and we will discuss some of these ideas in a following section.

2.3. System Parameters and Characteristics

The various physical and mathematical parameters related to the specific application also need to be considered. For instance, in computerized tomography[17], there are a set of parameters relating to the signal being detected and to the imaging and displaying system. In this case, the object parameters such as size, shape, and contrast, and also the image forming parameters such as the spatial strength of signals used, the rate of collecting data, and noise are considered in the evaluation of the system. If the images are intended for a human observer, we need to define the display system, the viewing conditions, and the observer a priori knowledge. Of course, a more quantitative model can be established to determine the important image characteristics if the images are going to be processed automatically. All these parameters affect the success of an imaging system, and should be included in any evaluation.

Furthermore, several characteristics of the imaging system provide a guide to determine the useful quality measures. These are linearity, isotropy, contrast sensitivity, spatial invariance, spatial resolution, and also the image characteristics such as uniformity and sharpness.

3. ANALYTICAL METHODS

In the previous section, we discussed the various factors that can be considered in evaluating the quality of an image. In this section, we describe the different methods used to evaluate the image quality. We consider both image processing and image understanding techniques. In image processing, an input image is transformed to an output image in which features are enhanced, while in image understanding, the goal is to extract meaningful information and to derive a description of the scene. To achieve this goal, image understanding systems incorporate many scientific disciplines including image processing, pattern recognition, artificial intelligence, physics, and neurophysiology.[18]

In the design and the evaluation of either technique, we can use either analytical or experimental methods. In the analytical approach, models are developed to describe the interaction between the imaging device and some simple and standard signals; these models are used to predict the performance in practical applications. This approach is more general and does not require expensive equipment. However, because of the approximation involved in applying it, the results obtained may not accurately reflect the actual performance. Also, in many cases, we need to use simulation methods to measure the system response for the signals of interest because the complexity of the system makes the analytical solution extremely difficult. In the experimental approach, test patterns -or phantoms- are built to represent the various objects of interest; performance is then measured by either rating the images using human observers or by introducing a figure of merit which takes the different imaging parameters into account.[1]

In this section, we begin with a discussion of the analytical methods that are used to evaluate image processing systems. Then, we describe in detail the different models used to evaluate the performance of an image understanding system. In the following section, we will survey some experimental methods used in both image processing and image understanding systems.

3.1. Image Processing Systems

In measuring the performance of an image processing system, we distinguish between two cases depending on the ratio of the energy of the signal to that of the noise. If the signal -to- noise ratio (SNR) is high, the system performance is basically defined in terms of parameters such as the point spread function and the modulation transfer function. When the SNR is low, factors such as noise equivalent quanta, and the detection efficiency determine the system performance. The contrast can also be a tool to distinguish noiseless from noisy systems. Wagner defines a noiseless system as one processing high contrast images in contrast to noisy system processing low contrast images.[19] In the following section, we review methods that apply to noiseless, and noisy systems.

3.1.1. Noiseless System

When the SNR is high, system performance is determined by the sharpness and clarity of the images produced. Another important factor is the ability to resolve close patterns and to detect small size objects. A set of measurements in the spatial and frequency domains allows us to predict system performance for the above mentioned signals. We begin with the spatial measurements.

a. Spatial response measurements

The spatial response is one method that can be used to measure the image quality. The spatial response can be defined in terms of the response to an input point source $\delta(x,y)$ which is known as the point spread function (PSF) of the system.[3,20] The point spread function is also known by other names such as the impulse response, Green's function, or Fraunhofer diffraction pattern [3]. In optics, the PSF can be determined by the image of a star, considering the star as a point source. The PSF can be seen as the degradation caused by the system on the point source (blurring effect). Similarly, the line spread function (LSF) is determined when the point source is replaced by a line infinitely long and narrow. If the input is an abrupt step in brightness, i.e. a straight edge, then the output is the edge spread function (ESF).

The spread functions are a good basis to assess characteristics of the image processing technique. Spatial resolution can be deduced from the PSF. For instance, in optics, the PSF is a diffraction pattern with minimas and maximas, and the central bright patch is known as the Airy disc. The Rayleigh's criterion gives the resolution as the radius of the Airy's disc.[2] The shape, size, and diameter of the central lobe of the PSF not only are related to the spatial resolution, but also to the sharpness of the images being produced. Another characteristic, isotropy, applies if the PSF exhibits central symmetry.

Although the spread functions are simple and easy to determine in many applications, their use is limited to linear and spatial invariant systems. When these characteristics apply, the spread functions are really appropriate to the evaluation task, because they completely describe the performance; the system response to any arbitrary input image can be determined in terms of a convolution with the impulse response. On the other hand, if they do not apply, the determination of the performance is more delicate, and may be completely inaccurate.

The various spread functions are related for linear and spatial invariant processing techniques. First, it should be noted that the PSF has two dimensions, while the ESF and LSF have one. However, LSF and ESF exist for each line or edge orientation. If $PSF(x,y)$ represent the impulse response at a point of spatial coordinate (x,y), and $LSF(x')$ the line spread function for a line of orientation y', where x' is orthogonal to y' then, the LSF is the integral of the PSF in the direction y':[21]

$$LSF(x') = \int_{-\infty}^{+\infty} PSF(x,y)\,dy'. \tag{1}$$

Moreover, the LSF is the derivative of the ESF:

$$LSF(x') = \frac{d}{dx'}ESF(x'). \tag{2}$$

For isotropic systems, the LSFs and ESFs at different line and edge orientations are all identical because the PSF is rotationally invariant.

Another method to measure the spatial response is the resolving power which indicates the ability to discriminate fine details in an image.[3,13] Resolving power is expressed in terms of discernible line pairs per unique distance. The resolving power is easy to measure and can be applied to nonlinear as well as linear systems; therefore it is widely used in spite of the many questions in regard to its accuracy. Resolving power - or resolution - alone is not a sufficient measure for determining the relevance of the information presented by an image.[22] Although a practical and convenient guide to the performance, it is unreliable if it is used as a unique measure. Resolving Power is different for objects of various shape, size and contrast; hence the resolution in real images may be considerably different from the resolution measured.

Other spatial measurements that are helpful in determining the system performance, are the image uniformity, which measures the amplitude distortion for constant regions, and the system sensitivity, which determines the smallest amplitude that can be detected.[23,24]

b. Frequency response measurements

An important contribution to the evaluation of image quality has resulted from the two dimensional Fourier analysis. In the Fourier domain, another category of functions are defined: the transfer functions.

The Fourier transform of the PSF gives the optical transfer function (OTF):

$$OTF(u,v) = \iint PSF(x,y)\exp\left(2\pi i(ux+vy)\right)\,dx\,dy. \tag{3}$$

In general, the OTF is a complex function for which the International Comission on Optics defines its magnitude as the modulation transfer function (MTF) and its phase as the phase transfer function (PTF):

$$OTF(u,v) = MTF(u,v)\exp\left(i\,PTF(u,v)\right). \tag{4}$$

The term optical may seem to restrict these very general definitions to optical systems. However, the methods of treating an optical image are analogous to those of processing a signal. Transfer functions can serve to predict the quality of the formed images for any systems with few exceptions. They have the same inconveniences as those of the spread functions for which linearity and spatial invariance are necessary conditions to ensure confidence in the evaluation of the quality.

Indeed, they considerably simplify the analysis of systems whose characteristics are linearity and spatial invariance, because the OTFs and MTFs of a series of separable cascaded systems can be obtained by multiplying the OTFs and MTFs of each individual subsystem:[1,25]

$$OTF(u,v) = \prod_i OTF_i(u,v). \tag{5}$$

Conversely, the PSF requires convolution, a tedious process, of the separate PSFs. Just as the PSF, the OTF is a complete function to determine the output O of a system; the response is easily computed in terms of a product in the spatial-frequency domain of the input I with the OTF:

$$O(u,v) = I(u,v) \times OTF(u,v). \tag{6}$$

The OTF specifies the output that result from sinusoidal pattern input (as the PSF is the output that result from a point source) for all spatial frequencies. The sinusoidal pattern input undergoes changes in modulation expressed by the MTF and in phase expressed by the PTF, function of its spatial frequencies u and v. Its profile remains unaltered because no harmonic distorsions are introduced. Burgess noticed that the Fourier transform of the LSF gives a cross section of the OTF at the same angle.[26] For isotropic systems, all LSFs are identical; therefore the OTF is rotationally invariant as the PSF.

The MTF can be determined by measuring the ratio between the output and the input of a sinewave function. However, in some applications, it is easier to measure the square-wave response function (SWRF) and then determine the MTF in terms of the SWRF components. [27] Another frequency response function that can be applied to linear and nonlinear systems is the contrast function.[28]

Some of the image quality parameters in the frequency domain are; the amount of the amplitude, phase, and harmonic distortion, and the high- frequency cutoff.[3]

3.1.2. Noisy images

Any component of the signal that does not convey relevant information can be considered noise. Examples of noise are the fluctuation in the source signal, randomness in the detector output, and superimposed structures which are not related to the signals of interest.[29] If these variations are relatively large compared to the signal, they will be the limiting factor in the performance of the imaging system. Therefore, it is necessary to develop the appropriate tools to evaluate noisy systems. Such tools are derived from a statistical analysis, the basis of the theory of signal detection. One of the characteristics of a noise bound system is the smallest signal difference that can be detected. [19,30]

In dealing with noise, one simplified model considers the noise at various locations to be independent. For this model, a simple technique is to evaluate the standard deviation σ that measures the spread of the noise values. In computerized tomography, the noise is evaluated by experimentally measuring σ. A uniform phantom composed from only one material is scanned and reconstructed. Then, the sensitivity to the noise can be studied by estimating the standard deviation σ:

$$\bar{\sigma} = \left(\frac{\sum_{i,j} (\hat{f}(i,j) - \bar{\mu})^2}{N-1} \right)^{\frac{1}{2}}, \qquad (7)$$

where $\bar{\mu}$ is the sample mean and N the number of pixels. The advantages of using a uniform phantom is that the reconstructed image is free of artifacts and distortions. Therefore, σ is related only to the quantum and scattered noise. For certain reconstruction techniques, it is theoretically possible to relate the noise in projections to that in the reconstruction image.[31]

Such an assumption is not always true, especially after the noise is processed through the system. A more powerful descriptor related to the noise correlation is the noise power spectrum or Wiener spectrum.[32] The Wiener spectrum is determined by the Fourier transform of the autocorrelation function that indicates how the noise is correlated from point to point (Wiener-Khinchin theorem). The Wiener spectrum deals with all the various kind of noise appearing in the system and, furthermore, at various spatial frequencies. For instance, the Wiener spectrum $W_O(u,v)$ at the output of a linear system is easily related to the Wiener spectrum $W_I(u,v)$ at the input, MTF of the system, and additional noise components $W_a(u,v)$ at the output:

$$W_0(u,v) = W_I(u,v) \times MTF^2(u,v) + W_a(u,v). \qquad (8)$$

Another more accurate model to measure the performance of imaging detectors for which the noise structure is taken into consideration, is the noise equivalent quanta (NEQ) and detective quantum efficiency (DQE).[33] The noise equivalent quanta measures the ratio of the effective number of information bearing quanta used to form an image, and the detective quantum efficiency determines the efficiency of the photon detectors in terms of the ratio of NEQ to the actual number of quanta used. These descriptors combine together the MTF, the Wiener spectrum, and the sensitometric response of the system.

3.2. Image Understanding Systems

The idea of applying some image understanding measures to evaluate the image quality was introduced a few decades ago. However, the emphasis was on human image understanding. Recently, automatic image understanding has become feasible, and, for some specific applications, is the only practical solution.[18] In [34], an example of an automated computer tomography system is given. It is important to note, however, that very little has been done in this area, and more work is needed. In this section, we survey some of the methods that can be used to evaluate the performance of image understanding systems. This includes definitions of detection, orientation, recognition, and identification; the receiver operating characteristic (ROC); and measures based on information theory. In addition to these methods, any of the image processing techniques can be also used in evaluating image understanding systems.

3.2.1. Detection, orientation, recognition, and identification

The process of extracting information is called acquisition. There are different levels of acquisition which depend upon various parameters: size, contrast, noise, target and background characteristics, viewing conditions, automatic procedures, etc. Johnson considered the case when human observer processes the information and divide the acquisition into four categories: detection, orientation, recognition, identification.[15]
a. Detection: an object is present, but the recorded information is insufficient to assign a class to it.
b. Orientation: an object is present and its orientation, symmetry, or asymmetry are discerned.
c. Recognition: this is the first level of sorting the detected object into classes (house, man, animal, car, ...).
d. Identification: this is the second level of sorting the detected object into elements of specific classes (motel, policeman, dog, jeep, ...).

These four levels correspond to different levels of image quality: the first level requires the lowest quality; the last, the highest.

Johnson conducted a set of experiments to measure the minimum number of resolvable lines across the critical dimension of various targets required for each level of acquisition. Then, he produced tables giving the minimum number of resolved lines per minimum dimension of a specific object necessary at a stated level of acquisition. He found that, if the experimental conditions are the same for the targets and the test bars, the transformation targets into the number of resolved line pairs per critical dimension is independent of contrast and scene noise. His experimental results show that an object is detected for about 1 line pair, oriented for about 1.5, recognized for about 4, and identified for about 6.5 line pairs per critical object dimension.

Other methods to measure human performance are given in [35, and 36].

3.2.2. Receiver Operating Characteristic

The receiver operating characteristic (ROC) measures the relation between the probability of false alarm and correct detection as the decision level is changed. It is a useful tool for measuring image understanding performance when the image description is limited to few choices, such as the existence or nonexistence of abnormality in a patient,[16] or deficiency in a product. The ROC is more suitable for automatic image understanding systems.

3.2.3. Information theory measures

In some image understanding applications, we want to find the lowest level of signals that can be used to detect a given object. In other applications we may want to find the smallest features that can be detected. In either case, information theory may be helpful in establishing such bounds because it can relate the parameters of the system to the information required.

The information we would like to acquire may be small areas of size a (pixels) needed to be resolved and small density changes d over the area a needed to be detected. This information may be accepted with a tolerable probability P. P can be defined by $\frac{1}{R}$ where R is the number of pixels in which on the average one pixel will be classified incorrectly. The information required is represented by the triplet (a, d, P). Thus, the parameters should be determined to obtain the desired information in terms of (a, d, P). For instance, the exposure E necessary to record the features of interest can be related to (a, d, P). Examples of work in this area are given in [37, and 38]. Clearly, this analysis can be applied to either manual or automatic processing systems.

3.2.4. Image Segmentation measures

Many image understanding systems require dividing the scene into segments which have similar properties, as a first step toward classification. These properties may describe each pixel independently such as the signal intensity, or relate to a local area such as texture.[39] Recently, some effort was directed toward the performance evaluation of such systems. Methods to evaluate edge detection operators was described in [40]. In [41] various texture algorithms were compared. General analysis of image segmentation techniques were reported in [42, and 43]. Judging by the existing literature, it is clear that more needed to be done, especially in unifying these results with those obtained for image processing systems. All the work discussed so far corresponds to what is known as low level image understanding systems, because they make little use of the knowledge available about the contents of the scene. A more difficult problem is the analysis of high level image understanding systems; a survey of such systems with some qualitative comparison is given in [44].

An example is the work on low level image segmentation.[43,45] In this work, a segmentation error that measures the distance between two different segmentation outputs is used as a measure of performance. These measures are used to evaluate a segmentation system that divides images into areas and lines. Such methods are extremely important for the development of a reliable image analysis model.

4. EXPERIMENTAL METHODS

All the image quality measures, described in the previous section, are analytical. In this section, the experimental approach to measuring image quality is described. This approach is flexible and in many cases more accurate than the analytical model, because it can be made as close as possible to the actual application. Its disadvantage is that it is more costly and time consuming. In the early stages of design, experimental methods are based on simulation of the system. Later on, the same measurements are made using the actual system. Such measurements are usually more accurate and expensive than the analytical measurements.

Experimental measurements are usually made on test patterns that represent the interesting features in the images being processed. They can be as simple as a bar chart or as complicated as a 3-dimensional body phantom. The following are examples of such test patterns.

a. Resolving power charts.[3]
b. Spatial resolution patterns.[17,28]
c. Star test patterns.[26]
d. Perceptibility measurement patterns.[46]
e. Organ phantoms patterns.[28,31]
f. Industrial patterns.[47,48]

Basic resolution patterns consist of parallel bars having the same size and shape, with a spacing between bars equal to their width. These basic resolution patterns can be assembled in groups of different characteristics (contrast, size, orientation) to form the resolution test chart. Instead, a circular test pattern made of equally spaced wedges of identical sizes can be built to form a star pattern. The advantages of such a test pattern is that the density along a circle centered at its center is a square wave which has a spatial frequency proportional to the number of constituting wedges and to the inverse of the radius r of the circle. The patterns (a-d) are examples of charts constituted of bars and wedges. On the other hand, patterns or phantoms (e-f) represent as close as possible the objects (body tissues, industrial parts, ...) in the real application. They can be very complex and diverse depending on the application.

4.1. Qualitative methods

Any of the previous patterns can be processed using the imaging system being evaluated, and the performance can be measured either qualitatively or quantitatively. In the qualitative approach the processed images are shown under the same conditions to a group of observers who are asked to judge their quality. The observers may be chosen from expert or non-expert viewers.[1] Ultimately, qualitative methods are used as simple, natural, and somewhat reliable methods. However, to ensure confidence in the judgements, many observers must participate, which makes the qualitative methods cumbersome to employ. Although these subjective methods are suitable for the complicated test patterns described in e and f, they may also be applied to any of the other test patterns.

4.2. Quantitative measures

A better way for measuring the image quality for the patterns (a - d), is to introduce quantitative measures. These measures can be the resolution limits or the modulation transfer function. Also, it can be a one number merit function chosen such that it correlates with a subjective evaluation.[1] Examples of merit functions are the mean absolute error and the mean square error. The mean absolute error is defined in the general form:

$$MAE = \frac{\iint_a |\gamma(f(x,y)) - \gamma(\hat{f}(x,y))|\, dx\, dy}{\iint_a |\gamma(f(x,y))|\, dx\, dy}, \qquad (9)$$

and the mean squared error is:

$$MSE = \left(\frac{\iint_a [\gamma(f(x,y)) - \gamma(\hat{f}(x,y))]^2\, dx\, dy}{\iint_a [\gamma(f(x,y))]^2\, dx\, dy} \right)^{\frac{1}{2}}. \qquad (10)$$

where γ is an arbitrary operator, f the original image and $\hat{f}$ the degraded image. The domain of definition of f is a. They are the standard measures used to judge various processing techniques. Several transformations have been determined for the operator γ in order to compare the performance of the systems intended for human observers.[1] To get more reliable measures γ must be adapted to important factors such as the end user of the system.

5. USE OF IMAGE QUALITY MEASURES

In the previous sections, many measures of image quality were reviewed. In turn, we would like to discuss the usage of quality measures; quality measures can be applied to evaluate, to design, and to control imaging systems. We consider these three different important applications separately.

a. Performance evaluation. Image quality measures are used to evaluate the performance of processing and understanding techniques. It is important to use standard and qualified evaluation methods with confidence to compare several imaging systems.

b. Design and optimization. A second application of image quality measures is the design and the optimization of imaging systems. It is very important when we design a new system to minimize its cost, and also to maximize the processing speed and image quality. Therefore, the design engineers must be able to choose optimum parameters that satisfy image quality requirements.

c. Control. A more efficient system requires quality measures that can serve to control in real time the parameters of the system. Such a system is adaptive to the input images and can select the optimum parameters that produce the best image quality. These quality measures must estimate the relevance of the output information in real time to adapt the system parameters or the processing algorithms. Moreover, since they control the system, a large confidence in using them for this purpose is required. It is important to note that in certain field, particularly in image understanding, a successful search for new measures that can do this job without a reference to standard images is required.[45]

6. CONCLUSION

In this paper, we described the various factors that should determine the image quality measures. In addition, we discussed many of the methods that are used in the evaluation of image quality, for both the image processing and image understanding applications.

Many methods have been developed for the image processing application. They correspond to various approaches either analytical, such as spatial response measurements and frequency response measurements, or experimental. These measures have been adapted to many fields of application. However, there is still a need to introduce a unified model for the measurement of image quality and develop standard test patterns or test objects to compare the performance of various imaging systems.

On the other hand, very little has been done in the image understanding area. Major design measures that reliably indicate the performance of any image understanding technique still need to be developed. With the increasing interest in automatic image understanding. standard test patterns should be defined and used to measure the performance of various image understanding techniques. This will help in comparing the algorithms developed at different research centers.

Finally, judging from the existing literature, it is clear that while image quality evaluation has been applied to many areas such as medical radiology, aerial photography, industrial inspection, and design of optical systems, more work is still needed. We hope that this paper will inform the scientific community about the need for such work.

A Spatial Knowledge Structure for Image Information Systems Using Symbolic Projections

Shi-Kuo Chang and Erland Jungert*
Information Systems Laboratory
Department of Computer Science
University of Pittsburgh

ABSTRACT: We present a new pictorial data structure for image information systems. This pictorial data structure consists of a run-length encoded basic data structure for images, symbolic projections representing the orthogonal relations among objects or subobjects in an image, and rules to derive complex spatial relations from the symbolic projections. Based upon this approach, a knowledge-based image information system can be designed, which supports spatial reasoning, image information retrieval, and image manipulation.

1. Introduction

Image information systems (IIS) are heavily dependent on how images are stored in an image database according to certain pictorial data structures. Many different pictorial data structures have been proposed: some are pixel-oriented [CHOCK84], some utilize quadtrees or their variants [SAMMET84], and some are vector-based [JUNGERT85]. To make an image information system more intelligent and more flexible, it is important that the system be capable of integrating a knowledge-base into its pictorial data structure. The pictorial data structure should also be object-oriented, so that users can easily retrieve, visualize and manipulate objects in the image database.

In this paper, we present a new approach for image information system design, based upon a pictorial data structure using symbolic projections [CHANG86]. The basic data structure for image encoding is the run-length code (RLC) [JUNGERT86]. The technique of symbolic projection is used to generate a description of the RLC-encoded symbolic picture [CHANG86]. When the objects have complex shapes and their minimum enclosing rectangles overlap, orthogonal relations can be found to preserve basic spatial relations. Production rules can then be applied to derive more complex spatial relations from the 2D string representation of symbolic projections. Based upon this approach, a knowledge-based image information system can be designed, which supports spatial reasoning, image information retrieval, and image manipulation.

Figure 1 is the schematic diagram of an image information system with the proposed pictorial data structure. The icon-oriented user interface utilizes the following modules to perform its function:

-simple query processor: retrieves objects based upon their names or coordinates.
-knowledge-based query processor: processes complex queries involving spatial relations.
-spatial operators: for creating new objects or testing certain spatial relations.
-image overlay system: performs image display, window management and image overlay.
-image generator: converts RLC structures into images.

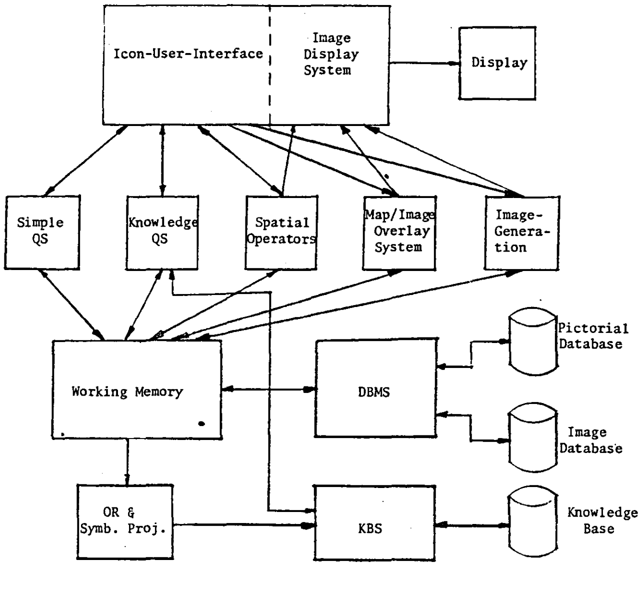

Figure 1 Schematic Diagram of an image information system

Raw images are stored in an image database. The image attributes, the symbolic projections, and the RLC encoded images are

CH2345-7/86/0000/0079$01.00 © 1986 IEEE

stored in a pictorial database managed by the DBMS (database management system). The production rules are stored in the knowledge-base and managed by the KBS (knowledge-base management system). A working memory is used to keep all temporary data, such as newly created objects, extracted orthogonal relations, derived spatial relations, and other kinds of application-dependent data.

The image information system with the proposed data structure is especially suitable for geographic information systems, but it will also be suitable for many other application areas.

2. Basic Data Structure using Run-Length Codes

Run length code has been used primarily for compacting image data. It can be used as a basic object-oriented data structure in image information systems. The principle of the data structure is illustrated in Figure 2. In this example, map overlays are used. A map overlay is an image used for map production and contains normally just one single object type, e.g., lakes or forests. Figure 2 shows that contrary to the general RLC, the information outside the objects is not saved. Only the object information or the object lines that belong to an object are saved. However, so far we cannot talk about objects, just about lines belonging to an object of some type. For each line we keep the coordinates of its starting point, the length of the line and the type of the object to which the line belongs. This structure is well adapted to a relational database. The relational scheme of the run-length coded lines is:

RLC - C (y, x, length, type, nc)

where the identifying key is underlined.

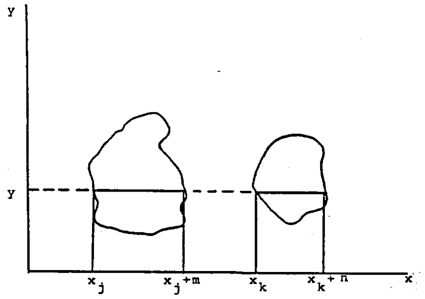

Figure 2 Run-length encoding of image

To identify each single line, only the coordinates of the starting point of each line are needed. As will be seen later the order of the coordinates are of importance. The attribute nc, is used for identification of objects and will be discussed further below.

So far we have only discussed object types which are spatially distributed in such a way that it is possible to "walk" around them, i.e., they are closed object types. The RLC encoding is, however, also valid for object types that are linear, e.g. roads, or of point type, e.g. landmarks. For these types, the lines are always one pixel long. The latter types are trivial compared to the closed types. It has to be pointed out that the linear object types are equivalent to vector structures. The relations for the linear and the point types are respectively:

RLC - L (y, x, type, nc)

RLC - P (y, x, type, nc)

In an object-oriented system, all objects must be identified in an uniform way. This can be done either by using the name of the object or by using unique coordinates. Here both methods are used. Names are used because the users are more familiar with them.

In order to simplify retrieval of objects in the database each object in the database will include coordinates that correspond to the minimum enclosing rectangle of the object. Figure 3 illustrates the correspondence between the object and the rectangle.

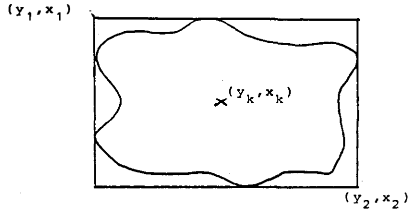

Figure 3 Minimum enclosing rectangle of an object and its key.

The object relations corresponding to the description given above will include not only the given attributes but also application dependent attributes, e.g. the depth or ph-value of a lake. However, such attributes will not be discussed further here. An object relation for closed object types will therefore look like:

OBJ - CR (Name, Yk, Xk, nc, Y1, X1, Y2, X2)

The relations for linear and point object types will be similar although there are no rectangles needed for the point object types.

The nc attribute is a unique integer

attribute that corresponds to the name of the object. Since RLC relations always include this attribute, there is a logical link between each RLC-line and the object in the object relation.

By using run-length encoded data a user can define an image (such as a map) covering a certain area and display it. Furthermore, it is easy to display the data, because compared to e.g. vector data the problem of cutting the image in order to make it fit into the display device is just a question of cutting horizontal run-length lines.

An important advantage in using the RLC data structure is that since the lines are first ordered with respect to their y-coordinates, all lines on a certain y-level can be accessed in sequence. Therefore, all lines within the interval [Ymax, Ymin] can be read in sequence and the lines displayed in the same sequential order. Consequently, the process of displaying and reading image data is always done in sequence and it does not have to be changed when handling the same relation. This process is illustrated in Figure 4.

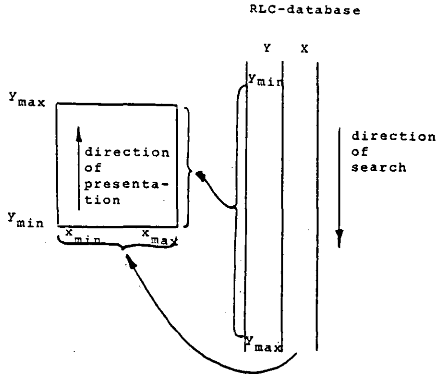

Figure 4 Sequential presentation of image data from RLC.

The RLC structure has some additional advantages for map presentation. First, the method is scale independent for at least some scale intervals. Hence it is fairly simple to implement zooming. Second, there is no need to implement any "fill" operations for the displaying of objects, because filling will be performed automatically when interpreting RLC objects. Similarly, the holes inside an object will be generated automatically when the object is displayed.

3. Spatial Operators on RLC Objects

The creation of new objects from existing RLC objects can be done by set theoretic operations such as union, intersection, exclusive or, etc.

(a) Union: Suppose 01 and 02 are two overlapping objects of closed type (i.e. the boundary is a non-self-intersecting closed curve). As illustrated in Figure 5a, the union of these two closed objects, 01 ∪ 02, can be constructed by combining the RLC for each specific y value as follows (assuming x1 =< x2):

```
     01: y, x1, m
     02: y, x2, n
01 u 02: y, x1, m ; x2, n   (for x1+m<x2)
         y, x1, x2+n-x1     (for x1+m>=x2)
```

(b) Intersection: Suppose 01 and 02 are two overlapping objects of closed type. As illustrated in Figure 5b, the intersection of these two closed objects, 01 ∩ 02, can be constructed by intersecting the RLC for each specific y value as follows (assuming x1 =< x2):

```
     01: y, x1, m
     02: y, x2, n
01 n 02: y, x2, x1+m-x2     (for x1+m>=x2)
         no line            (for x1+m<x2)
```

(c) Exclusive Or: As illustrated in Figure 5c, the exclusive-or of two overlapping closed objects can be constructed as follows (assuming x1 =< x2):

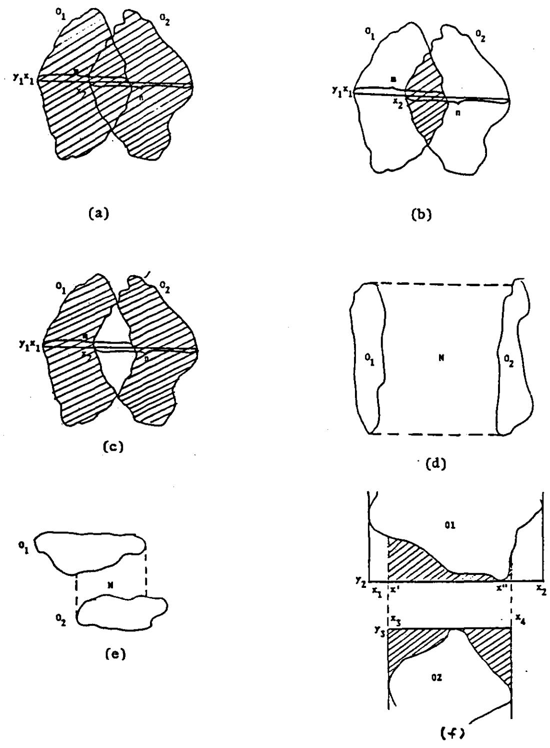

Figure 5 Spatial operators on RLC objects

```
        01: y, x1, m
        02: y, x2, n
 01 xor 02: y, x1, x2-x1; x1+m, x2+n-x1-m
            (for x1+m>=x2)
            y, x1, m; x2, n
            (for x1+m<x2)
```

The above described operators can be used to create new objects from existing objects, or to test the relationships among objects. For example, to decide whether an object 01 is contained in another object 02, it suffices to show that 01 ∪ 02 = 02, or equivalently, 01 ∩ 02 = 01. Using this test, we can find the objects situated inside another closed object, for example, the islands inside a lake. The complement of an object 01 contained in another object 02 can be found by 01 xor 02.

To decide whether a point object (or a linear object) 01 is contained in another object 02, we can check the RLC for each specific y value as follows:

```
     01: y, x1
     02: y, x2, n
   Test: x2 =< x1 =< x2 + n
```

(d) Horizontal Extension: Suppose 01 and 02 are two nonoverlapping closed objects. As illustrated in Figure 5d, the horizontal extension of 01 and 02 can be constructed as follows:

```
     01: y, x1, m
     02: y, x2, n
  01~02: y, min(x1,x2), (max(x1+m,x2+n)
                         -min(x1,x2))
```

In the above, min(x,y) = x if y is undefined, and max(x,y) = x is y is undefined.

(e) Vertical Extension: Similarly, we can define the vertical extension of two nonoverlapping closed objects 01 and 02, as illustrated in Figure 5e. To facilitate computation, the vertical RLC for 01 and 02 should first be found. The vertical extension of 01 and 02 can be constructed as follows:

```
     01: x, y1, m
     02: x, y2, n
  01|02: x, min(y1,y2), (max(y1+m,y2+n)
                         -min(y1,y2))
```

Figure 5f illustrates an alternative way to compute the vertical extension by first finding x' = max(x1,x3) and x" = min(x2,x4), and then taking the union of the two shaded areas and the rectangle (x',x"; y2,y3).

4. Symbolic Projections

We now describe the methodology of symbolic projections [CHANG86]. Let V be a set of symbols, or the vocabulary. Each symbol could represent a pictorial object, a pixel, etc. A 1D string over V is any string x1 x2 ... xn, n >= 0, where the xi's are in V. A 2D string over V, written as (u,v), is a pair of 1D strings.

We can use 2D strings to represent pictures in a natural way. As an example, consider the picture shown in Figure 6.

```
-------------
| d |   |   |
-------------
|   | b | c |
-------------
| a | a |   |
-------------
```

Figure 6   A symbolic picture f

The vocabulary is V = {a, b, c, d}. The 2D string representing the above picture f is,

(u,v) = (a d < a b < c , a a < b c < d)

In the above, the symbol '<' denotes the left-right spatial relation in string u, and the below-above spatial relation in string v. Therefore, the 2D string representation can be seen to be the symbolic projection of picture f along the x- and y- directions.

A symbolic picture f is a mapping M x M -> W, where M = {1, 2, ..., m}, and W is the power set of V (the set of all subsets of V). The empty set {} then denotes a null object. In Figure 6, the "blank slots" can be filled by empty set symbols, or null objects. The above picture is,

f(1,1) = {a}	f(1,2) = {}	f(1,3) = {d}
f(2,1) = {a}	f(2,2) = {b}	f(2,3) = {}
f(3,1) = {}	f(3,2) = {c}	f(3,3) = {}

In [CHANG86], we have shown that given f, we can construct the corresponding 2D string representation (u,v), and vice versa, such that all left-right and below-above spatial relations among the pictorial objects in V are preserved. In other words, let R1 be the set of left-right and below-above spatial relations induced by f. Let R2 be the set of left-right and below-above spatial relations induced by (u,v). Then R1 is identical to R2, for the corresponding f and (u,v).

2D string representation provides a simple approach to perform subpicture matching on 2D strings. The rank of each symbol in a string u, which is defined to be one plus the number of '<' preceding this symbol in u, plays an important role in 2D string matching. We denote the rank of symbol b by r(b). The strings "ad<b<c" and "a<c" have ranks as shown in Table 1:

string v	string u
a d < b < c	a < c
1 1 2 3	1 2

Table 1 Ranks of strings

A substring where all symbols have the same rank is called a local substring.

A string u is contained in a string v, if u is a subsequence of a permutation string of v.

A string u is a type-i 1D subsequence of string v, if (a) u is contained in v, and (b) if a1 w1 b1 is a substring of u, a1 matches a2 in v and b1 matches b2 in v, then

(type-0) r(b2)-r(a2)>=r(b1)-r(a1) or r(b1)-r(a1)=0

(type-1) r(b2)-r(a2)>=r(b1)-r(a1)>0 or r(b2)-r(a2)=r(b1)-r(a1)=0

(type-2) r(b2)-r(a2)=r(b1)-r(a1)

Now we can define the notion of type-i (i=0,1,2) 2D subsequence as follows. Let (u,v) and (u',v') be the 2D string representation of f and f', respectively. (u',v') is a type-i 2D subsequence of (u,v) if (a) u' is type-i 1D subsequence of u, and (b) v' is type-i 1D subsequence of v. We say f' is a type-i sub-picture of f.

In Figure 7, f1, f2 and f3 are all type-0 sub-pictures of f; f1 and f2 are type-1 sub-pictures of f; only f1 is type-2 sub-picture of f. The 2D string representations are:

f	(ad<b<c, a<bc<d)
f1	(a<b, a<b)
f2	(a<c,a<c)
f3	(ab<c, a<bc)

```
-------------
| d |   |   |
-------------
|   | b | c |
-------------
| a |   |   |
-------------

      f

---------       ---------       ---------
|   | b |       |   | c |       | b | c |
---------       ---------       ---------
| a |   |       | a |   |       | a |   |
---------       ---------       ---------

   f1              f2              f3
```

Figure 7 Picture matching examples

Therefore, to determine whether a picture f' is a type-i sub-picture of f, we need only determine whether (u',v') is a type-i 2D subsequence of (u,v). The picture matching problem thus becomes a 2D string matching problem. Efficient 2D string matching algorithms have been developed [CHANG86] and applied to pictorial information retrieval problems.

5. Orthogonal Relations

All run-length encoded objects have the minimum enclosing rectangle available, hence three types of spatial relations between objects can be identified. These are for objects with:

-nonoverlapping rectangles
-partly overlapping rectangles
-completely overlapping rectangles

The case with non-overlapping rectangles is trivial and will never cause any problems because the object relations are simple. The other two might sometimes cause problems, especially when one of the objects partly surrounds the other. Figure 8 demonstrates a problem of this type. The fundamental issue here is to find a method that easily describes the relations between the objects. The method is called orthogonal relations, because it deals with spatial relations that are orthogonal to each other.

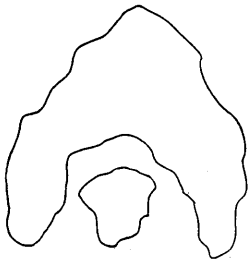

Figure 8 Two objects with overlapping MERs

The basic idea is to regard one of the objects as a "point of view object" (PVO) and then view the other object in four direction (north, east, south, west). Hence, at least one or at most four subparts of the other object can be "seen" from the PVO. The part of the object that actually is "seen" is in the interval where the two rectangles overlap, partly or completely. This is illustrated in Figure 9 and Figure 10. The subobject can be regarded as point objects, i.e. the centroid of the rectangle that enclose each subobject. It is a fairly simple operation to identify and generate these points from the RLC. The next step is then to identify the relation between the objects by using the 2-D projection method described in section 3.

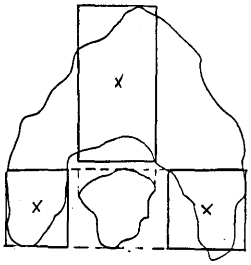

Figure 9 The PVO and its corresponding orthogonal relations

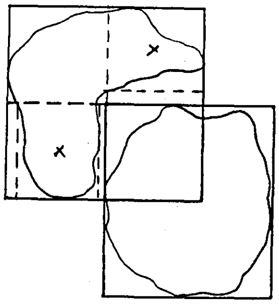

Figure 10 The PVO and its corresponding orthogonal relations for partly overlapping MERs

Each one of the sub-objects constitutes an orthogonal relational object of the original object and since they are regarded as points, a sparse vector description of the original object is generated. From this viewpoint it does not matter whether the original object is of closed or linear type. This makes the methods powerful. However, it is of importance that the subobjects are interpreted correctly. Figure 11a shows a correct interpretation of a north and a west segment while the interpretation of the same element in Figure 11b is erroneous. The natural interpretation is to look clockwise. Hence, nine different combinations can be identified.

2 points: N - E, E - S, S - W, W - N

3 points: N - E - S, E - S - W, S - W - N, W - N - E

4 points: N - E - S - W

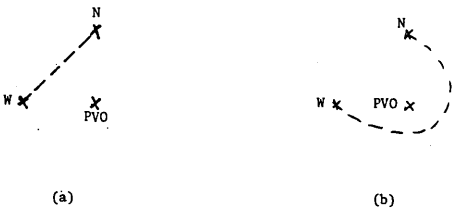

Figure 11 A correct (a) and an erroneous (b) interpretation of orthogonal relations

No other interpretations are allowed. It is also possible to regard the element in between the orthogonal ones. But this is not necessary since enough information is available anyway (see Section 5 for further discussions).

The technique of finding orthogonal relations is described in the following algorithm.

```
Procedure Ortho(x,y)
begin
  /*Ortho(x,y) finds orthogonal relations
    of object x with respect to object y*/

  /*find the minimum enclosing rectangles*/
  find Mer(x); find Mer(y);

  /*find four relational objects of object y
    intersecting the extensions of object x*/
  y-W = W-extension(Mer(x)) ∩ Mer(y);
  y-E = E-extension(Mer(x)) ∩ Mer(y);
  y-N = N-extension(Mer(x)) ∩ Mer(y);
  y-S = S-extension(Mer(x)) ∩ Mer(y);

  return( {y-W,y-E,y-N,y-S} );
end
```

6. A Knowledge-based Approach to Spatial Reasoning

From the 2D string representation, we can derive the spatial relations without any loss. From these spatial relations, we can derive even more complex spatial relations. Therefore, combining the 2D string representation with a knowledge-based system, we can provide flexible means of spatial reasoning, image information retrieval and management.

The knowledge-based approach to spatial reasoning is illustrated by two examples below.

Example 1: An island outside a coast line.

Figure 12 illustrates the orthogonal relations. The 2D symbolic projections are then

U : C1 < C2 i

V : C2 < C1 i

The following rule is now applied

if U : r1 < r2 p and V : r2 < r1 p

then

** facts ** (south r p) (west r p)

** verbalization ** "The object <p> is partly surrounded by the object <r> on its south and west side".

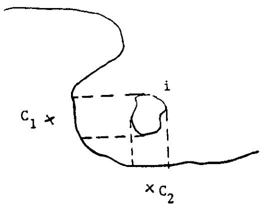

Figure 12 The orthogonal relations between an island and a coastline.

When applying this rule to the example, r will be substituted by C and p by i, i.e., (south C i) and (west C i). These facts are now stored in the fact database. The verbalization is sent to the user.

Example 2: A forest near a lake.

In Figure 13, L1, L2 and L3 illustrates the orthogonal relational objects which are part of the lake. The 2D symbolic projections are:

U : L3 < F L1 < L2

V : L3 F L2 < L1

This is matched with the following rule

if U : r1 < p r2 < r3 and V : r1 p r3 < r2

then

** facts ** (west r p)(north r p)(east r p)

** verbalization ** "The object <p> is partly surrounded by the object <r> on its west, north and east side".

In this example, we will substitute p by the Forest f and r by the lake L.

By successively applying rules that correspond to each one of the basic orthogonal relation types, it is possible to identify all object-to-object relation. For example, the fact identified in Example 2 is (west L F), (north L F) and (east L F).

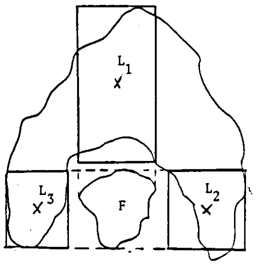

Figure 13 The orthogonal relations between a forest F and a lake L.

7. Discussion

As mentioned in Section 1, an image information system should support both simple query processing and knowledge-based complex query processing. Complex query processing may involve the generation of objects using set-theoretic operators described in Section 3. For example, we can retrieve all type-1 and type-2 objects within a specified area, and generate the union (or intersection) of these objects. As illustrated in Figure 14, the icon-oriented user interface is well-adapted to this task. By searching the knowledge-base and matching against the symbolic projections, we can answer complex queries such as:

"find all objects to the south of X"
"find all spatial relations between objects X and Y"

A pictorial example of such queries using an icon-oriented approach will allow the user to have a friendly and intuitively meaningful way for specifying queries. The pictorial query can then be transformed into symbolic projections and used to retrieve matching pictures in the database.

Generally speaking, expert systems are not particularly good at handling spatial data [WATERMAN86]. Symbolic reasoning is generally not possible because this type of data requires large amount of memory to keep track of the various spatial relations. Moreover, this process is normally slow when conventional methods are used. Orthogonal relations represented as chains of 2D symbolic projections constitute a basis for efficient use of spatial knowledge. For example, another potential application is path finding in a map. The symbolic projections can be used by a planning expert system to generate an approximate route. The approximate route can then be algorithmically refined to a definite path using previously developed algorithms [LOZANO83, WONG86]. The proposed pictorial data structure therefore can be very useful in designing expert systems for spatial reasoning, as well as knowledge-based image information systems.

DOCUMENT IMAGE UNDERSTANDING

Sargur N. Srihari

Department of Computer Science
State University of New York at Buffalo
Buffalo, NY 14260

ABSTRACT

A digital document image is an optically scanned and digitized representation of a printed page that consists of blocks of text, line drawings, half-tone pictures, and icons. Document image understanding is a goal-oriented problem involving detecting and interpreting different blocks and coordinating the interpretations to achieve an end result. We examine several solutions to subproblems in document understanding tasks. The subproblems range from pixel processing issues to symbolic linguistic reasoning to global control.

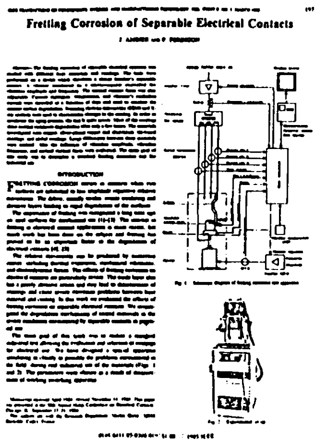
1. INTRODUCTION

A *document image* is a visual representation of a printed page such as a journal article page, a magazine cover, a newspaper page, etc. Typically, it consists of blocks of text, i.e., letters, words, and sentences that are interspersed with half tone pictures, line drawings, and symbolic icons. A digital document image is a two-dimensional array representation of a document image obtained by optically scanning and raster digitizing a hard copy document. It may also be an electronic version that was created in that form, say, for a bit-mapped screen or laser printer. An example of a document image is shown in Figure 1.

Document image *understanding* (or simply, document understanding) is a goal oriented problem that may involve interpreting photographs (which is a *vision* problem), interpreting text (which may involve *natural language understanding*), interpreting line drawings such as graphs, in such a way that the interactions of the different components is accounted for. Some examples of document understanding tasks are: (i) integrate the pictorial content of a newspaper photograph with accompanying narrative title, (ii) determine the paste-on destination address on a colorful magazine cover: it is necessary to locate and orient the most plausible textual block, to read it and verify that it has the correct syntax, and (iii) make inferences from an annotated *x-y* plot.

Document understanding implies the correct recognition of each of its constituent components. The recognition has to be both in terms of high level components such as columns and paragraphs, as well as in terms of low level components such as words and lines in the case of text; curves, rectangles, and solids in case of graphics; and image regions in case of half-tone pictures.

Document image *analysis* is the task of deriving a high level representation of the contents of a document image. The spatial structure of a document can be represented in several ways. Two representations of the image of Figure 1 are shown in Figure 2. The first is an analogical representation that gives the spatial extent of blocks including paragraphs and the second is a propositional representation in the form of a partial semantic network whose nodes represent document entities and arcs represent relationships. Each of them assumes blocks as units where each block can be associated with details like size, shape, number of black pixels and texture information. This information can then be utilized to discriminate between blocks. Methods for deriving the blocks can take advantage of the fact that the structural elements of a document, i.e., columns, paragraphs, titles, figures, lines of text, symbols, etc., are generally laid out in rectangular blocks aligned parallel to the horizontal and vertical axes of the page.



Fretting Corrosion of Separable Electrical Contacts

Figure 1. An example of a document image.

Document Understanding Components

Document understanding involves the use of several types of knowledge including *visual, spatial,* and *linguistic*. In determining objects from the background, say, by thresholding or by edge detection and grouping, the parameters necessary to perform such operations constitute visual knowledge. Labeling regions involves the use of spatial knowledge, e.g., the layout of a typical document. Determining the font and identity of characters also involves spatial knowledge, i.e., the structure of textual symbols, words, and the distinguishing characteristics of each font. Reading words in blurred or poorly registered text, is a process that involves spatial as well as linguistic knowledge, e.g., lexicon of acceptable words. Determining the role of a block of text, e.g., "is this a title?," is a process requiring spatial, syntactic as well as semantic knowledge. Considerable interaction among different types of knowledge may be necessary. For instance, assigning a role to a textual region may require not only knowledge of spatial layout, but also an analysis of its textual syntax and semantics, and an interpretation of neighboring pictorial and iconic regions.

The various processes necessary for document analysis are shown in Fig. 3. The task has been divided into three phases. Phase 1 consists of two steps: optical scanning and digitization and binarization. Phase 2 consists of block segmentation and labeling. The result of phase 2 is a set of regions (possibly overlapping) labeled as text, graphics, half-tone, etc. Phase 3 consists of several parallel operations for processing text, graphics, and half-tone images. Document understanding involves feedback paths not shown in Fig. 3.

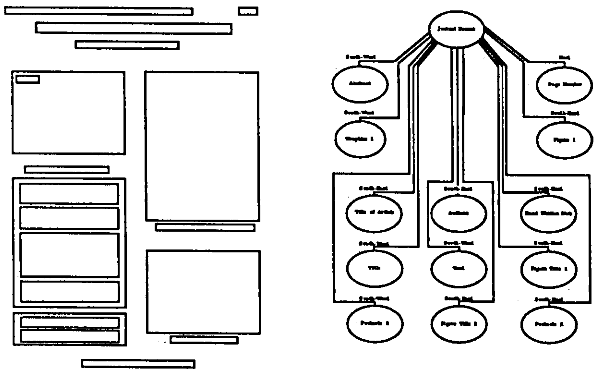

Figure 2. Document image representations.

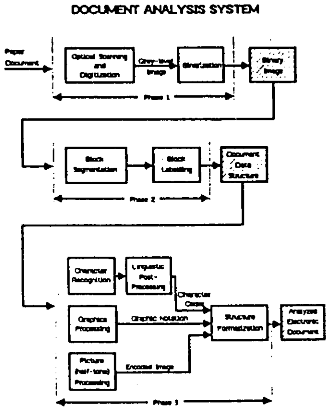

Figure 3. Document Understanding Components.

2. SCANNING AND BINARIZATION

An optically scanned document image is usually an integer (gray-valued) array; it is obtained by a process of spatial sampling and simultaneous conversion of light photons to electric signals. A high-resolution *bit map* is sufficient to capture shades of gray in the eye of the human perceiver (such images are called *half-tone*). An optically scanned document image can be converted into a bit map by a *global* thresholding operation: pixel values below the threshold are deemed to be black (value 1) and those above deemed white (value 0). The threshold itself can either be predetermined or calculated from the image histogram, e.g., the valley of a bimodal histogram.

A global threshold, i.e., one that applies to the entire image, may sometimes be impossible to obtain due to varying background color. One solution is *adaptive* thresholding which is to compare the gray value of the pixel to the average of the gray values in some neighborhood about the pixel. If the pixel is significantly darker than the neighboring pixels, it is called black; otherwise it is white. One such adaptive thresholding algorithm [14] that is appropriate for a printed document considers a 9 x 9 region around a pixel (x, y). The central 3 x 3 region including (x, y) is called A_1 and four 3 x 3 regions 8-connected to A_1 are jointly called A_2. The average pixel value of A_1 is compared to the weighted average pixel value of A_2. The idea in choosing the regions in this manner is that of a black pixel that is part of a line of text should only be compared to the white spaces above and below the line.

Color

A document with significant colored regions is usually scanned as three gray level images with red (R), green (G), and blue (B) filters. A colored image can be converted into a single bit map by approximate methods. Color thresholding is useful to extract regions of a particular color. Thus if the objective were to determine the address label which is known to be white then one can focus only on the white regions and perform further feature tests (e.g., rectangularity, presence of text) [21].

Resolution

Scan resolution is of importance in document understanding. Scanning resolution for text and line drawings can be decided as follows. The width of a *typical* character stroke is about 0.2mm (0.008 inch), with some of the widest strokes up to about 1mm; a 10-point character measures about 0.5mm (0.014 inch) between ascender and descender lines. A sampling rate of 240ppi corresponds to about 0.1mm/pixel which guarantees that at least one pixel will fall totally within the stroke; this resolution corresponds to 33 pixels between the ascender and descender lines. In the case of engineering drawings the minimum line width is approximately 0.3mm. Thus the minimum resolution needed is approximately 100 ppi.

3. BLOCK SEGMENTATION

Approaches for segmenting document image components may be roughly divided into techniques that are top-down or bottom-up. Top-down techniques divide the document into major regions which are further divided into sub- regions, etc. They often use knowledge about document structure, e.g., that the layout is in the form of rectangular blocks. Bottom-up methods progressively refine the data by layered grouping operations. Although no practical system takes a pure approach, every system can be identified as being predominantly aligned with one of the two philosophies.

3.1. Top-Down Approaches

We will describe three top-down approaches: smearing, projection profile cuts, and the Hough transform.

Smearing

The smearing technique [24] involves scanning documents as black/white images A run-length smearing algorithm (RLSA) then operates on the image under which any two black pixels (1's) which are less than a certain threshold t apart are merged into a continuous stream of dark pixels. White pixels (0's) are left unchanged. For example, if the input sequence was 0001100000110010001 and the value of t was 3 then the result of the RLSA on this sequence would be

11111000001111100001.

The RLSA is first applied row-by-row and then column-by-column, yielding two distinct bit maps. The two results are then combined by applying a logical AND to each pixel location. The resulting RLSA image contains a *smear* wherever printed material appears on the original image. The thresholds t_x and t_y in the two directions need not be the same. The segmentation is expected to yield blocks each of which should contain only one type of data (text, graphics, half-tone, etc.).

Projection Profile Cuts

Based on the observation that printed pages are primarily made up of rectangular blocks, a page can be recursively cut into rectangular blocks. Thus the document is represented in the form of a tree of nested rectangular blocks. The application of cuts is based on the configuration of the pixels. A "local" peak detector is applied to horizontal and vertical "profiles" to detect local peaks (corresponding to thick black or white gaps) at which the cuts are placed; it is local in that the width is determined by the nesting level of the recursion, e.g., gaps between paragraphs are thicker than those between lines [11, 25].

A complete hierarchical recursive tiling of a page can be represented as a tree. An *X-Y tree,* is obtained by using horizontal or vertical partitions at alternating levels of the tree. The root represents the entire page and can be considered either a single horizontal or vertical partition. The succeeding nodes, and finally the leaves are obtained by a process of alternating horizontal and vertical cuts. The number of horizontal or vertical cuts placed at each level is variable, so the resulting tree is not binary. A node that represents a horizontal (vertical) partition has a set of descendents that represent a complete vertical (horizontal) tessellation of the parent node.

Hough Transform

A document typically contains several straight lines. Forms and tables contain solid lines. Line drawings, e.g., block diagrams, predominantly have straight lines. Columns of text are separated by straight rivers of white space. Text usually consists of several parallel textured thick lines.

The Hough transform is a technique for detecting parametrically representable forms, e.g., straight lines, in noisy binary images. It involves transforming each black pixel (x, y) in the original image into a curve in the parametric space. In the case of detecting straight lines the transformation used is $K = x \cos T + y \sin T$. For each point (x_i, y_i), T is varied from 0 to J to yield the corresponding curve in the (K, T) space. An array of accumulators is set up by quantizing values of K and T. The accumulators corresponding to values of (K, T) yielded by the transformation are incremented by one. It can easily be shown that if points are collinear along the line specified by parameters (K_0, T_0), then each such point (x_i, y_i) will necessarily increment accumulator (K_0, T_0). Thus each value in the accumulator array corresponds to the strength of evidence for a straight line with the corresponding parameters. For a 512 x 512 image, K values extend from –368 to +368 (This value is arrived at by assuming the origin of the (K, T) space to be at the center of the 512 x 512 image and hence the maximum value of K is 256 x 2).

The accumulator array resulting from applying the Hough transform to a portion of the document image of Figure 1 is shown in Figure 4. The portion corresponds to the "abstract" in the left column. In general the array can be checked for the particular orientation which has the maximum number of transitions to and from a minimum value. Transitions corresponding to text are usually regular and uniform in width and thus are easy to identify. In the case of text containing both upper and lower case, they register a maximum value at the center line of the characters and slightly lower values corresponding to the ascender and descender lines. Textual lines have another property that there are "white" lines perpendicular to the beginning and ending columns and this information can be used to confirm line orientations. First, the number of vertical columns in a page needs to be determined because a multi-column page may not have any (K, T) orientation with low counts. Subsequently, the spacings between the text lines can be identified, on the basis of the average width of significant (K, T) values for a particular T.

The distance histograms along the line and its perpendicular orientation can be used to get the inter-word and inter-line distances. By incorporating these, the thresholds for the run-length smearing algorithms can be derived and big blocks of data can be grouped together [16].

3.2. Bottom-Up Approaches

Bottom-up analysis is based on successive steps of refinement of the input image. The image is first processed to determine the individual connected components. At the lowest level of analysis, there would be individual characters and other large figures. In the case of text the characters are merged into words, words are merged into lines, lines into paragraphs and paragraphs into even larger blocks, if such a merging is possible. In a bottom-up technique it is usually necessary to determine whether a connected component is a part of: text, line drawing, or threshold region of a half-tone picture. Possible features for performing this classification are: size, branching structure, topology, and shape measures.

Size

A commonly used method is to determine the size of a component, by counting the number of pixels, and consider it not to be a character if it lies within a range. A disadvantage of this method is that the size of characters has to be known beforehand, which is not always possible. However, size is a useful first feature.

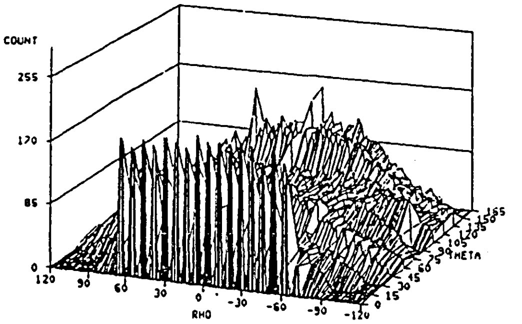

Figure 4. The Hough Transform accumulator array. Text lines appear as a series of peaks in the 0° column.

Branching Structure

The geometrical complexity of an object can be measured in terms of the number of linear components (branches) that the figure is composed of. If the complexity is high then the object is probably part of a line drawing, half- tone picture, or form, i.e., it contains too many branching structures to be a printed character. An algorithm can be designed to determine geometrical complexity of several components while the image is scanned raster fashion. This is done by keeping track of the several components in each line and their connectivity with respect to components in the previous line. A description of each connected component consisting of, say, its size, location, horizontal and vertical extents is maintained. Clusters of structures of similar type can then be identified. An example of this clustering approach is shown in Figure 5. A pass is made on the binary data to determine all connected components, which are individual characters. On the basis of proximity, size and other features the characters are merged into lines [2].

Topology

The topological properties of a component are useful in determining if it is a character. The Euler number of a binary image is defined as the number of components minus the number of holes. For a component which is a character the Euler number is one (1), zero (0), or negative one (–1). A fast algorithm can be designed for computing the Euler number of a binary image. More generally, the adjacency tree of a binary image contains all topological information (Figure 6).

Control for Bottom-Up Grouping

The order of application of different operators can be based on their complexity, e.g., most characters can be quickly determined by their component size. However if characters touch a line, as often in the case of line drawing graphics, the characters have to be segmented from lines. One technique for segmenting characters from line structures is to determine the high neighborhood line density (NLD) areas in the line structures [8]. Such areas are candidates.

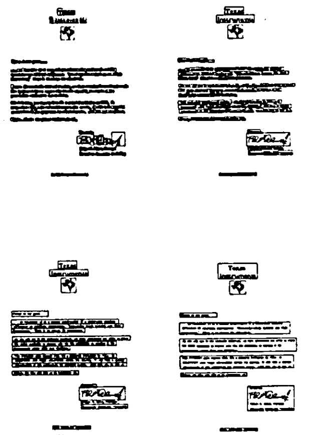

Figure 5. Bottom-up grouping technique. Character blocks are merged into words, words into lines, etc. using a clustering technique.

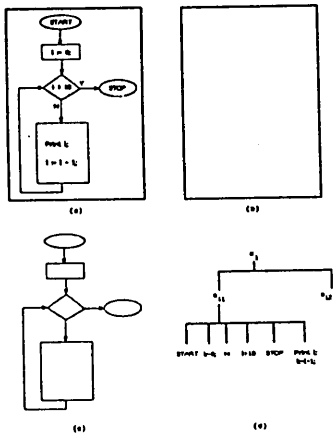

Figure 6. Adjacency tree: (a) input graphics, (b) outermost component a_1, (c) inner component a_{11}, and (d) complete adjacency tree.

The application of different operators for bottom-up grouping can be coordinated by a production system. Examples of specific rules in such a system are:

if connected components [*c*]'s size [*s*] is larger than *t*,
then the component is graphics with likelihood L_1,
if neighborhood line density (NLD) on graphics is high,
then the high NLD area is a character area with likelihood L_2.

A sketch of control flow follows:

1. Size, position, and direction data of every connected component is collected.
2. The components are classified according to size into graphics, characters, and noise and their likelihoods are determined.
3. Character components are grouped together as character areas using vector distance rules.
4. High NLD areas in graphics components are separated out as characters touching lines and their likelihoods are determined.
5. If another character exists near the touching character area its likelihood value is increased.
6. The cut-off part in a faded line is repaired.

4. LABELING

Blocks determined by a segmentation process usually need to be labeled in a subsequent step. There are several techniques for classifying a given block into one of a small set of predetermined document categories.

Statistical Approach

Simultaneously with component coloring, the following measurements are taken: total number of black pixels in the segmented block, minimum *x-y* coordinates of a block and its *x-y* lengths, total number of black pixels in the original image for the block, and number of horizontal white-black transitions in the original image block.

The next step is to classify each block according to content. This is done by computing several features for each block from the above measurements and then using a linear pattern classifier. The features computed are: the height of a block, its eccentricity, the ratio of the number of black pixels to the area of the surrounding rectangle, and the mean horizontal length of the black runs in the original data from the block.

A block is determined to be text if it is a textured stripe of mean height H_m and mean length of black run R_m. The distribution of values in the *R-H* plane derived from sample documents are observed to determine the discriminant function. Low *R* and *H* values represent regions containing text. To determine the threshold values of *R* and *H* that define the text region in the R-H plane, an adaptive method is used. This method estimates R_m, H_m and the standard deviation of *R* and *H*. These values are then used to classify the various blocks by using the following pattern classification scheme that assumes linear separability:

- **Text:**
  if $R < C_{21} \times R_m$ and $H < C_{22} \times H_m$,
- **Horizontal solid black lines:**
  if $R > C_{21} \times R_m$ and $H < C_{22} \times H_m$,
- **Graphic and Half-tone images:**
  if $E > 1 / C_{23}$ and $H > C_{22} \times H_m$, and
- **Vertical solid black lines:**
  if $E < 1 / C_{23}$ and $H > C_{22} \times H_m$.

A Distance Mapping Shape Measure

A shape measure for determining whether a component is a character, line drawing, or thresholded gray-level image is as follows [22]. Given a connected component *S* first a distance *d* is computed for each pixel of *S* as follows. Distance *d* is a function of the two Cartesian coordinates *x*, *y* ($(x, y) \in S$) and an angle φ measured from the *x* axis (0° ≤ φ 180°). It is defined as the length of a line segment B_1B_2 that passes through the point (*x*, *y*) of *S* and makes an angle φ with the horizontal. The two opposite border points B_1, B_2 of *S* are such that the line segment B_1B_2 is entirely inside *S*. Three distance mappings are:

$D_{min}(x, y) = \min_{\varphi}[d(x, y, \varphi)]$, or the length of the shortest chord through (*x*, *y*),

$D_{max}(x, y) = \max_{\varphi}[d(x, y, \varphi)]$, or the length of the longest chord through (*x*, *y*), and $D_{ecc}(x, y) = D_{max}(x, y) / D_{min}(x, y)$.

These mappings reflect geometrical properties of objects within binary images. By averaging D_{min} within *S* the mean minimum border to border distance dmin can be calculated. This provides a fairly good estimate for the mean line thickness of line shaped patterns. To discriminate between line shaped patterns and more compact ones, the average of D_{ecc}, d_{ecc} is a useful measure. Similarly, dmax reflects the mean maximum border to border distance.

Further shape factors are desirable: d_{min} can be used to derive a shape factor which equals one for the most compact pattern, an ideal circle, and is greater than one in all other cases: $f1 = A / d^2_{min}$ with $C_1 = 16 / 9\pi$ in continuous space (or number of pixels in disscrete space). This global measure reflects the "line shapeness" of pattern, i.e., their compactness independent of A more specific characterization can be obtained by means of additional features, e.g., $f_2 = C_2 \times A / d^{-2}_{max}$ with $C_2 = 4 / \pi$ in continuous space (1.2.388 in discrete space) which is invariant with respect to the size of the pattern. Unlike f_1, f_2 is capable of discriminating a straight line from an L-shaped line having about an equal number of pixels and about equal line-thickness.

Handwriting versus Print Discrimination

Given a region that contains either printing or cursive script, a method can be devised to determine its nature by observing regularities of white-to-black and black-to-white transitions. Figure 7 illustrates.

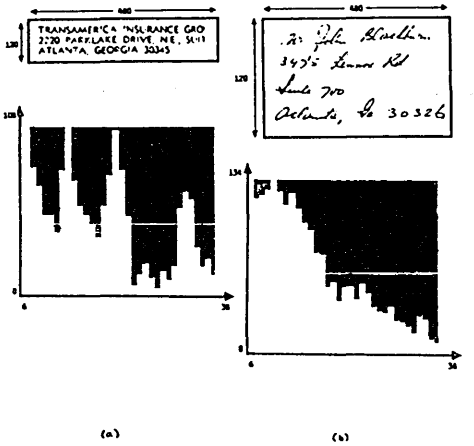

Figure 7. Printed text can be distinguished from cursive script by determining regularities: (a) printed text and histogram of black-white transitions in vertical direction, (b) cursive script and corresponding histogram.

The method involves computing several filter histograms of the test region. One example of a filter is a white-to-black transition separated from another white-to-black transition by n units along the horizontal direction. The histogram is obtained by counting the number of such transitions that occur for each value of n. Different histograms are obtained by considering a white-to-black transition separated from a black-to-white transition in the horizontal/vertical directions. The histograms for printed text tend to have several regular peaks while handwriting tends not to have such peaks. Thus the test becomes one of classifying the histogram as regular/irregular. The classification can be done either by treating the histogram itself as a feature vector or by extracting an appropriate feature vector from the histogram.

Rule-Based Approach

A method of associating labels like line-of-characters, paragraph, title, author, abstract, text columns or text lines, column, photo, etc., to the blocks on the basis of their extent, absolute and relative position is then needed. This can be done by a rule-based expert system that uses a knowledge-base comprising layout and composition rules for specific classes of documents [11]. Using physical (syntax) information, the rule-based system proceeds on its labeling of the blocks (referred to as semantics).. These rules can determine line-of-characters, paragraphs, columns, photos etc. using concepts of width, aspect ratio, number of cuts, number of siblings at a particular stage and other such related information. Rules are of the following type:

- line of characters: sequence of adjacent character blocks of some height, separated by character-segmenting rule,
- paragraph: sequence of blocks of line-of-character of same length, separated by line finding rule,
- column: large blocks with approximately equal frequency of "1" and "0" pixels, and
- photo: sequence of paragraph blocks of same width, separated by paragraph-cutting rule.

For a complete consistent set of rules, the labeling process has worst case complexity equal to the product of the number of blocks and the number of labels.

5. GRAPHICS PROCESSING

Line drawings and tables are commonly encountered in documents. Their analysis involves a raster to vector conversion. The aim of a raster to vector process is to convert a binary pixel representation of line-work into a connected set of segments and nodes. A segment is typically a primitive such as a straight line or a parametric curve. Straight lines in vector form are specified by their start positions, extent, orientation, line width, pattern, etc. There have been several different approaches to vectorization, including: pixel- based thinning, run-length based vectorization, and contour-based axis computation.

Pixel-based thinning algorithms require multiple passes through the data set. During each pass object pixels are deleted based on local neighborhood criteria. Such methods gradually thin thereby thinning the image down to unit width (Figure 8). A single pass algorithm could be obtained by using a set of local 3 x 3 operators and applying them in a quasi-parallel manner to generate a marked skeleton; quasi-parallel application means dividing the image into four disjoint sub-images and applying the operators to each sub-image in turn [5]. These techniques are slow as they operate on individual pixels rather than on groups of pixels. Also a lot of time is wasted in looking at white pixels more than once; only about ten percent of the pixels on any page of text are black and hence this wastage is quite considerable.

Run-length based vectorization [15] differs from pixel-based thinning in that the image does not go through multiple passes to get at a thinned image of unit width. Instead, vectors are drawn with certain approximations resulting in this. The method aims at this by tracking the black segments along scan lines and using aggregates of such segments to operate upon. The algorithm achieves the objective by converting the input run length encoded image into a graph and analyzing the graph. The graph also has information which could be used to provide many more useful features for character recognition. It is found that this method works better for lines perpendicular rather than parallel to scan lines. The complexity of pixel based thinning is of the order of the number pixels. The complexity of run-length based thinning is approximately of the order of the number of run length code segments.

Some problems that need to be specially examined are handling of dotted lines, determining end points of lines, effectiveness of thinning, determination of vector intersection and curve fitting versus piecewise linear approximation. Issues in understanding of graphics are discussed in [3, 4, 10].

6. TEXT RECOGNITION

A text recognition or reading technique takes an image of text and maps it into an ordinal machine representation, e.g., ASCII. Methods of reading text can be divided into two related but distinct categories: *isolated character recognition* and *character recognition in context*. When the types of font are known *a priori*, or when few fonts are encountered, a highly reliable isolated character recognition technique can be designed.

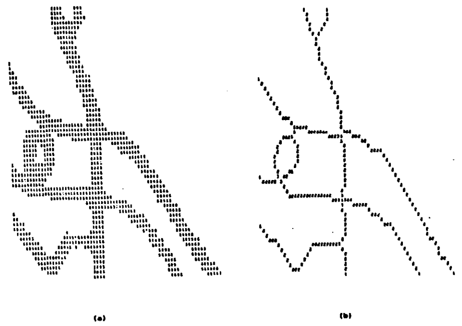

Figure 8. Example of Thinning Line Drawings.

Isolated character recognition involves extracting a set ot predetermined features from the character image. The features used are chosen for their ability to discriminate between classes. For instance, character height in millimeters is useful for distinguishing between lower case letters *with* ascenders, (e.g., b, d, h, k, l, t) and letters without, (e.g., a, c, e, n, o, r, s, u, v, w, x, y, z). Thus the character is regarded as a point x in a multi-dimensional feature space. Classification is accomplished by using discriminant functions which effectively partitions the feature space; typically each class i has an associated discriminant function d_i and x is assigned to the class that maximizes $d_i(x)$. The discriminant functions d_i, or their parameters, are determined statistically from a large set of samples during a training phase. Character recognition techniques quite often use only binary-valued features. since they lead to simpler feature representation and discriminants

6.1. Isolated Character Recognition

Typical of such a method is one [17] that treats a binary character image on a 16 x 16 grid as a 256-element binary feature vector x. The classifier uses second order polynomial discriminant functions derived using least mean squared error considerations. The form of the discriminant function is: $d_i = a_{0i} + a_{1i}y_1 + a_{2i}y_2 + \dots + a_{mi}y_m$, where y_i are either components of x or products of pairs of components. Since the number of such terms is large, (i.e., $256 + {}^{256}C_2$), only a subset is used. Approximately $m = 1200$ is determined where the pairs of pixels are heuristically chosen. In the 16 x 16 raster field, more pairs are chosen at the center than in the periphery. The set of coefficients a_{ji} are represented as a matrix A of size $k \times m$. Thus the computation of the k discriminant functions can be expressed as the matrix multiplication: $d[k \times 1] = A[k \times m] \,.\, y[m \times 1]$. The index of the member of d which is closest to unity is the class to which the input is assigned.

6.2. Character Recognition in Context

In most printed documents characters hardly ever appear in isolation. Several approaches to recognizing characters in context are known [19]. Contextual information is usually in the form of a lexicon of acceptable words. It can also be in the form of *n-grams*, i.e., legal letter types, or letter transition probabilities.

One approach is to recognize characters of words and then post process (correct) any errors by using a lexicon of words and a distance measure between words. Another approach is to use lexical information to limit the number of possibilities in recognizing individual characters to find the nearest word. This is done by weighting the choices for a given character by (i) its occurrence in the lexicon and (ii) its frequency of occurrence in the text. Thus the unlikely choices are eliminated and the resultant is guaranteed to be in the lexicon. Integrating contextual information into the character recognition process leads to better performance than the two step approach of character recognition followed by error correction [20]. The third approach is to extract features from the entire word and attempt to classify it using a lexicon organized by word feature. A simple set of features are used in a first level analysis to select a neighborhood of words and a more detailed analysis discriminates between a small subset of character classes [6].

6.3. Type Font Analysis

A document analysis system needs to distinguish between text of different fonts. In the terminology of typography, a *font* is a collection of upper and lower case letters and special characters of one particular typeface, style, and size. The tvpeface determines the overall design of one character shapes. The style refers to the average stroke width of the characters, boldface versus lightface (normal), and the posture of the body, italic versus roman.

The task of character recognition is considerably simplified if the font is determined ahead of recognition. Variability of characters is due to two sources: the type font and noise. Given the English alphabet in several fonts, the style of any given letter, say "B," is different in each font. However within any one type font certain aspects of the style of the "B" are identical to the stylistic aspects of the other characters in that font, e.g., the lower left sides of "B" and "D." By providing a framework within which this repetition of stylistic aspects in a type font can be expressed explicitly, it can be used subsequently to augment the recognition algorithm, e.g., knowing the font, a decision procedure for that font can be applied.

Determining the stylistic consistency of a given font involves finding elements such as serifs and then finding their relationships to strokes to which they are joined. A set of rules for type font analysis considering only machine printed fonts taken from the Roman and sans-serif families is given in [1].

6.4. Linguistic Analysis

The role of language in the recognition of images of text has been little explored beyond the word level. Here we describe a linguistic approach to recognize whether a given two dimensional block of text is an address. If it is an address, a parse tree is obtained. The method exploits spatial information in its analysis, i.e., the space between words or lines is important.

In determining the destination address on a mail piece image with several two-dimensional blocks of text, it is necessary to syntactically analyze the recognized characters in a candidate block by using spatial information such as character, word and line spacing [21]. A system has been developed to perform this syntax analysis by attempting to parse (label) subelements of the block of text and produce a parse tree representing the labeling of the constituents [13]. This labeling identifies words corresponding to the city, state, zip code, and street name, among others. Several significant changes have been made to a standard Augmented Transition Network (ATN) parser [18] including word abbreviations, spatial feature analysis, and heuristic parsing.

This module takes as input a sequence of lines of sentences (subsequently called a *sentence block*). This input, in the form of ACSII characters, is then preprocessed to record the number of horizontal blocks before each word and record this spatial information as lexical features of the input word. A similar preprocessing operation is performed to record the vertical spacing between lines in the block but with the spatial separation recorded as a special *word* inserted directly between the line of the input and later handled as another word in the input stream. This provides the parser with spatial information needed to check if a word or line is "too far away" from the remaining words to be considered.

This preprocessed sentence block will be *accepted* by the parser if and only if the sentence block has the syntax of an address block. If the input sentence block is acceptable in terms of the grammar and lexicon, then the structure (parse tree) of the region will be passed to the generalized rule-based region labeler for use in the determination of the correct sending address as opposed to the return address.

The address recognition module incorporates the four assumptions described below:

1. When a block in initially segmented and passed to this address recognition unit, extraneous printed material may be present in the block. This is dealt with by adding heuristic arcs (described below) to the grammar which will allow crude matching of the beginning of each line and result in the skipping of the remainder of the text line suing the generalized TO arc [18].
2. If the text block contains an ambiguous address, then the output will be a parse tree representing all possible interpretations of the block.
3. This unit will not perform context matching between the city, state, and street name with the five of nine digit zip code. Context checking is also not performed between other components of the address since it is not a necessary condition for a text block to be an address block.

Parser Modifications

The major changes to the standard parser include the capturing of spatial features such as end of line and word spacing, and the addition of abbreviation handling.

Spatial Properties: A major parser modification was the addition of a spatial acquisition mode for capturing the number of spaces before each word and adds this spatial information to each lexical form of the current input word. This information includes the number of blank spaces prior to a word, the distance to the left, top, and right margins and also the length of the word. Below is a partial input to the parser after the initial conversion of physical spaces in the input to lexical features associated with the words.

```
(buffalo(((root . buffalo)
(ctgy . city)
      (parts . 1)
      (head-space 3)
      (left-margin-space 3)
      (top-margin space 0)
      (word-length 7)
      (right-margin-space 29)
      (line-length 32)))

...)
```

If vertical spacing is present in the input, then the block will be linearized with the insertion of a new line *word* of the form: @*nnnn* where @ represent the start of a new line, and the *nnnn* represents the number of units (lines) in the vertical spacing.

Abbreviations: Since many of the words in an address block are abbreviations such as Ave, St, NY, PA, S, N, W, a method was developed to associate these abbreviations with their expanded forms. To facilitate the lexical look-up of abbreviations and avoid the repetition of lexical words with similar meaning, a new property was used to equate a word with a series of other words.

A grammar corresponding to the bottom two lines of a standard address has includes the structures of the PO box, street, city, and state fields as well as the five (or nine) digit zip code. This grammar is complicated by the possible presence of punctuation between words and the spatial information mentioned above. Sometimes the punctuation and spatial information is important. For instance, if a comma is present, then it is a separator between the city and state name. Also, if a new line word is present, then it is most likely the termination of a multiple word phrase such as a city, state, or street name.

The grammar, in addition to containing arcs representing the bottom two lines of a standard address also contains heuristic rules for detecting and skipping other possible input lines. That is, if the first word on a line is a personal title (Dr., Mr., Ms., Miss, or Mrs.), or a personal first name, then the remainder of the line would be ignored. Another skipping rule is for the detection of a standard presort codes usually present on the top line of an address block.

For a sentence block to be parsed as an address region, several constituents must be identified. For instance, if more than one line is present in the address region, then the city/state/sip line must start on a new line. Another necessary element for a block to be parsed as an address block is the presence of a state name followed by a zip code (either on the same input line of on the following input line).

The grammar, initially, makes one pass through the input, attempting to locate a possible state name. If a state name is not found, then the parse will fail. If, however, a state name is found, then the state name and line number are recorded for later processing and a second pass is made through the input utilizing a more robust grammar for detection of other constituents. This preliminary detection of the state name provides an efficient means for detecting a necessary component of the address and reduces the computational cost of parsing the entire address region.

Lexicon

The lexicon contains generally five different types of entries corresponding to the street, city, and state names, street keywords (such as avenue, street, circle, parkway), and other keywords most often present in the address region of mail pieces such as personal names and titles. As was mentioned previously, the lexicon need not contain all possible street and city names but parses of an input sentence blocks containing these "missing" cities of street names would result in weak parses.

The grammar entails 106 states, 178 arcs, and a small text lexicon which contains 188 unique words with entries for all 50 states (and their abbreviations), 32 cities, 20 street names, and 20 street keywords. To judge the effectiveness of the keyword approach in guessing a city name, the Directory of Post Offices (DOPO) data base was used. A total of 25,630 on word city names were encountered with over thirty percent (7,843) of these city names ended in the above mentioned letters. For two word city names. 7.437 cities were encountered with over seventy-four percent (5,522) of these having first or last words as those mentioned above for two word city names. This shows that these patterns are a good indication of a city name, however, testing was also done to compare the number of English words (advertising material) that would be wrongly mapped into a city name based on these rules. Using the Brown Corpus containing 43,264 English words, a total of only 79 (0.18%) English words matched the one word patterns. A comparison of the two word pattern was not possible with the lack of contextual information in the corpus.

The parses of an input sentence which has been accepted using the grammar and lexicon is shown below, where the preprocessed input sentences are also stored in the parse tree as the first element using the form mentioned above.

```
(address(input-sentence
    (|1241| main @2 n |.| java n |.| y |.|152102| |;|4128|)
    (line starts (00)))
    (spatial (word (0 W4 1 W4 0 W1 0 W1 1 W4 1 W1 0 W1
              0 W1 0 W1 1 W5 0 W1 0 W4))
              (line (L9 2 L23))))
    (prepass (states((state (state-name (new york))
            (puncts (|.| |.|))))
    (level (01)))
    ((street-line (street-number |1241|) (direction nil)
                  (street-name main) (street-keyword nil)
                  (apartment nil) (puncts nil) (street-guess nil))
     (bottom-line (city (city name (north java))
                  (parts 2 (puncts (|.| nil)) (guess t))
                  (state (state-name (new york)) (puncts (|.| |.|)))
                  (zip (zip-location after-state)
                       (ninezip |151024128|) (fivezip nil))))).
```

7. PICTURE PROCESSING

A document image understanding system needs to integrate the information contained in photographs with the information contained in other fields such as with the text and line drawings. Often an understanding of the photographs is critical to understanding the narrative. Deriving descriptions of the contents of photographs is the subject of many computer vision projects today.

8. CONTROL STRUCTURES

The coordination of several processes is of central importance in a document understanding system. The control structure allows the application of the appropriate process. For instance, there may be more than one way of binarization. The method to be applied is determined by the control structure.

Several efforts towards designing control structures for document understanding are described [8, 9, 12, 23]. A method based on production systems and blackboard communication first proposed in the context of speech understanding holds promise for document understanding.

The mechanism described in [8] is based on a production system. When the production system needs data the mechanism causes the appropriate module to start collecting data. In this mechanism each connected component is treated as a data unit. An array, which is a specialized *blackboard* is used for the read/write area in both the production system and program modules. The blackboard is made up from three planes of identically sized arrays. Data, indicators, and program modules names and arguments are respectively stored in these planes. Data concerning positions, size, likelihood, and attributes for connect components are stored in the first data plane. The indicator plane indicates whether or not the value in the corresponding position in the first plane has already been collected. When the production system requires some data for matching, the indicator is checked first. If the desired data has already been collected, the values in the data plane are transferred to the production system. In the case where the data has not yet been collected, the program module stored in the third plane is activated and its function is carried out. The program module function determines the data and forwards the values to the data array.

Advantages of using production systems in document understanding are:

- easy to apply either an additional technique to an object that is hard to interpret with only one technique, or a retry process having modified parameters,
- processing knowledge is expressed as rules, thus software maintenance (e.g., modifying or patching of a program) becomes easier, and
- as the processing is not carried out over the entire picture uniformly, but only in necessary segments, high efficiency is obtained.

An Expert System

A production system that is organized with different levels of production rules that perform an analysis of a document image, and interpret and classify the various regions of printed matter on the document is given in [12]. The control flow is as follows: the document is first digitized and the resulting digital image is segmented to obtain data about the various printed regions in the document. This data includes the intrinsic properties (e.g., shape, size, aspect ratio, etc.) of each of the identified regions, as well as the spatial relationships between the various identified regions in the document image. The control structure then uses the knowledge base to examine this data, and attempts to arrive at a consistent classification for each of the identified regions, or blocks. The system consists of three levels of rules.

If the data from the initial segmentation of the image is not sufficient for an unambiguous interpretation of the document image, then the system decides to obtain more data from the given image. Thus, any further image processing operations that are required are progressively invoked under the supervision of the inference engine. These operations could include further segmentation of the image, color filtering, text reading, etc.

A goal-driven (top-down) approach is used by this system, which uses a hypothesize-and-test strategy for arriving at its conclusions. Thus, the system makes hypotheses about different intermediate conclusions and chains backwards through the rules in order to test the hypotheses. In trying to satisfy a hypothesis, some other hypotheses may be generated which must first be tested before the original hypothesis can be considered to be justified. Thus, an entire set of backward-chaining processes are set up, and the system only reaches a satisfactory conclusion when all these processes have run to completion.

The Knowledge Base

The knowledge base consists of a set of rules that embody knowledge about the general characteristics about document images. These rules are expressed in terms of predicates in first order predicate logic. The rules in the knowledge base are *Knowledge rules*. These rules define the general characteristics expected of the usual components of a document image, and the usual relationships between such components in the image. The usual relationships, e.g., the title being above the author names, the abstract being above the first paragraph of text, the footnotes being at the bottom of the page, etc. are generally true of such documents. Intrinsic properties, like the block-to-white pixel ratio for half-tone figures in the image being larger than the corresponding ratio for text, are also true in general for such blocks. From such known facts about these kinds of document images, rules are constructed that can be used by the inference engine to make inferences about the various identified *blocks* on the given document image.

The Control Structure

The control structure for the expert system consists of an inference engine which uses the knowledge base to make unambiguous inferences about the classification of various blocks in a given document image. The inference engine is also rule-based, and contains two levels of rules: *Control Rules* and *Strategy Rules*. These rules regulate the analysis of the document image, and decide when a consistent interpretation of the image has been obtained. The inference engine uses a top-down approach in arriving at its solution, since the solution space is not very large, and a lot of knowledge exists (in the knowledge base) about the domain. A backward-chaining process is used by the control structure.

The rules comprising the inference engine are also coded in terms of predicates in first-order predicate logic. The control structure determines the order in which these rules are executed in order to test various conditions effectively. Control rules can be *focus-of-attention* rules or *meta-rules*. For example, at any given stage of the analysis, control rules can decide that all the relevant knowledge rules for footnotes be executed so as to test whether the given block is a footnote. Strategy rules can guide the search in a more general way, i.e., they can determine what strategy is to be followed at any given time for analyzing the image. This means that the strategy rules determine what the order of execution of the control rules will be.

Representation of Uncertainty

The system has to deal with many situations where a combination of rules, rather than a single rule, lends credence to a particular hypothesis. Thus, the success of each of these rules adds evidence towards that hypothesis. If the total evidence obtained from the successful rules is sufficiently high, then the hypothesis is assumed to be true, and the next stage in the analysis process can then be tackled with the assumption that the given hypothesis has been confirmed. To deal with such a scenario, each Knowledge Rule in the system is given a certain *confidence value* between 0 and 1. When the knowledge rules for testing the characteristics of a certain type of block are executed, the confidence values for all the rules that succeed are added up. The sum thus obtained indicates the *certainty factor* for the conclusion obtained from the control rule which invoked these knowledge rules. This certainty factor is used for the purpose of ordering the conclusions at any given stage so that the more likely conclusions can be examined in further detail *before* the less likely ones. This has the effect of making the search process more efficient, thus reducing execution time in the system.

Discussion

The wisdom of using production rules to represent knowledge has been the topic of discussion among many AI researchers. In the domain document understanding, a rule-based system is extremely elegant because unlike natural scenes, documents are very structured in character, and thus knowledge about features of documents can be very effectively formulated in terms of production rules. There are other advantages to using production rules in document image understanding. First, it is easy to apply either an additional strategy to a region that is hard to interpret with only one strategy, or a retry process having modified parameters. Second, software maintenance becomes easier, since addition/modification of rules is a relatively simple process that does not disrupt the rest of the system. Third, in a production system the processing is not carried out over the entire image uniformly, but only on necessary segments; thus, high efficiency is achieved. All these reasons make production rule-based systems eminently suitable for use in the domain of document understanding.

9. DISCUSSION

Document image understanding is a task that begins with pixel processing and ends with complex symbolic reasoning. Thus it is an area of research that draws upon techniques of image processing, pattern recognition, computer graphics, natural language processing, and artificial intelligence. There is an intense level of activity in this field in Japan and in Europe. Interest in this topic is also growing in the United States.

Several of the components for building a document understanding system are now well-understood, e.g., component detectors, line detectors, single font character recognizers, text parsers, etc. Several other components need to be refined, e.g., techniques for text region determination. Multifont character recognition without operator input will continue to be a challenging problem for the foreseeable future. The problem of raster to vector conversion of line drawings is not as formidable but several problems remain, e.g., handling of dotted lines, global considerations in thinning, etc.

The coordination of component processes is a problem that has been addressed in other domains such as speech understanding. The coordination of document understanding processes will have to be done using similar techniques with access to domain knowledge. Due to advances in several related areas it can be concluded that document analysis is now a task that is well defined and of a moderate level of complexity. Thus the prospects of tangible results are reasonably good.

ACKNOWLEDGEMENT

Several members of the Document Image Understanding Group at Buffalo contributed to this work. In particular, Jon Hull, Debashish Niyogi, Paul Palumbo, Joseph Piazza, Steve Tylock, and Ching-Huei Wang. Gregory Zack of Xerox Webster Research Center provided the impetus for this work and many suggestions. This work was supported in part by the United States Postal Service contracts 104230-84-D0962 and 104230-85-M3349.

LIVING IN A DYNAMIC WORLD

Holmdel, NJ 07733

ABSTRACT

Today's robot systems take an egocentric view of the world, assuming that the world is largely static and changes from state to state only in response to robot actions. To a large extent, this is a consequence of the limited bandwidth of current environmental sensing systems, in particular, doing any kind of vision takes most of a second or more.

We have designed and constructed a vision system based on a VLSI chip that locates objects at the full 60 Hz camera frame rate. Two systems provide a three dimensional description of object motion. In this environment, the robot must be capable of a sense of time: it must consider new data in the context of the old, and it must be aware of the temporal characteristics of its mechanism and processing electronics. We are exploring these concepts by creating a robot ping-pong player.

1. INTRODUCTION

Conventional robots live in a world that changes in very discrete steps, in response to clearly defined causes. Robot actions are interlocked with status lines and control signals to the outside world:

```
move_to input_bin
wait_for part_present
withdraw part
move_to punch
activate punch
wait_for punch_done
withdraw part
wait_for output_empty
move_to output_bin
release part
```

All events of interest are either directly sensed or directly caused by the robot, typically requiring a large number of discrete binary sensors. Sensors like vision can be brought into this framework by suitably restricting their functionality to discrete events (their function is also limited to start with), for example: take a picture now, the part is missing, the part is bad, or a good part is at (10 cm, 15 cm, 45 deg). The program can be represented by a simple finite state machine, and the time variable is effectively suppressed. We will refer to this model of programming as the discrete time approach. Although we can solve many useful tasks this way, it begins to break down as the robot, task, and environment become more sophisticated.

Consider retrieving an object from a conveyor belt. The manipulator must be at the right place at the right time at the right velocity to make a smooth pickup. The conventional approach is to take a single snapshot of an object to find its position, then update its position using an encoder mechanically mounted on the conveyor belt. Paul [10] illustrates servoing to a moving frame of reference such as a conveyor. Pragmatically, this may be fine for many low accuracy applications, but suppose one would like to pick up the object using visual information exclusively. One approach is that of Weiss [11], who considers servoing directly based on visual feedback, though our eventual application precludes this.

An alternative approach which appears similar to how a person might perform the task is to try to lead the object by a distance proportional to the expected time to get there at some reasonable expenditure of energy. As the arm approaches the object, we can refine its target position based on the currently observed object position and the arm's position and velocity. In contrast to the previous discrete time model, this strategy is a continuous time approach.

Continuous time systems require high sensor bandwidth — many sensor data points per second, and low latency — the time from the acquisition of data until it is applied to the control output. The latency is often significantly larger than the reciprocal of the bandwidth due to the use of pipelined parallel processing. In the case of single shot events, latencies include the fixed overhead of initiating and completing an operation.

The system latency is the sum of latencies due to the sensors, the processors, and the actuators. The real world doesn't stop while each latency expires, so in a rapidly changing environment, the sensor data is incorrect by the time the actuator reaches a position based on that data. An object moving at only a meter per second (moderate walking speed) moves a millimeter per millisecond, so a millisecond error will cause most assembly operations to fail, and an error of one robot trajectory generator cycle causes a 2-3 cm error, enough to totally miss an object to be picked up from the conveyor. Since people perform assembly operations at up to 15 m/sec, timing into the tens of microseconds range might be required.

We are interested in creating systems which can operate in situations with tight timing, position, and velocity constraints characteristic of a continuous time environment. The work described here is only part of a larger effort to make more intelligent robot controllers. In this paper we will scrutinize the requirements of a sense of time and outline a hardware and software approach to achieving it. We will begin by discussing our test problem in more detail.

2. ROBOT PING-PONG

As a sample problem, we have chosen a robotic form of ping-pong proposed by Billingsley [4,8]. Ping-pong requires low latency in the sensors, actuators, and processing stages, and accurate system timing if the ball is to be directed along the desired trajectory. The robot controller must be capable of satisfying simultaneous position, velocity, and acceleration constraints.

The modified ping-pong table is shown in Figure 1. It has been scaled down from a standard table to make it easier for (stationary) robots. The rules are generally structured to make the game as feasible as possible, and to make it possible for any successful robots to be able to play each other. For example, the ball must pass through each end of the table; no shots off the side are allowed, and both robots and the background must be black.

Ball velocity can approach 10 meters per second, so available response time can range down to 0.2 seconds. A typical value is more like 0.4-0.5 seconds. Required paddle velocity is 1-2 m/sec, tightly controlled as a function of direction. The paddle velocity need not be too high as the outgoing ball velocity is twice the paddle velocity plus the incoming velocity, subject to the elasticity of the paddle/ball.

Complexity is added to the system by the mechanical configuration of the robot. The robot/paddle configuration must be able to cover a large (relative the robot's size) position and orientation set, and able to generate a controlled high speed motion at each point with minimal windup.

To generate the required speed and reach, we use a PUMA 260 robot with the paddle at the end of a roughly 0.5 meter stick perpendicular to joint six. A relatively slow motion of joint six provides large paddle speeds. The robot is hung upside down to keep the robot base from getting in the way. The paddle swings down on the ball rather than up. The robot positioning informally maximizes the usable working volume. Other robots with a larger reach, such as the PUMA 560, lack the necessary speed. SCARA robots are fast enough but don't have six degrees of freedom.

Ping-pong requires only 5 degrees of freedom, but the robot produces six. The free dimension corresponds to rotating the handle of the paddle in the plane of the paddle surface. Since the robot's wrist is half a meter away, the paddle orientation has a drastic effect on reachability and orientability, and picking it well is essential to good performance.

For simplicity, we ignore both spin and drag in trajectory calculations. The paddle velocity may be computed in closed form by requiring the paddle velocity to be normal to the paddle surface. Incoming and outgoing spins will require approximate techniques, perhaps with learning (iterative numerical solutions would be too slow).

2.1 Computer System Architecture

Our system is physically distributed over several processors. Each processor consists of a Pacific Microsystems PM68K processor (SUN-type 68000 based), a SKY Computers floating point board, 1 MB of memory, a network interface, a clock board we will discuss later, and miscellaneous I/O devices. The network is a custom small-area network featuring high bandwidth and low latency [1]. Star connections fan out from a backplane bus to the individual processors.

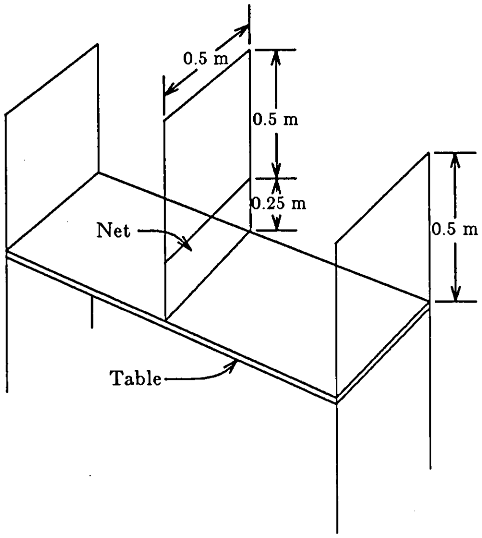

Figure 1. Robot ping-pong table.

The processor runs a multi-tasking operating system designed for real time performance, but with UNIX® (AT&T Bell Laboratories) look-alike calls [5]. The primary intertask (intra- or inter- processor) communications structure is a channel, a form of bi-directional UNIX pipe. A short (say 10 byte) message may be sent from one processor to another in about a millisecond, including all software overhead.

Software is written on a microVAX® (DEC) host running Unix, and downloaded into the 68000's for execution. The 68000s may access files on the host, typically to read calibration data and write debugging output.

2.2 Software Architecture

Although the network is homogenous, we overlay a structure by means of the channels we open, and the allocation of peripheral devices to processors. The allocation is performed "by hand" based on observed execution times for different systems components. The structure for robot ping pong is shown in Figure 2. Rtd is a specialized debugger, "chief" is a sequencer, and the SP2000 is a video tape system, the Kodak/Spin Physics Motion Analysis System, able to record 2000 full frames per second. Debugging tools are an important factor in constructing working systems.

Two vision processors drive two moment generator systems each, such that each processor has a stereo pair. One pair is looking at the far side of the table, one at the near side to achieve the proper field of view. All four cameras are genlocked together, so the vision processors can synchronously output an (x,y,z) triplet or "I don't see anything" at the 60 Hz frame rate. The image being processed is quite simple, consisting solely of a white ball against a black background. However, the ball can be greatly blurred due to its motion relative the camera. The vision system will be described in greater detail in a following section.

The next processor ("tranal") takes the (x,y,z) data and segments and fits it on the fly to create parabolic segments. The trajectory data is predicted forward to find the intersection of the trajectory with a fixed vertical plane at the end of the table, which serves as a common "point of reference." This intersection

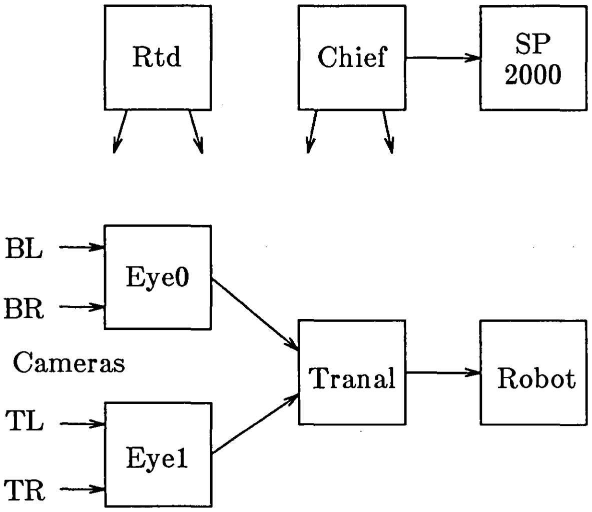

Figure 2. Task Structure.

data is then passed on to the final processor, the robot controller, still at the 60 Hz rate but with some additional latency.

2.3 Robot Controller Architecture

The robot itself is a Unimation PUMA 260. However, the electronics have largely been replaced. The LSI-11 and six 6503s normally controlling the robot have been replaced with a total of four 68020 based machines: one is a PM68K machine with a 68020 daughterboard, the other 3 are custom machines also with 68020 daughterboards (Figure 3). The standard PM68K processor serves as the main processor. Two custom boards serve as joint processors, each controlling three joints. The third slave processor is strictly computational, off-loading the main processor. The memories of the slave processors are accessible to the host but not vice versa, and slaves can interrupt or be interrupted by the host, but not each other.

To execute a typical motion, the program running on the main processor (the "user" program) calls up a motion initiator which performs the initial planning, computing variables for the path interpolation. The data is placed in the computational slave's memory, where the slave uses it to compute way points along the trajectory at a "major cycle" rate, say 16 msec, in response to interrupts generated by the main processor. The way points are sent to the joint processors by the main processor. The joint processors are interrupted at a "minor cycle" rate of 1 msec by an external source, causing the servo function to be executed. One of the joint processors interrupts the main processor every sixteenth minor cycle to create the major cycle.

The purpose of this involved structure is to minimize the amount of work required of the main processor to support ongoing motions, maximizing the time available for planning, while keeping the details visible to the planner. A totally shared memory architecture would even further reduce the nuisance work required of the main processor.

3. REAL TIME VISION WITH MOMENTS

The cornerstone of the research described in this paper is a vision system which operates in "real time." The system provides data with a sufficiently high bandwidth and sufficiently low latency that the data may be regarded as continuous for the class of problems we wish to consider, those involving interaction with a relatively macroscopic robot arm. A real time system is one that does its job in a time determined by external constraints, not just a system which is fast. Such a system can be used to watch moving objects, both in a conventional sense, or in more specialized domains such as aligning holes to be punched, or the apparent motion may be induced by the motion of the camera, when the camera is mounted on a robot arm or positioner. We would like to construct systems capable of extracting information useful for manipulation and inspection from gray scale images of three dimensional scenes in real time.

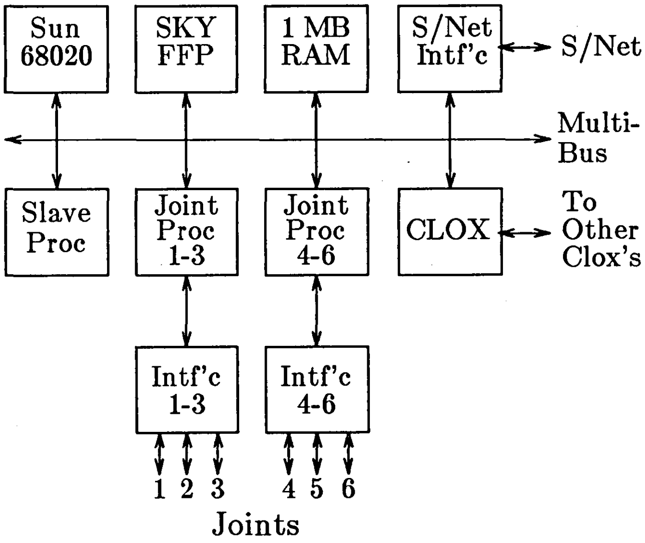

Figure 3. Robot controller architecture.

In general, we need to have full six dimensional information about the scene, three translational degrees of freedom describing object position, and three rotational degrees of freedom describing object orientation. For a vision system watching unknown objects, at least two camera views are required to extract the six degrees of freedom, i.e. stereo (binocular) vision is required. Ping-pong balls are rotationally symmetric (three degenerate degrees of freedom), therefore only the three translational degrees of freedom need be computed. The 3-D vision system must first process each two dimensional monocular image, then combine the results to form the three dimensional analysis. Let us take a brief look at existing vision systems.

Commercial vision systems are monocular, and most are capable of processing only binary images, typically by thresholding and run length compressing the image to reduce the amount of data before storing it in a fairly general purpose processor. Once read in, the data is processed for many tenths of a second before some decision is made. The canonical basis for these schemes is [6]; there are many current commercial imitators. Most of these systems are too slow to even be considered for continuous time robot control, but some systems using specialized hardware are approaching this regime. The extensibility of these binary image schemes into the gray scale three dimensional world is limited, however.

Image processing algorithms used for satellite image processing and television graphics, for example, can sometimes be made to run in real time with appropriate hardware when they operate on only local areas of the image. These algorithms take an image as input, and produce an image as output, such as an edge finding operator that produces a "line drawing." Such algorithms are not directly useful for robotics as they don't reduce the amount of information which needs to be processed, although they may simplify subsequent feature extraction operations. Reducing the amount of data to be processed without eliminating essential image content is fundamental to processing images in real time.

Research systems typically read a gray scale image into a frame buffer before processing it for several seconds, minutes, or even hours. Both two and three dimensional systems are under study. Although these systems are steadily advancing in capability, their low processing rate precludes their use for robot control. As research continues, we expect more of the features of these systems to be integrated into hardware running at real time rates.

A primary objective in constructing the vision system to be described was to build a system capable of processing simplified scenes at the "real time" rate necessary to use the data for robot control, to see what sort of system was necessary, and what would happen when we tried to use it. The overall approach is to make a "feature extractor" capable of extracting certain useful information from a complete video image streaming by at 60 frames per second, without having to store it for later processing. More complicated systems might be built by combining multiple types of feature extractors operating in parallel with multiple image processors connected in series. Once we can perform the necessary monocular processing at the proper rate on a reasonable sized piece of hardware, we can duplicate monocular processors and add further processing to generate the full three dimensional data. We'll start off by describing the monocular processing.

3.1 Moment Generator

Moments have been in use in computer vision for some time [7,9], and their use in physics and statistics goes back much farther. The equation defining the moments $M^{m,n}$ of an intensity array $a_{i,j}$ is:

$$M^{m,n} = \sum_{i,j} a_{i,j} i^m j^n \qquad (1)$$

where $m+n\,(m,n \geqslant 0)$ is the **order** of the moment, i is the column, and j is the row.

The zero through second order moments are sufficient to find the area, center of gravity, angle to major axis, and standard deviation along major and minor axes for an object, approximating the object as an ellipse. Second and higher order moments may be combined to form invariants which are used to characterize an object for purposes of discriminating among members of some set of objects.

The amount of time required to compute gray scale moments has hindered their use. On a VAX 11/780 with floating point accelerator, a direct calculation of the zero through second order moments of a 256*256 image takes 6.5 seconds.

The moment computation has been integrated onto a VLSI chip capable of computing a single zero through second order moment of a gray scale image in real time. Since there are six such moments, the moment processor module contains six chips. A number of techniques have been used to make the chip possible, which will be discussed below.

3.1.1 Power Vector Generation. We consider moment generation as a dot product:

$$M^{m,n} = \sum_t a_t p_t^{m,n} = (\bar{a}, \bar{p}^{m,n}) \qquad (2)$$

where the elements of the vectors are in the same order as a normal TV scan: $t = i + 256j$. The element $p_{i,j}$ of $\bar{p}$ will be referred to interchangably with p_{i+256j}.

The equation defining $\bar{p}^{m,n}$ is

$$p_{i,j}^{m,n} = i^m j^n. \qquad (3)$$

The element $p_t^{0,0}$ is one for all t. The first order moments require a counter for either x or y, depending on the moment. We can write the next value of each second order $\bar{p}$ as a function of the previous one, for example:

$$p_{i+1,j}^{2,0} = p_{i,j}^{2,0} + 2i + 1 \qquad (4)$$

with special cases for top of screen and left margin. We can build an iterative $\bar{p}$ generator composed of a single counter, a shifter, an adder, some "and" gates, and a small control programmable logic array (PLA).

3.1.2 Bit Decomposition. We can decompose $\bar{a}$ as

$$\bar{a} = 2^7 \bar{a}_7 + 2^6 \bar{a}_6 + \cdots + \bar{a}_0 \qquad (5)$$

If we substitute equation (5) into (2) and distribute, we obtain:

$$M^{m,n} = 2^7(\bar{a}_7, \bar{p}^{m,n}) + 2^6(\bar{a}_6, \bar{p}^{m,n}) + \cdots + (\bar{a}_0, \bar{p}^{m,n}) \qquad (6)$$

Computation of the dot products in Equation (6) requires only 1 by n bit multiplication, which may be implemented by n "and" gates, where n is the number of bits in $\bar{p}$.

At the end of each frame, we must compute

$$M^{m,n} = 2^7 F_7 + 2^6 F_6 + \cdots + F_0 \qquad (7)$$

where

$$F_k = (\bar{a}_k, \bar{p}^{m,n}) \qquad (8)$$

Equation (7) can be evaluated only once per frame (60 times per second) using Horner's Method of polynomial evaluation. The calculation is performed by the vision processor which controls the system.

The F_k accumulators are identical, simplifying the layout of the chip. The bitwise decomposition used to obtain fast operation also provides significant flexibility, making possible the computation of moments of different regions at the same time, for example.

3.1.3 Implementation. The techniques described above allow a moment generating I.C. to be constructed (Figure 4). The chip was designed using the MULGA symbolic layout system [12] in a 2.5 micron CMOS process and contains 10,214 transistors.

Six moment generator chips are placed on a Multi-Bus® (Intel) board with associated support logic. A preprocessor works independently on the intensity for each F_k bit, "and"-ing together an intensity map output and a location map output.

The intensity map converts intensity values to the desired precision and alignment. The map may implement binary thresholding, intensity windowing, non-linear response correction, or any combination of the above, for example. The intensity map may be used to correct for scene illumination

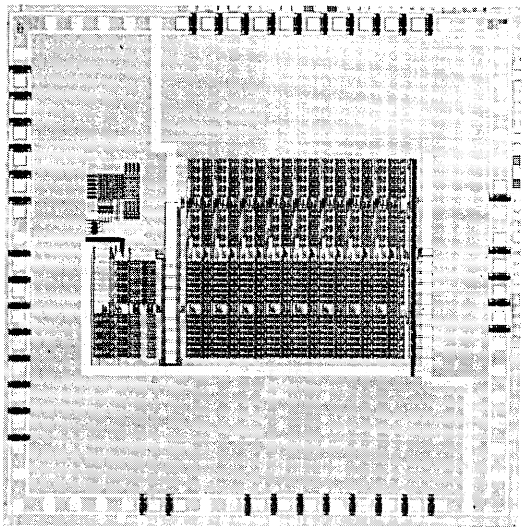

Figure 4. Moment generator chip.

problems or changes.

The location map defines the region of activity of each F_k; a bit is on if that F_k is to be activated at that position on the screen. To reduce the size of the location map, and simplify the host's job, regions are quantized into 8 by 8 pixel blocks.

Additional information on the chip design may be found in [2], and on its use in [3].

3.2 Three Dimensional Processing

Two moment generator systems are capable of processing the images from a pair of TV cameras at the full 60 Hz rate. Moments are a linear operator that commutes with other linear operators, so in theory, the moments of the background could simply be subtracted from the moments of the image, leaving the moments of the ball. In practice, noise from the camera and analog front end dominates the signal from the ball.

Instead, the intensity maps are used to separate object and background as follows. Intensities below a certain threshold are clipped to zero, saying in effect that anything sufficiently black should be ignored, in particular, various highlights off the backgrounds and supporting structures. On the other hand, any intensity above the threshold is considered as a gray scale value (relative the threshold). Importantly, this means that as the image of the ball is smeared towards black by the motion blur, the ball doesn't suddenly vanish, and the gray scale processing effects anti-aliasing, improving the numeric quality of the resulting centroids.

In the thus simplified scenes, once the vision processor has executed Equation 7 several times and performed

$$\bar{x} = \frac{M^{1,0}}{M^{0,0}} \qquad (9)$$

$$\bar{y} = \frac{M^{0,1}}{M^{0,0}}$$

the location of the centroid is known in each image. While the second order moments aren't needed to find the location of ping pong balls, it is interesting to notice that they contain information about the motion blur that can be recovered quantitatively.

Given that we have only a single object in the field of view, the standard problem of stereo vision, finding corresponding points in the two images, is eliminated. Since the orientation of the cameras is hard to control in practice, rather than a disparity based calculation, we represent each camera as a 4×3 matrix, and find the ball location by solving four equations (one for each coordinate of each camera) in three unknowns (x, y, z) using least squares. The calculation can be done in closed form in 3 msec on the 68000/SKY combination.

3.3 Experiment: Catching Balls

The three dimensional vision system and robot controller function, and have been used to conduct a preliminary experiment: catching a hand thrown ping pong ball in a styrofoam coffee cup. The system reliably caught balls on trajectories resulting in viable robot configurations. The program made no attempt to catch balls that were not catchable by its straightforward strategy. Work progresses on replacing the "user" robot program for catching with a much more sophisticated one for hitting the ball, but the other system components remain largely unchanged.

This initial experiment verified the operation of the vision system and robot controller, and served as an impetus for the analysis in the following sections.

4. LOW LEVEL EFFECTS OF TIME

As soon as the rate of change of the environment becomes comparable to the time constants of the components of the robotic system, we have to consider its effect on every part of the system, from sensor to processor to actuator. The next several subsections will detail these effects for each component.

4.1 Sensors

Unless the variables we are sensing are constant over time, any particular sensor output is meaningless unless associated with some particular time. The statement (sensor output) "the ball is 3 feet off the table" is useless, as it is inaccurate as soon as generated. Sensor values must be stamped with the time at which they are taken, as this defines the only time they have any validity.

Furthermore, the design of the sensor must be compatible with rapidly varying inputs, and able to define a precise timestamp for a given sensor reading. For example, sample and holds on the inputs to analog to digital converters prevent incorrect results from being generated, and the sample/hold's control input defines the sampling time very precisely.

Vision systems are no exception to the rule. TV cameras are designed for relatively slowly changing scenes. The electrical output of a camera is some complex function of the time varying light input over the time interval $(-\infty, now)$ depending on the type of camera.

For example, vidicons have a decay function such that the output at any time might be affected by some bright image many frames ago, in effect, the same as the persistence effects seen on CRT displays. Each point of the image is sampled at a different time as the beam sweeps over it, so a vertical bar moving horizontally generates pictures of a diagonal bar. This clearly makes the image interpretation process more complex.

On the other hand, CCD cameras operate as pipelined device, integrating one image while reading out the previous one.

There is no coupling from one image to the next, and no time varying response characteristics. Every pixel is effectively sampled at the same time. Because the electrical output due to a photon is not (strongly) dependent on the interval from its arrival to the end of the sampling interval, the center of gravity of a blurred image represents the average center of gravity during the sampling interval. For objects moving at essentially constant velocity over a sampling interval, we can assert that the object was at the center of gravity of the blurred image at the midpoint (center of gravity) of the sampling interval. The center of gravity is not affected by the motion blur from CCD cameras, so we can further assert that at the middle of the integrating interval of the frame, the object really was at the computed location. In addition to their better accuracy versus vidicons, this is another good reason for using CCD cameras (which we do).

4.2 Actuators

The primary question with actuators is understanding just what the temporal component of a command signal is. For example, consider a simple binary output to close a gripper. The semantics of this signal have an implied "now" component: close it **now**! However, from a planning perspective, for example a program trying to minimize robot cycle time, these semantics are unhelpful, as the gripper may in fact take forever to close. A conservative designer in a discrete time architecture might even put in a microswitch that says "the hand is now closed," which may ensure that the system works, but does nothing to help planning.

What we really would like to be able to assert is that after a certain period of time, a certain state will result. In the gripper example, this means we should be able to assert that after 50 msec perhaps, the gripper will be closed. By making this additional piece of information available to the system, we make possible additional optimizations such as starting to close the gripper before the manipulator has arrived at the part.

Of course, adding more arbitrary time constants to a system isn't desirable, which indicates the utility of systems modeling: we need to have good models of our actuators, whether they are binary actuators or whole manipulators. The gripper-closed limit switch is an aid to making models.

When applied to servo systems, the control signals may similarly be given temporal characteristics, one common example being the position waypoint to which a servo is trying to position the joint. In our system the semantics of the waypoint from the trajectory generator to the servo is that the servo should position the joint at the specified position at exactly the start of the next major cycle, when the next waypoint is specified.

In order for the servo system to be successful at convincing the joint to arrive at the specified destination at the specified time, various perturbing torques must be compensated. The output torque which must be generated to make an action occur must be supplied by the terms found in the servo equation of the joint. If the torque actually required by the manipulator differs from that computed by the servo function with no errors, the torque discrepancy must be "made up" by terms that are present, generally by a position or velocity error as the joint is moving. For example, the velocity damping necessary for stability will cause steady steady state position errors (lags) unless the desired velocity is fed forward into the servo equation [10]. Similar effects arise due to acceleration, friction, gravity, and inertial couplings between joints. Integrators can help, but only under quasi-static conditions, and make performance worse in rapidly changing conditions.

To summarize the section, we must add temporal semantics to the control signals sent to actuators, and we should develop good models of the system's response to the control signals. The better the models we have, the better the system performance.

4.3 Processing

Software events are not dependable in a multiprogramming environment because they are subject to the vagaries of the scheduling of device interrupts, the execution of higher priority tasks, and refresh interrupts. Newer processors are subject to additional factors such as instruction and memory management cache hits which are variable depending on previous events. Accordingly, we can't count on the processor performing the same repetitive action at the same relative time. Events can be well defined only by the hardware, not by software.

The imprecision of software controlled events suggests that we should be careful to build robot peripheral devices such that the application of control signals or latching of sensor readings is performed by hardware clocks, rather than under software control. Rather than having an interrupt request the program to directly read a value, we should have the interrupt latch the value into a register, which is then read by the program. Likewise, outputs should be latched by the peripheral devices under software control, but not applied to the actuators until the next hardware servo clock. As well as protecting against other competitors for CPU cycles, an additional level of latching isolates data dependencies in the control algorithm timing (we may even use different algorithms at different times) from affecting actuator timing. This amounts to pipelining the system. The slight additional cost of a register is compensated by the gain in repeatability of timing. Our robot controller is pipelined both at the major cycle rate and at the minor cycle rate.

The processing system also has significant latencies which must be taken into account. At some point in time, the software must commit to generating a control signal for some specific time. For example, consider changing the target of a robot motion while the arm is moving. To obtain a smooth trajectory, the preliminary setup calculations used to drive the trajectory interpolation must be evaluated based on some assumed initial position and time in the future. The program must know its execution time from the commit point to actually generating the control signal. This time should be minimized to reduce the number of potential interferences.

Once again, the more the program "knows," the better its performance. If the processing can be broken into two sections, an invariant portion that doesn't depend on the time varying variables and can be done first, and a second (minimal) section which does require this information, the program can obtain a timestamp at the completion of the first section reflecting the actual prevailing conditions. This time varying code can make the system hard to debug, but eliminates stored latency times, which must be conservative and tend to become outdated.

A sufficiently well controlled program may also be able to predict that the processor will be occupied by an interrupt for a certain time, and be able to compensate its own latency estimate accordingly. Clock driven interrupt processes can easily be predicted based on the time of their last occurrence and frequency.

4.4 The 'Clox' Board

We need to make accurate timing information available to the processor. Even though most microprocessor systems have free running timers (clocks) that are readable by software (often with substantial overhead), they are not useful for timestamping sensor or actuator data. The presence of software in the measurement path guarantees inaccuracy, because the processor may execute a fairly arbitrary sequence of instructions between the time of occurrence of the event and the time the software reads the timer.

In a real robotic system like ours for ping-pong, the sensors and actuators are distributed across multiple processors. Humans have trouble getting to meetings at the same time because we all have wristwatches with a different time (though this isn't the only factor at work). Likewise, in a distributed microprocessor system each processor has its own time, and times from different processors are not comparable. What we need to maintain a consistent view of time across the system is a "wall clock" accessible to all processors at once.

We implement the wall clock with a specialized "clox" board that resides in each processor, and a specialized clock bus connecting them. A wall clock must have the same value at each instant to each processor on a network. At first glance, this may seem to require that the clox boards be connected by a large number of wires, one for each bit. Since a clock has only two degrees of freedom, only two signals are actually required: one to specify the rate, and one to specify the offset. The simplest implementation uses one wire to carry an actual 1 Mhz hardware clock (square wave), and another to carry pulses one clock long to effect synchronization. One board is selected to generate the clock signal for all of the boards. Its clock frequency may be externally calibrated to ensure that the absolute accuracy is commensurate with the resolution. We are implementing the wall clock by a network of synchronized wristwatches.

Each processor must have a way of determining the occurrence times of events in devices attached to it. In general, this would require that a wire be attached to some suitable signal in the device and to the clox board, but this isn't particularly convenient. As an implementation technique, we can instead monitor activity on the processor's interrupt lines, which are generally driven directly from the same hardware signals we need to monitor. This has the advantage of not requiring odd wires jumping around between boards. An interrupt line must be dedicated to each signal the clock board is to be used to monitor. An event register latches the time of occurrence of the interrupt transition for subsequent reading by the processor when it handles the interrupt.

The clox board contains a software readable clock register which may be used by programs for time variant decision making. In addition, it is useful to be able to obtain software event times for diagnostic purposes: how long does this routine take on average? at most? Because of the simplicity of the access protocol, we need not call it via an operating system trap. The low cost of access means that we may routinely track execution times.

A novel consequence of having a "wall clock" is that software event occurrence times may be compared across processors, directly measuring software latencies across the network, for example. Such numbers may be obtained even for rare single shot situations. A simple example measures the latencies of a processor to processor write. Processor A executes:

```
timel = now ();
write (channel, buffer, count);
time2 = now ();
```

and processor B executes:

```
time3 = now ();
read (channel, buffer, count);
time4 = now ();
```

where **now** is a macro that gets the current time. By examining the times 1-4, we can easily determine: the execution time of the write, the execution time of the read, whether the read or the write began first, and most importantly, the time from when processor A started sending the data to the time processor B had it and could perform further processing.

5. TOWARDS A SENSE OF TIME

In the previous sections, we have taken a detailed look at the microscopic treatment of time. In this section, we'd like to take a broader look at the overall implications and trends.

5.1 Knowledge of Manipulator Capabilities

A recurring theme was the need for the system to know more information about itself: sensor characteristics, actuation delays, processing latencies. The same need is present in higher levels of the system, not only for timing related information, but general knowledge about robot capabilities as well.

Present robot controllers are sadly ignorant of their own capabilities in the temporal sense. Most controllers can compute that they can move to certain position, but not be able to specify the time required to do so, or be able to make the motion occur in a prespecified length of time. The former capability is necessary to evaluate alternative motions or plan intercepts with moving objects, the latter to be able to execute them.

We have these capabilities in our system, but only in a crude sense, treating each joint as decoupled and with only a rough joint performance figure. For maximum accuracy and thus performance, we need to be able to model the robot dynamics, including actual actuator torques, inertias, and couplings. As the specification of the motion becomes more complex, such as straight line motion or a series of continuous motions, it becomes more and more difficult to predict the motion time without actually executing it, at least in simulation.

5.2 Continuous Sensor Integration

New data can be generated by sensors like the moment generator at a 60 Hz rate. If we evaluate each data point independently, we suffer the expense of generating an entirely new plan for each data point, and the risk that the series of plans may be incompatible with one another. A better approach is to evaluate new data in the context of the old.

The processing time required to generate an initial plan is almost certainly much greater than the time required to fine tune an existing one. In robot ping pong, the initial plan requires selecting the desired return, appropriate robot configuration, and a series of trajectory segments. As new data on the ball trajectory becomes available, tuning a few details may suffice to update the plan.

On the other hand, when a sudden discontinuity in input data occurs, for example, after a ball bounces with a lot of spin, we must take a drastically different action. Rather than picking a totally new plan, we should operate within the confines of actions we have already taken, as the arm will be in motion, and this constrains the possible destinations. The decision criteria for making a switch in overall plan should be expressed in terms of the actions, not the input data, so that we avoid needless thrashing.

The process of understanding new data in the context of the old and making incremental refinements in the planned actions seems much more similar to a human's continual perception of time than the discrete time approach of robot controllers.

The work described in the section is still in progress, and is being driven by the observed needs of the task. The natural requirement for self-knowledge, especially about processing capabilities, is an interesting development which bears further observation. As the tasks get more complicated, the amount of self-knowledge must increase. Perhaps this is a step (albeit a small one) in the direction of machine self-awareness.

6. CONCLUSIONS

As we improve robot performance and increase the complexity of robot tasks, we will need to change the way we think about robots from an event driven perspective to a continuous time model. The development of real time sensor systems is accelerating the trend. We can start now by paying careful attention to the sources of timing related effects. Ultimately, robot systems will have to be able to understand the dynamic nature of the world they live in.

7. ACKNOWLEDGEMENTS

Robotics is a multi-disciplinary field; I've been fortunate to be able to stand on the projects of many other researchers. Thanks to Bob Gaglianello and Howard Katseff for Meglos, and Brian Ackland and Neil Weste for MULGA. Thanks also to John Jarvis for helping all this take place, and Richard Paul for letting me tap his formidable experience. Special thanks to Richard Seide and George Whyte for admirable work as construction crew.

CMU Sidewalk Navigation System:

A Blackboard-Based Outdoor Navigation System

Using Sensor Fusion with Colored-Range Images

Y. Goto, K. Matsuzaki

Robotics Institute, Carnegie-Mellon University
Pittsburg, PA. 15213

Abstract

We describe the CMU Sidewalk Navigation System, which can drive a vehicle in the outdoor environment of the CMU campus. The system includes all modules necessary for outdoor navigation -- modules for route planning, local path planning, vehicle driving, perception, and map data. The perception module uses sensor fusion with color and rage data to analyze complex outdoor scenes accurately and efficiently.

1. Introduction

The goal of the CMU SCVision group is to create an autonomous mobile robot system capable of operating in outdoor environments.[1] The complexity of the environment requires the system to have a powerful perception ability, capable of analyzing natural objects, and a planning ability which can work in non-uniform conditions. Because this navigation system will be very large, we need mechanisms to combine programs into whole systems and mechanisms for parallelism in computation.

We already have several systems towards the goal: a road following system with color classification [5], road network navigation with a simple map [1], scene analysis with a laser range sensor [2], and the blackboard [4].

The CMU Sidewalk Navigation System is a milestone system toward our goal. In this system, we focus on two points. The first is to build a whole system based on a good system architecture so that the system is both complete (containing every necessary module) and efficient. We achieve that goal by adopting a blackboard-based architecture. The second point is to create perception modules with sensor fusion that work well in our outdoor environment.

The test site for the CMU Sidewalk Navigation System is the CMU campus, containing a network of sidewalks and intersections, along with grass, slopes, and stairs. The system can drive the vehicle through these objects to get to its destination.

2. System Architecture for the Outdoor Navigation System

2.1. Hardware Configuration

The hardware for the CMU sidewalk navigation system consists of three SUN-3 workstations, the vehicle, the color TV camera, and the laser range sensor. The workstations are linked together with Ethernet, and the workstations and the vehicle are linked with radio communication. Figure 1 shows the vehicle called *Terregator.*

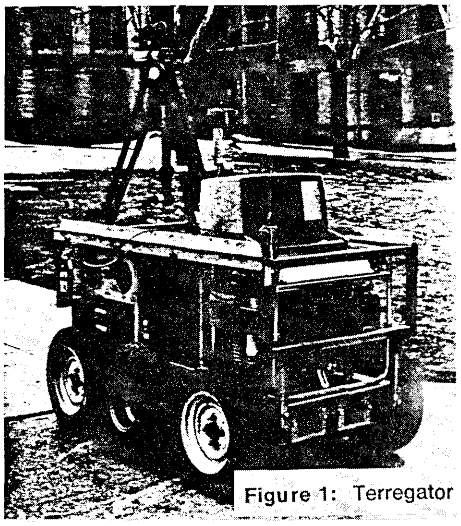

Figure 1: Terregator

2.2. System Architecture

2.2.1. Stages of Navigation

In order to create a reasonable system architecture, we have to start by analyzing outdoor navigation.

If the navigation system uses only one uniform navigation mode, the system architecture issue is not essential. But, in general, outdoor navigation includes several navigation modes. The example shown in Figure 2 illustrates this situation. The vehicle running from the starting point to the destination has to *follow the road*, *turn at the intersection*, *climbing the slope* and *cross the terrain*. *Turning at the intersection* needs a more complex method to drive the vehicle than *following the road*. Perception for *crossing the terrain* is different from perception for *turning at the intersection*. In *following the road* we can use assumption that the ground is flat, which makes perception easier. But *climbing the slope* does not satisfy this assumption. This is one reason why the

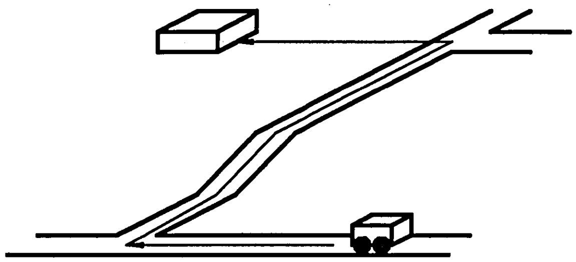

Figure 2: Outdoor Navigation

outdoor navigation system needs good system architecture.

We decompose navigation into two processing stages. The first stage is the *route planning stage*, and the second stage is *local navigation*. In the route planning stage the system selects the best navigation route, from several possible routes to get to the destination from the starting point. The system divides the whole route into a sequence of *route segments*. In each route segment, objects on which the vehicle can run are constant. The navigation system can drive the vehicle using a single uniform driving mode, for example, *following the road* or *turning at the intersection*, and a single perception mode. In this stage, using the map data is essential.

Local navigation is navigation within one route segment. In the local navigation stage, the navigation mode is constant and the main task is to drive the vehicle along the route segment. Local navigation uses perception to find a safe passage for the vehicle, and to determine the actual vehicle driving path.

In contrast, our earlier and simpler navigation system did not have the route planning capability and has only one navigation mode for local navigation.

The system architecture of the CMU sidewalk navigation system is indicated in Figure 3. We decomposed the whole system into several modules. The modules indicated with blocks are separate processes, running independently, and communicating with each other through the BLACKBOARD. In selecting this decomposition of the whole system into these modules, we followed the principle of *information hiding*. The CAPTAIN module and the MAP NAVIGATOR module are responsible for the route planning, and they do not know the result of perception or how to drive the physical vehicle. The PILOT module, the PERCEPTION module and the HELM module are responsible for the local navigation, and they do not know the destination, the whole route, or the sequence of route segments. What they know is limited to only one route segment at one time. We will explain the system architecture in detail in the following sections.

2.2.2. The Blackboard-Based Architecture

Our BLACKBOARD provides modules with communication and synchronization facilities [4]. Using a blackboard-based architecture brings two main advantages to building our navigation system.

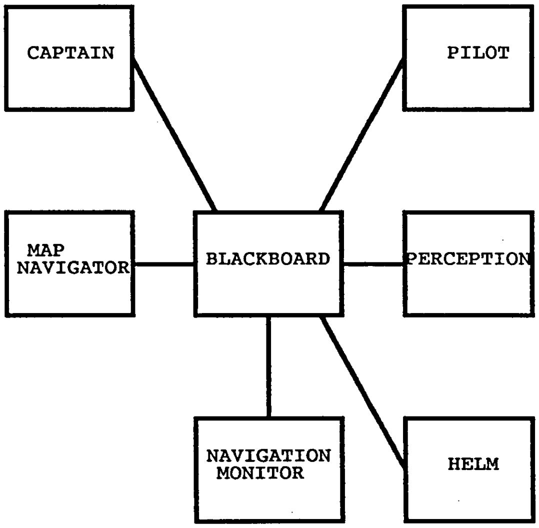

Figure 3: System Architecture

The first advantage is parallelism in execution. We decompose the whole system into several parallel modules. Because the most time consuming operation is perception, it is an independent process, the PERCEPTION module, running on its own machine, and not disturbing other modules. Because the HELM module which drives the physical vehicle needs real-time response, it is another separate process. Communication and synchronization of all modules are handled by mechanisms of the BLACKBOARD.

The second advantage is that using a blackboard makes it easier to combine several programs into a whole system. Our BLACKBOARD provides a good mechanism to connect modules, and limits the interactions among modules. For instance, each module can work in its most natural and convenient coordinate frame, with the BLACKBOARD converting among reference frames. We use the principle of *information hiding* so that the interfaces between modules are small. This keeps communication costs low and allows good modularity. The details of the BLACKBOARD are explained in following sections.

2.3. Module Structure

In this subsection we explain each module.

2.3.1. The CAPTAIN Module and the Mission

At the upper level of the system is the *CAPTAIN* module that receives instructions from the controlling person and oversees the mission. The mission consists of a number of steps, and the CAPTAIN sequences through the steps. For each step, there is a *destination* that tells where to go and one or more *constraints* that tell how to go. For example, "go to intersection D" gives a destination and "keep right" gives a constraint. Each mission step also has a *trigger* condition and an action which will be executed if the trigger condition is satisfied. Triggers can be used to move on to the next mission step when one step is completed.

The CAPTAIN sends the destination and the constraints of each mission step to the MAP NAVIGATOR one step at a time, and gets the result of mission step, *success* or *fail*, from the MAP NAVIGATOR.

2.3.2. The MAP NAVIGATOR and Route Planning

The MAP NAVIGATOR does the route planning based on a destination and a constraint sent from the CAPTAIN, gives the PILOT directions for driving along the route, and reports the result of the mission to the CAPTAIN.

The MAP NAVIGATOR contains two main parts, the ROUTE SELECTOR, and the ROUTE SEGMENT DESCRIBER (see Figure 4). The ROUTE SELECTOR creates the route plan, and decomposes it to a sequence of the route segments so that each route segment has only one *navigation mode*. The current system has several navigation modes: *follow-road*, *turn-at-intersection*, *go-through-intersection*, and *go-through-slope*. Our future system will have another navigation mode, *cross-country*, in order to navigate on open terrain.

The ROUTE SEGMENT DESCRIBER generates the description of the route segment. The purpose of *route segment description* is to provide the PILOT with the information necessary for navigation within the route segment. It includes path objects (e.g., pieces of road, intersections), navigation modes, the conditions to exit from the route segment, the constraints to drive the vehicle, and object descriptions. *Path objects* are the objects on which the vehicle should run. *Object descriptions* describe the location and the shape of the objects (such as landmarks) which the PERCEPTION module can see while running on the route segment. This description is created by copying a part of the Map data, and is used as a prediction for the PERCEPTION module. One important point is that only the MAP NAVIGATOR maintains the Map data.

The route segment description is sent to the BLACKBOARD and forwarded to the PILOT. When the PILOT finishes the route segment, it reports the result. If the result is *success*, the ROUTE SEGMENT DESCRIBER sends next route segment description.

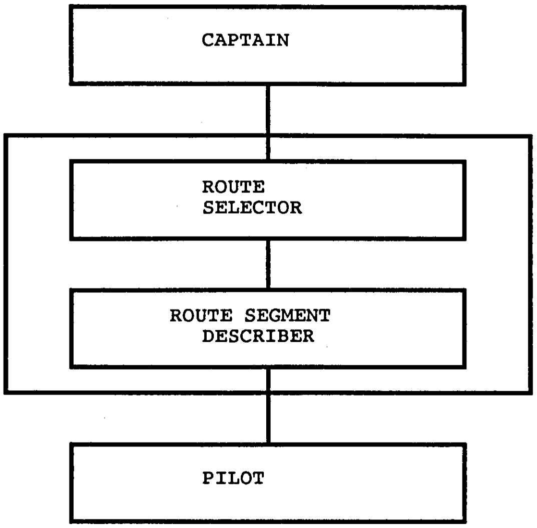

Figure 4: The MAP NAVIGATOR Module

2.3.3. The PILOT and Local Path Planning

The PILOT, the PERCEPTION and the HELM work together for local navigation. The PILOT operates continuously to conduct the navigation within the route segment. The PILOT contains several sub-modules that form a sequence as shown in Figure 5, to process each area to be traversed.

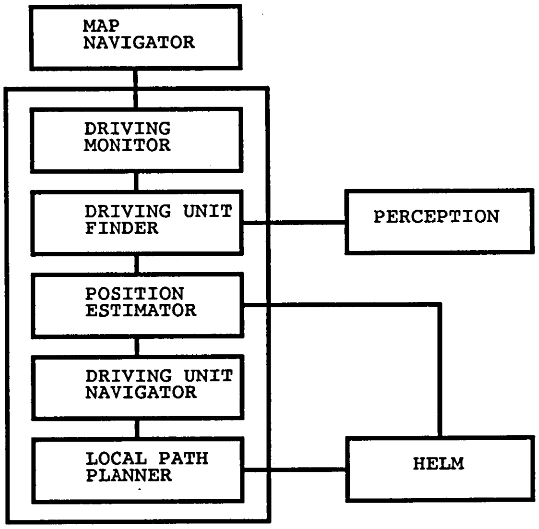

Figure 5: The PILOT module

The DRIVING MONITOR, the top level of the PILOT, receives route segment descriptions whenever a newly created route segment appears in the BLACKBOARD. The DRIVING MONITOR breaks the route segment into pieces called *driving units*, so that the PERCEPTION can detect one driving unit separately (see Figure 6). The DRIVING MONITOR builds a *driving unit description* for each driving unit, describing the location of the driving unit and the objects which PERCEPTION should see. Following the principle of information hiding, the driving unit description tells where and what objects the PERCEPTION should see, but it does not tell how to detect them.

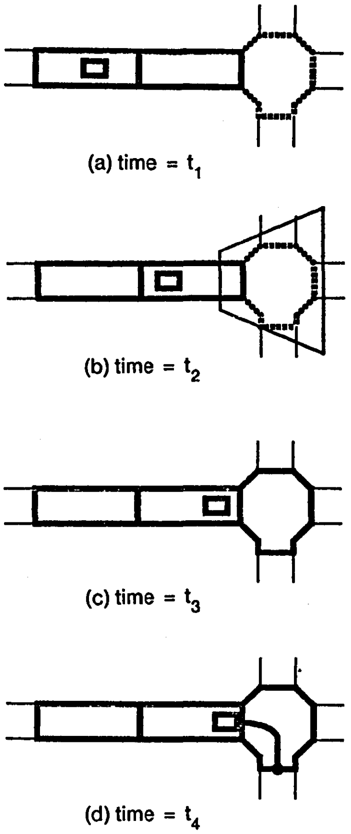
The DRIVING UNIT FINDER works as an interface to the PERCEPTION, getting the newly created driving unit description from the DRIVING MONITOR and sending it to the PERCEPTION through the BLACKBOARD. If the result of perception is written in the driving unit description in the BLACKBOARD, the DRIVING UNIT FINDER retrieves it into the PILOT.

The POSITION ESTIMATOR determines the vehicle position using position estimations generated both by perception and by dead reckoning. When PERCEPTION sees objects which can be landmarks, PERCEPTION can estimate the vehicle position using predicted object locations and shapes. For example, stairs and intersections are good landmarks. Sidewalks are not sufficient as a landmark, because PERCEPTION looking at only a sidewalk cannot tell the location along a sidewalk. It can tell only the distance from the edge of a sidewalk. Therefore, the position estimation by the PERCEPTION is sometimes complete and sometimes is not complete. The position estimation by dead reckoning is given by the HELM. The POSITION ESTIMATOR combines both of them and determines the vehicle position.

The BLACKBOARD stores two kinds of vehicle positions. One is *perceived vehicle position*, and the other one is *moving vehicle position*. Because the perceived vehicle position is estimated by only the POSITION ESTIMATOR once per driving unit, it is discrete. On the other hand, the moving vehicle position is estimated by not only the POSITION ESTIMATOR but also the HELM using dead reckoning. Because the HELM updates the moving vehicle position frequently, it tells the vehicle current position. Because both positions are stored in the BLACKBOARD, all modules can use them. Currently they are used by the PERCEPTION and the LOCAL PATH PLANNER.

The DRIVING UNIT NAVIGATOR plots *local path constraints* in the driving unit using the result of perception and the driving constraints given by the MAP NAVIGATOR.

The LOCAL PATH PLANNER gets the local path constraints and creates the *local path plan* from the vehicle's current position, through all intervening driving units, reaching to the far edge of the newly scanned driving unit. Because the vehicle is not in the newly scanned driving unit, the LOCAL PATH PLANNER keeps the old local path constraints to calculate local path plan, and discards them if they are not necessary. The algorithm for local path planning is based on Lozano-Perez's method [3]. This method generates a sequence of line segments, which the LOCAL PATH PLANNER converts to a smooth path. Therefore, the vehicle turns along a curved line. The generated local path plan is passed to the HELM through the BLACKBOARD.



(a) time = t_1

(b) time = t_2

(c) time = t_3

(d) time = t_4

Figure 6: Process Sequence in the PILOT

Figure 6 illustrates the process sequence in the PILOT. The black painted box is the vehicle. The bold line indicates the driving unit detected by the PERCEPTION already. The dotted line shows the driving unit newly created by the DRIVING MONITOR. At time t_1 the DRIVING MONITOR creates new driving unit description and sends it to the DRIVING UNIT FINDER. The DRIVING UNIT FINDER sends it to the PERCEPTION. When the vehicle reachs the best place to detect the required driving unit, the PERCEPTION inputs image data with the sensors (time t_2). The thin line shows the sensor view frame. At time t_3, the PERCEPTION finishes processing and reports the object shapes and the vehicle position. The DRIVING MONITOR starts creating next driving unit description. And at time t_4 the LOCAL PATH PLANNER generates new local path plan and passes to the HELM.

2.3.4. The HELM and Driving the Vehicle

Whenever a new local path plan appears in the BLACKBOARD, the HELM discards the old path plan and picks up new one. The HELM converts the local path plan, which tells only trajectory, into vehicle driving commands, and feeds them to the vehicle. In addition to driving the vehicle, the HELM is responsible for maintaining the *vehicle moving position* stored in the BLACKBOARD. Because the task of the HELM needs quick response to control the vehicle, it is implemented as an independent process.

2.3.5. The PERCEPTION Module

PERCEPTION picks up a driving unit description from the BLACKBOARD when a new one appears. PERCEPTION has two tasks: detecting navigable passages, and, if possible, estimating vehicle position. The details of PERCEPTION are explained in the next section.

2.3.6. The BLACKBOARD

The BLACKBOARD provides the modules with facitilies for communication and data management. Our BLACKBOARD looks like a traditional blackboard, with several additional properties that make it useful for navigation:

1. **parallel asynchronous execution of modules.** This property makes it possible to execute all modules in parallel.
2. **transparent networking between processors.** This property makes it easier to build interfaces between modules.
3. **no pre-compilation of data retrieval specification.** This property makes it easier to pick up desired data from the BLACKBOARD.
4. **geometric reasoning.** Coordinate transformation and geometric calculations are done by the BLACKBOARD. Data retrieval from the BLACKBOARD with geometry is used in several places.

2.3.7. The MAP

The MAP is the main data base in our navigation system. It consists of two parts, GEOGRAPHICAL MAP and OBJECT DATA BASE.

The GEOGRAPHICAL MAP is similar to usual maps which we use in daily life, and tells object locations with their outlines. The MAP NAVIGATOR uses the GEOGRAPHICAL MAP to pick up objects belonging to the route segment. Figure 7 shows current GEOGRAPHICAL MAP.

The OBJECT DATA BASE stores the object descriptions.

1. **Perception Feature:** Both of the object's three dimensional shape and its color are stored to produce object description for the PERCEPTION. Three dimensional shape is expressed with surfaces.
2. **Role in Navigation:** Some objects can be landmarks, and other objects can be paths. Therefore, the OBJECT DATA BASE indicates roles of objects: *landmark*, *path*, *obstacle* and *no meaning*. Also, navigation costs on objects are stored. These data are useful when the MAP NAVIGATOR performs route planning.

The MAP is stored in the BLACKBOARD and accessed only by the MAP NAVIGATOR. Currently we assume that the MAP has all necessary information and it is correct and complete. But our future work will include "map revising", starting with an incomplete map, and updating it during navigation.

(b) stairs and slope

Figure 7: The GEOGRAPHICAL MAP

2.3.8. The NAVIGATION MONITOR

The NAVIGATION MONITOR is a graphics system which displays the current navigation situation. It displays the route segment, the driving unit, the sensor view frame, the vehicle position, and the local path plan. Because the NAVIGATION MONITOR is implemented as an independent process, it does not disturb other modules. Whenever the data to be displayed appear on the BLACKBOARD, the NAVIGATION MONITOR retrieves and displays them.

3. Perception Using Colored-Range Image

3.1. Requirements and Approach

The basic problem for the perception is caused by the complexity of outdoor scenes. Some objects have very complicated shapes and colors from which it is difficult to extract surfaces or edges. This requires powerful sensors and algorithms for object detection. Also, the processing time of the perception is critical, because it eventually constrains vehicle speed. Even if we have a very powerful perception program which can detect complicated objects, it will be computationally expensive. Therefore, having a *single* powerful object detection program is not an adequate solution.

To overcome these difficulties, we take a sensor fusion approach. There are several types of sensor fusion methods [4]. This PERCEPTION module uses two types of sensor fusion.

The first type is low level sensor fusion, doing segmentation using color and range data simultaneously. We call the image which has color information in addition to range values a *colored-range* image. Using this method, we can segment objects with uniform color but varying surface orientation, as well as objects with smooth surfaces and varying colors. This method is used to analyze complicated scenes.

The second type of fusion is a higher level sensor fusion or sensor selection. The PERCEPTION module has both a *colored-range* segmentation program, mentioned above, and a color segmentation program, and uses these programs selectively. The former program can extract segments in complicated scenes, while the later program is adequate for simple flat scenes and uses much less processing time. This type of sensor fusion achieves both powerful perceptual ability and fast processing.

3.2. PERCEPTION Module Architecture for Sensor Fusion

The PERCEPTION receives perceptual requests from the PILOT, and analyzes sensor data to compute its response. The main effort to design the PERCEPTION module is how to combine several types of sensors and sensor data processing modules into one system and make them work efficiently. We designed a hierarchical structure and a monitor module which manages all parts of the hierarchy.

Figure 8 illustrates the structure of the PERCEPTION module. This is composed of the PATCH MAKER, the OBJECT FINDER, the POSITION CALIBRATOR, and the PERCEPTION MONITOR. Sensor data go through in the order of the PATCH MAKER, the OBJECT FINDER, and the POSITION CALIBRATOR.

The data interface between each module is designed to be independent of the algorithms used by each module. This allows each layer in the hierarchy to have several modules based on different algorithms. In the current system, the PATCH MAKER includes two types of segmentation modules, and one object finding module can work on the results of both segmentation modules because of the common data interface. The PERCEPTION MONITOR is a key for this hierarchical processing. We describe it in detail in the next section. Other modules are explained in following paragraphs.

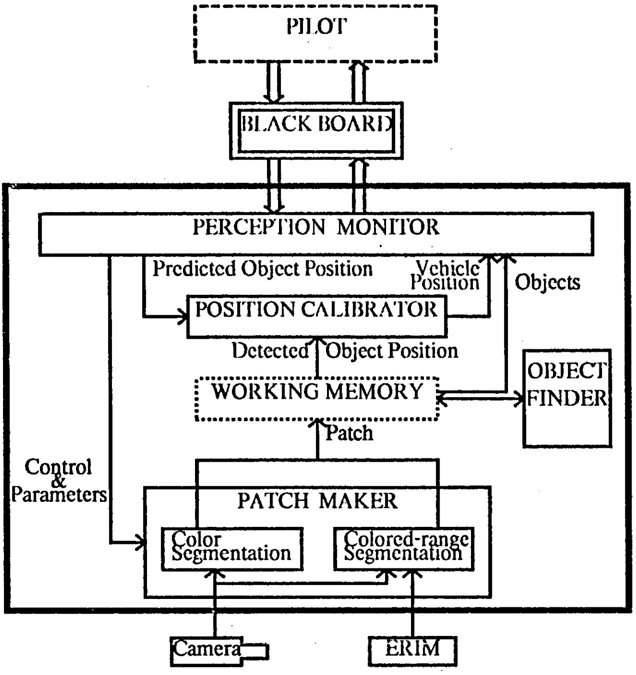

Figure 8: Structure of PERCEPTION Module

3.2.1. The PATCH MAKER

As a segmentation module (PATCH MAKER), this system has a color segmentation module, a range segmentation module, and a *colored-range* segmentation module. The color segmentation, the range image segmentation, and *colored-range* image segmentation are described in Section 3.4.

The data structure which holds patch data is common to both segmentation modules. These data include *color type*, *surface type and normal*, *polygons for boundary shape*, and *relation to neighbor segments*.

3.2.2. The OBJECT FINDER

The OBJECT FINDER identifies each segment as a part of a predicted object. This algorithm is described in rule-base style, with two kinds of rules. One kind identifies detected segments as parts of predicted objects, and the other type of rule finds the actual correspondence between perceived and predicted polygons. In other words, the first set of rules deals with symbolic matching, while the second knows about detailed geometry.

The OBJECT FINDER uses a WORKING MEMORY. The PATCH MAKER assigns the Patch data into the WORKING MEMORY. Also, the PERCEPTION MONITOR assigns predicted object shape and feature data into the WORKING MEMORY. These data include color, surface type, and shape. The OBJECT FINDER uses WORKING MEMORY data to match predicted with detected data.

3.2.3. The POSITION CALIBRATOR

The predicted objects are described in the current coordinate system, but the vehicle coordinate system is used to describe the detected objects. The POSITION CALIBRATOR then computes the vehicle position in the current coordinate system, applying the transformation matrix between two coordinate systems. The problem for this computation is that the predicted object shape and the detected object shape are not same because of imperfections in the MAP and the perception. Therefore, the POSITION CALIBRATOR has to find the most appropriate matching for these two shapes.

To get the best matching point, the POSITION CALIBRATOR calculates the distance between the predicted vertices and the detected vertices of object polygons, and finds the position which minimizes the distance. Sometimes, a scene is composed of only parallel lines (e.g., *sidewalk*) or a point (e.g., *tree*), which are insufficient to decide a matching point. In this case, the POSITION CALIBRATOR derives a line equation on which the vehicle is located instead of a point for vehicle position.

3.3. The PERCEPTION MONITOR

The PERCEPTION MONITOR has two major roles: communication with other modules (the PILOT) and control of internal submodules. As mentioned before, a design principle of this system is to provide a common structure for different sensors and algorithms. This tends to make the module interface rather high level. For example, an image input position is usually decided by an external module using sensor parameters. However, if there are several types of sensors with different view angles, the common interface for those modules will be ***where the PERCEPTION should see*** instead of ***where the PERCEPTION should look from***. This means the PERCEPTION module itself has to decide where the best position is from which to see the requested place. The communication with other modules means doing such kinds of interpretation between the high level module interface commands and actual commands to internal submodules.

Control flow of the perception process is rather simple. It progresses in order of segmentation, object finding, and position calibration. The PERCEPTION MONITOR activates the PATCH MAKER, the OBJECT FINDER, and the POSITION CALIBRATOR in this sequence. The functions for the interpretation of the high level commands from the other planning module (the PILOT) are described in following paragraphs.

3.3.1. Selection of Sensor and Segmentation Modules

The PILOT requests what objects to see, but does not say which sensor should be used. The PERCEPTION MONITOR decides which sensor and segmentation module is the best for the requested objects. The current system has two sensors and segmentation modules. If all requested objects are *sidewalks* or *intersections* on a flat plane, the PERCEPTION MONITOR selects the color segmentation module as a PATCH MAKER. If three-dimensional objects such as stairs, and slopes are included in the requested objects, the PERCEPTION MONITOR selects the *colored-range* segmentation module.

3.3.2. Decision of View Frame and Resolution

The PILOT requests to see objects as quickly as possible within a tolerable error allowance, but does not specify the resolution or view frame of PERCEPTION. The view frame of PERCEPTION depends on a tolerable error allowance for the PERCEPTION. If the error allowance is small, a meaningful view frame will be limited to near the vehicle, even if the view angle of the sensor covers a greater area. Also, the view frame is a function of PERCEPTION resolution. If the resolution is very fine, the view frame can be wider, keeping the same error allowance.

An interesting point is that the processing time of the PERCEPTION is a function of the resolution. Therefore there are two typical strategies for equal error allowance. One is a seeing a closer area with rough resolution in a short time. The other is a seeing a farther area with fine resolution in a longer time. The PERCEPTION MONITOR decides the optimal view frame and the resolution which allows the vehicle to run at maximum speed.

Figure 9 shows the relation between the velocity (V) and the distance the vehicle can run in one cycle (perception distance, D) for several error allowances. We got this result from two relations: the relation of resolution and the maximum perception distance for equal error allowance, and the relation of the resolution and the processing time (T). Velocity is defined as $V=D/T$.

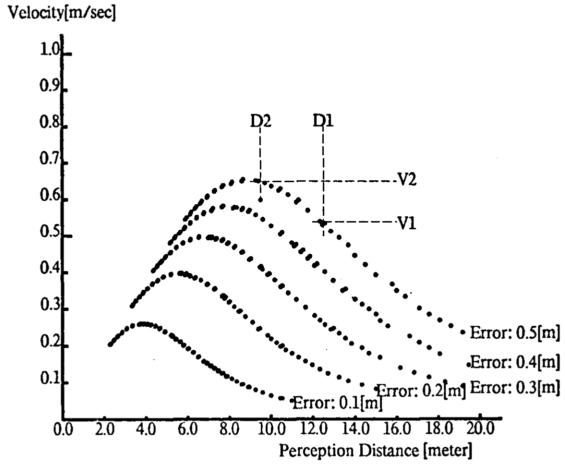

Figure 9: Distance and Velocity by Error Allowance

It is interesting to note that Figure 9 indicates that the maximum speed point of our system is at a rather short distance and low resolution. When the vehicle runs at a speed of V_1, the best perception distance and resolution is at D_1. This is because the PERCEPTION can see the widest area at that point. This increases the chance of finding landmarks or obstacles. Then, if the vehicle trys to run faster (at speed of V_2), the perception distance becomes shorter (D_2). This shows that as speed increases, the vehicle becomes short-sighted.

The PERCEPTION MONITOR has a data table in which are stored the values of optimal resolution and perception distance for the error allowance. Using this table, the PERCEPTION MONITOR provides the optimal resolution and perception distance.

3.3.3. Decision of Image Input Position

The PILOT indicates which region the PERCEPTION should see, but does not indicate when the PERCEPTION should see it. This is because the view frame of the PERCEPTION depends on the sensor used, and the PILOT does not know which sensor will be used. Furthermore, when the PERCEPTION uses a pan and tilt mechanism, only the PERCEPTION can decide image input timing and position.

The position decision algorithm has two steps. First, this module simulates the view frame and the vehicle's future path which is posted in the BLACKBOARD by the LOCAL PATH PLANNER. When the simulated view frame covers the region which the PILOT has requested the PERCEPTION to see, this vehicle position is defined as the image input position. Second, this module monitors current vehicle position by watching the moving vehicle position on the BLACKBOARD. And, when the moving vehicle position reaches the image input position, this module controls sensors to take an image.

3.3.4. Creation of Segmentation Parameters

To have good segmentation results, we need not only appropriate segmentation parameters, but also good algorithms. It is very difficult to know appropriate parameters unless PERCEPTION has scene knowledge. In this system, the PILOT predicts objects for the PERCEPTION, but the description is general and does not indicate segmentation parameters for the objects.

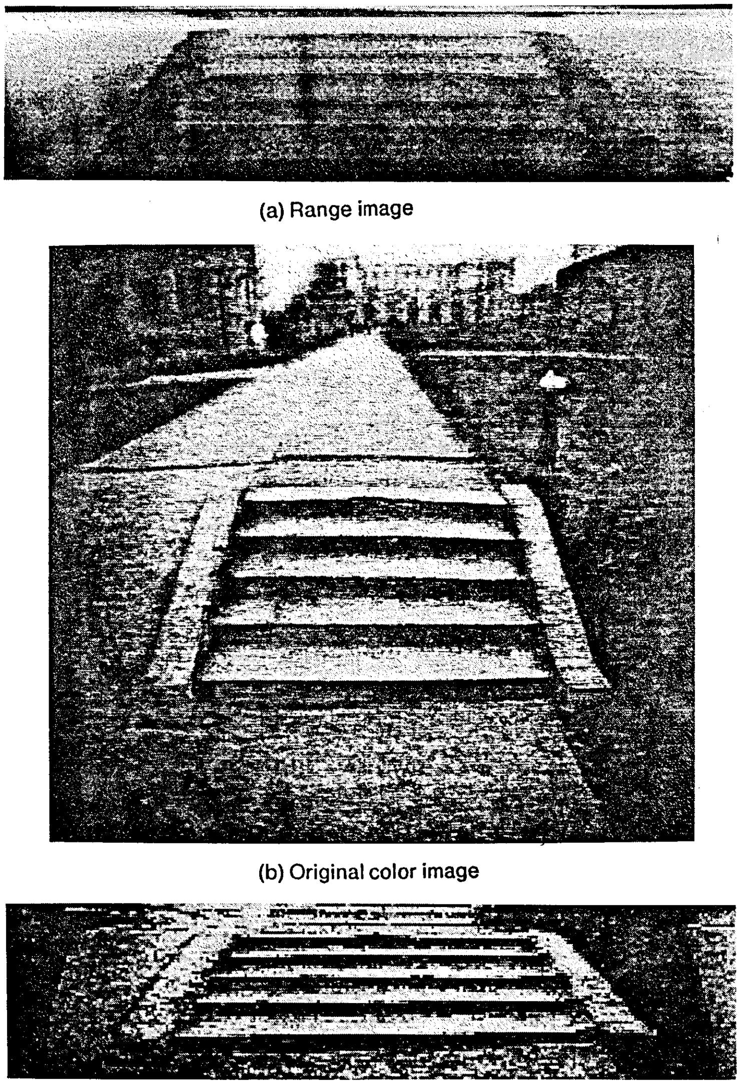
THE PERCEPTION MONITOR creates appropriate parameters, and the segmentation modules use them. Currently, the PERCEPTION MONITOR creates color type and minimum area of segments as segmentation parameters. For example, if the predicted objects are only a *sidewalk* and *grass*, the PERCEPTION MONITOR decides that types of color are *GRAY* and *GREEN*, and reports them to the segmentation module (the PATCH MAKER). Another example is the minimum area for segments. If there are no small predicted objects, the PERCEPTION MONITOR sets a rather large value for minimum segment area. This eliminates the noisy segments, and makes a simple segment list which is easy to analyze in the later object finding phase.

3.4. Colored-Range Image Analysis

It is very difficult to recognize complex objects in outdoor scenes using only one kind of sensor, but several different sensors can provide a lot of clues about the environment. For example, use of both range data and color images provides a very powerful vision system for outdoor scene analysis, because range data provide information about the geometry of a scene, and color images provide an important physical property of objects. In order to use these different sensor data, we must integrate them using sensor fusion techniques. The registration between range data and color images can be a first step to sensor fusion. In the following sections, we describe the registration algorithm for color and range image, the segmentation procedure for range data, the color segmentation algorithm, and how to use a *colored-range* image to recognize stairs and slopes.

3.4.1. Registration

We must know the relative positions and orientations of the color camera with respect to the range scanner to register range data into camera-centered coordinates. These can be computed using a calibration procedure. The calibration step consists of initial value estimation and optimum value finding procedures. In the initial value estimation step, the measured angles are used to simplify the problem, so the position of the camera relative to the range scanner and its focal length are the only unknown parameters. The unknown parameters are computed by solving a least-squares criterion. Once the initial values of the camera parameters are computed, we can obtain more accurate parameters using a modified Newton-Gauss method. In the experiment, the wide-angle lens is used to capture color images, which prevents us from using a linear perspective transformation for projection. Use of a third-order polynomial for projection provides good registration. The projection model is developed through a conventional camera calibration procedure. Since the camera/scanner transformation and the perspective transformation are computed, the range data can be registered with the color image. This is done by applying the transformation to each point of the range image, so the corresponding pixel point in the color image can be computed. The color intensity for the computed pixels in color image then are assigned to the range image. The registration procedure is illustrated in Figure 10.



(a) Range image

(b) Original color image

(c) *Colored-range* image

Figure 10: Colored-range Image Registration

3.4.2. Range Image Segmentation

The range segmentation module generates surface segments using three basic attributes at each pixel: jump edges, surface normal, and surface curvature. Each segmented region has a surface normal vector, a surface curvature, 3-D edges, and a label indicating smooth region or rough region. The detailed algorithm for range data analysis can be found in Hebert's recent work [2].

3.4.3. Color Segmentation

The color segmentation module uses Wallace's color classification algorithm [5] which uses a standard quadratic discrimination function for multivariate normal distributions of mean vectors and covariance matrices for the Red, Green, and Blue components of an image. This module cannot detect 3-D position data for segments. However, when we assume all objects are on a flat ground plane, this module can calculate 3-D values for segments using the relation between the perspective image and the scene [1].

3.4.4. Overlap Segmentation

The registration process creates an image in which each pixel has a color value and a range value. The segmentation for the *colored-range* image is done as illustrated in Figure 11. First, the color label and the surface label are obtained by color segmentation and surface segmentation. Then, the color-surface label for each pixel is obtained by an AND operation of the color label and the surface label. Overlap segmentation is done using this label value.

Figure 11: Overlap Segmentation by Color and Range Data

3.4.5. Result of a Real Scene Analysis

One good example to show the effectiveness of the *colored-range* segmentation module is a slope and stairs scene of a campus sidewalk. The slope and the stairs are made of concrete and have the same gray color. The slope and road-side grass are on almost the same plane. Therefore, segmentation using only color can not separate the slope and the stairs, and segmentation using only range can not separate the slope and the road-side grass. Overlap segmentation using *colored-range* image can extract the slope which is only navigable region in this scene. Figure 12 shows the results of color segmentation, range segmentation, and colored-range segmentation drawn with polygons.

4. Conclusion

We have developed the Sidewalk Navigation System which can drive the vehicle on the test site, the CMU campus. Because our test site involves sidewalks and intersections, slopes, stairs, and grass, the navigation system should have ability to select the best navigation mode depending on the situation. Our architecture works well in this environment, using both route planning and local path planning, selecting vehicle driving mode, and selecting sensors. The scene which includes the stairs, the slope, and the grass is hard to detect with only a TV camera or only a range sensor. But our perception module can analyze even this scene using sensor fusion with color and range data. And sensor selection dependent object prediction saves computation time. Our current system demonstrates the framework of an outdoor robot navigation system.

Our future work will include pipeline processing in the PILOT module, expanding the PERCEPTION module to detect other objects, and map revising. And we will add a capability for *cross-country navigation*.

Acknowledgements

The CMU Sidewalk Navigation System is created as a part of the Strategic Computer Vision Project at CMU. This system includes several programs produced by project members. The BLACKBOARD was produced by Steven Shafer, Anthony Stentz, and Charles Thorpe [4]. The color classification program was based on the code made by Richard Wallace [5]. The range image segmentation program was made by Martial Hebert [2]. The system architecture design is based on the proposal by Steven Shafer, Anthony Stentz and Charles Thorpe [4].

We would like to thank Regis Hoffman for creating the LOCAL PATH PLANNER, Paul Allen for writing the NAVIGATION MONITOR, and Ralph Hyre for useful blackboard facilities. Thanks to Mike Blackwell, Kevin Dowling, and James Moody for hardware, system interface, and video support. The civil engineers Red Whittaker, Chuck Whittaker, Francois Bitz, Steve Berman, and Kai Lee developed and maintain the Terregator vehicle.

ERROR MODELLING IN STEREO NAVIGATION

Larry Matthies and Steven A. Shafer

Computer Science Department
Carnegie-Mellon University
Pittsburgh, PA 15213

Abstract

In stereo navigation, a mobile robot estimates its position by tracking landmarks with on-board cameras. Previous systems for stereo navigation have suffered from poor accuracy, in part because they relied on scalar models of measurement error in triangulation. This paper shows that using 3-D gaussian distributions to model triangulation error leads to much better performance. The paper describes how to compute the error model from image correspondences, estimate robot motion between frames, and update the global positions of the robot and the landmarks over time. Simulations show that compared to scalar error models the 3-D gaussian reduces the variance in robot position estimates and better distinguishes rotational from translational motion. A short indoor run with real images supported these conclusions and computed the final robot position to within 2% of distance and one degree of orientation. These results illustrate the importance of error modelling in stereo vision for this and other applications.

1 Introduction

Consider a robot given the task of going from A to B. At a coarse level its route is planned from a pre-stored map, while at a fine level the route is determined by sensor information gathered along the way. Incremental motion estimates are integrated to keep track of the robot's position in the map, which in turn is used to predict upcoming landmarks, hazards, or arrival at the destination.

To realize this scenario, a robot needs sensors that can measure its position and detect the presence of 3-D objects nearby. Stereo vision can provide both kinds of information. Stereo matching at one point in time provides a local 3-D model for route planning and obstacle avoidance. Selected points in this model become landmarks that are tracked by the stereo system to monitor the robot's progress. Using to stereo in this way, to detect nearby objects and to estimate the motion of the robot, is what we refer to as stereo navigation.

We are interested in stereo in this scenario for a number of reasons. First, other motion sensors can be in error, such as shaft encoders when wheels slip or loose contact with the ground. Second, other sensors, such as sonar and radar, can be inappropriate for reasons of concealment, possible confusion with the broadcasts of other robots nearby, or because color and reflectivity information are important. Lastly, we are interested in stereo *per se* and believe that methods developed for this domain can be transferred to other applications.

Methods for extracting shape and motion information from image sequences can be classified as correspondence-based or flow-based. Correspondence methods [7, 11, 18, 24] track distinct features such as corners and lines through the image sequence and compute 3-D structure by triangulation. Flow-based methods [1, 25] treat the image sequence as function $\mathbf{I(x,y,t)}$ of row, column, and time, restrict the motion between frames to be small, and compute shape and motion in terms of differential changes in $\mathbf{I}$. This paper deals with error modelling issues in the correspondence paradigm.

One of the first systems for correspondence-based stereo navigation was that built by Moravec [18]. This system moved a robot in a stop-go-stop fashion, digitizing and analyzing images at every stop. Features were matched in stereo images to build a world model consisting of 3-D points. After moving and acquiring more images, the points in the world model were matched in the new images to find their coordinates relative to the new robot location. A least squares procedure was applied to the differences between the new and point locations to infer the actual motion of the robot. The contribution of each landmark point to this motion estimate was multiplied by a scalar weight that varied inversely with the distance to the point.

In earlier work with Moravec [17], we found the motion solving part of this system to be somewhat inaccurate and unstable. This has been a common experience with visual motion solving algorithms in general. In the case of correspondence-based algorithms, this can partly be attributed to inadequate modelling of measurement error in triangulation. In triangulation, 3-D structure is computed by finding the intersection of rays projected through corresponding points in two images. Small errors in locating the matching image points changes the direction of these rays and leads to errors in the inferred 3-D location of the point. Scalar weights do not adequately model this error and lead to poor performance in subsequent motion computations based on the point's location. More sophisticated methods have been used in a number of places. In photogrammetry [20], 2-D and 3-D normal distributions are used to model error in image coordinates and 3-D point locations, respectively. Gennery [11] has used 2-D normal

distributions of image coordinates in camera calibration for computer vision. .Hallam [15] used normal error models in conjunction with Kalman filters to track points and estimate robot motion from sonar data. Broida and Chellappa [5] used similar methods to track a known object in monocular image sequences. This paper shows how these methods can be applied to stereo navigation and demonstrates that they lead to markedly better performance.

The system described in this paper is shown in figure 1. The structure is very similar to that used in [18]. The main data structures are a set of 3-D points P_i, called the local model and described in robot-centered coordinates, and the robot's current estimate of its position in some fixed, global reference frame. The points in the local model are obtained by stereo matching are used as landmarks. When a new stereo pair is digitized, points from the local model are matched in the images to determine their current locations Q_i relative to the robot. A motion solving algorithm estimates the rotation and translation (R and T) relating the new and old coordinates. The model updating system transforms the old local model into the current coordinate frame and combines it with the new points to create a new local model. Finally, the motion estimate is used to update the robot's global position. The cycle then repeats with the acquisition of a new pair of images.

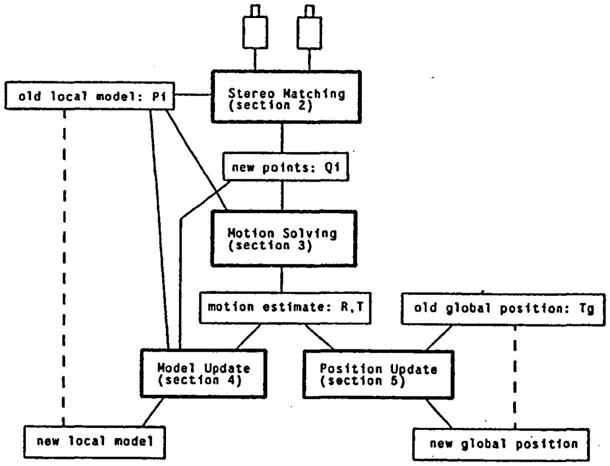

Figure 1: System block diagram

Section 2 shows how to model triangulation error in the stereo matcher with 3-D normal distributions. In section 3 this is incorporated in an algorithm for finding the rotation and translation between successive stereo pairs. The covariance matrix of this transformation is used in section 4 to update the local model with Kalman filters and in section 5 to estimate the robot's global position uncertainty. Simulations described in section 6 show that compared to scalar error models this system reduces the variance of position estimates and better distinguishes rotational motion from translation. An experiment with real images, using 54 stereo pairs covering 5.4 meters and fully automatic feature tracking, supported these conclusions and computed the final robot position to within 2% of distance and one degree of orientation. Conclusions are summarized in section 7.

2 Modelling stereo triangulation error

The geometry of stereo triangulation is shown in figure 2. For the moment we consider just the case of 2-D points projecting onto 1-d images. Two cameras are placed at offsets of ±b from a coordinate system centered between the cameras. Suppose point P projects onto the left image at x_l and the right image at x_r. Because of errors in measurement, the stereo system will determine x_l and x_r with some error. The error can come from many sources, including quantization of the image, photometric and geometric distortion in the camera, and the effects of perspective distortion on the matching algorithm. This error in turn causes the true location of P to be inferred with some error. Figure 2 illustrates this for errors caused by image quantization; because of resolution limits, the estimated location of P can lie anywhere in the shaded region surrounding the true location [22]. Additional random effects will cause this region to have less sharp boundaries, but the general shape will be similar. We want to take this uncertainty into account in any reasoning based on measurements of P.

Three approaches to modelling such uncertainty are discrete tolerance limits, scalar weights, and multi-dimensional probability distributions. Tolerance regions are often used. in object recognition and motion planning [4, 6, 14]; however, they are inappropriate for our application because of the combinatorial nature of the algorithms they require, the stochastic nature of matching errors, and the need to filter time sequences of data.

The idea behind scalar weights is that uncertainty grows with distance, so it can be modelled by weighting points inversely with distance [18]. However, as figure 2 shows, the uncertainty induced by triangulation is not a simple scalar function of distance to the point; it is also skewed and oriented. Nearby points have a fairly compact uncertainty, whereas distant points have a more elongated uncertainty that is roughly aligned with the line of sight to the point. Scalar error measures do not capture these distinctions in shape.

Normal distributions are commonly used in photogrammetry [20] and navigation [10, 26] to model uncertainty in two and three dimensional data. In computer vision, they have been used to model error in coordinates of image correspondences [11], monocular object tracking [5, 12], navigation and tracking with sonar [15], and recently in stereo work similar to ours [9]. To model triangulation error, we begin by treating image coordinates as corrupted by 2-D, normally distributed (ie. gaussian) noise and derive from this a distribution of the error in the inferred 3-D coordinates. Because triangulation is a non-linear operation, the true 3-D distribution will be non-gaussian. We approximate this as gaussian because it is simpler and gives an adequate approximation when the distance to points is not extreme. We will discuss shortly the cases where this breaks down.

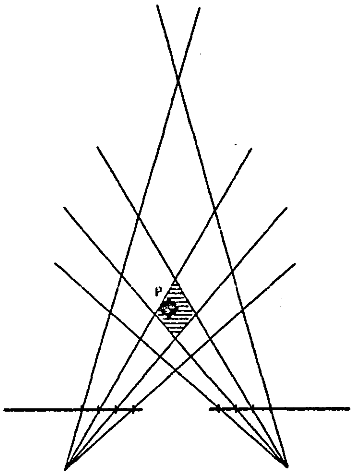

Figure 2: Stereo geometry showing triangulation uncertainty

We will now show the details of the triangulation and error model calculation for the general case of 3-D points projecting onto 2-D images. Let the image coordinates be given by $l = [x_l, y_l]$ and $r = [x_r, y_r]$ in the left and right image, respectively. Consider these as normally distributed random vectors with means μ_l and μ_r and covariance matrices V_l and V_r, respectively. From l and r we need to estimate the coordinates $[X, Y, Z]^T$ of the 3-D point P. We take the simple approach of using the ideal, noise-free triangulation equations $P = [X, Y, Z]^T = f(l, r)$ or

$$X = b(x_l + x_r)/(x_l - x_r)$$

$$Y = b(x_l + x_r)/(x_l - x_r) \qquad (1)$$

$$Z = 2b/(x_l - x_r)$$

(assuming a unit focal length) and inferring the distributions of X, Y, and Z as functions of random vectors l and r. If equation ((1)) was linear, P would be normal [8] with mean $\mu_p = f(\mu_l, \mu_r)$ and covariance

$$V_p = J \begin{bmatrix} V_l & 0 \\ 0 & V_r \end{bmatrix} J^T \qquad (2)$$

where J is the matrix of first partial derivatives of f or the Jacobian. Since f is nonlinear these expressions do not hold exactly, but we use them as satisfactory approximations.

The true values of the means and covariances of the image coordinates needed to plug into (1) and (2) are unknown. We approximate the means with the coordinates returned by the stereo matcher and the covariances with identity matrices. This is equivalent to treating the image coordinates as uncorrelated with variances of one pixel. Better covariance approximations can be obtained by several methods [2, 11].

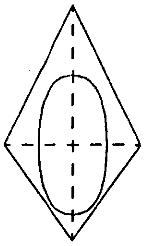

Figure 3: Quantization error with normal approximation

What does this error model mean geometrically? Constant probability contours of the distribution of P describe ellipsoids about the nominal mean that approximate the true error distribution. This is illustrated in figure 3, where the ellipse represents the contour of the error model and the diamond represents quantization error of figure 2 For nearby points the contours will be close to spherical; the farther the points the more eccentric they become. A covariance matrix with structure $V = wI$, equal to a scalar times the identity matrix, describes only spherical contours. This is the difference between attaching scalar weights to 3-D coordinate vectors and using the full 3-D distribution; that is, scalar weights are equivalent to spherical covariances whereas the full distribution permits ellipsoidal covariances. In the balance of the paper we will often refer to scalar weights as a spherical error model and the full distribution as an ellipsoidal error model.

Where the gaussian approximation breaks down is in failing to represent the longer tails of the true error distribution. The true distribution is skewed not unlike the diamond in figure 3, whereas normal distributions are symmetric. The skew is not significant when points are close, but becomes more pronounced the more distant the points. A possible consequence is biased estimation of point locations, which may lead to biased motion estimates. We will return to this issues section 6.

3 Solving for robot motion

The previous section showed how to model measurement error in stereo triangulation. In this section we show how to incorporate the error model into an algorithm for estimating the motion between successive stereo pairs. We will begin by showing how motion is computed with scalar weights, then derive an algorithm based on the 3-D gaussian error model, and finally give this algorithm a geometric interpretation.

Refering back to figure 1, at this stage in the cycle the robot has two sets of 3-D points that have been obtained by stereo matching: a local model of points P_i defined relative to its previous position and the coordinates Q_i of these points relative to its current position. The correspondences between P_i and Q_i are known, but the motion between them is not. Parameterizing the rotation in terms of Euler angles, we have a set of equations

$$Q_i = RP_i + T$$

in which P_i and Q_i are known point vectors, R is the matrix of the unknown rotation, and T is the unknown translation.

Using scalar weights, one finds R and T by expressing the errors of fit by

$$\varepsilon_i = Q_i - RP_i - T$$

minimizing the weighted sum of squares

$$\sum_{i=1}^{n} w_i \varepsilon_i^T \varepsilon_i \qquad (3)$$

where w_i are the weights. Although the rotation makes this optimization problem nonlinear, it has a closed form solution [19]. A solution for case where the rotation is parameterized by quaternions is given in [16].

As will be shown in section 6, the scalar model of uncertainty embodied in equation (3) leads to poor performance. Using the 3-D gaussian error model the solution takes a similar, but more complicated form. For simplicity we begin with the case of translational motion. The simplified motion equation is

$$Q_i = P_i + T$$

which we may rewrite as

$$Q_i - P_i = M_i = T$$

to emphasize the role of $M_i = Q_i - P_i$ as measurements of T. From section 2, P_i and Q_i are modelled as normally distributed random vectors with covariances U_i and V_i, respectively. Therefore, M_i will also be normally distributed with covariance $U_i + V_i$. Now if we consider M_i to be a sequence of noisy measurements of T, each corrupted by noise with zero mean and covariance $U_i + V_i$, application of the maximum likelihood method leads to minimizing the following expression over possible values of T [8]:

$$\sum_{i=1}^{n} \varepsilon_i^T W_i \varepsilon_i \qquad (4)$$

where $\varepsilon_i = M_i - T$ and $W_i = (U_i + V_i)^{-1}$. The solution to this is

$$T = (\Sigma_{i=1}^{n} W_i)^{-1} \Sigma_{i=1}^{n} W_i M_i$$

and the covariance matrix of the estimation errors is

$$V_T = (\Sigma_{i=1}^{n} W_i)^{-1}$$

The covariance matrix can be analyzed to assess the quality of the motion estimate. It is also used later in modelling the uncertainty of the robot's global position estimate.

An intuitive interpretation of equation ((4)) is shown in figure 4. The weight matrices W_i function as norms that measure distance differently for each point. Error vectors making equal contributions to the total error of fit lie on ellipsoidal contours. For example, in figure 4, residuals ε_a and ε_b contribute equally to the total error but ε_c contributes more because $\varepsilon_a^T W \varepsilon_a = \varepsilon_b^T W \varepsilon_b < \varepsilon_c^T W \varepsilon_c$. This effectively gives more weight to errors perpendicular to the line of sight than parallel to it, which, given the nature of stereo, is what we would like to do. The "spherical" error model obtained by using the scalar weights of equation (3) has the obvious mnemonic meaning that residual vectors making equal contributions to the total error lie on spherical contours. This distinction is what gives the ellipsoid model its power.

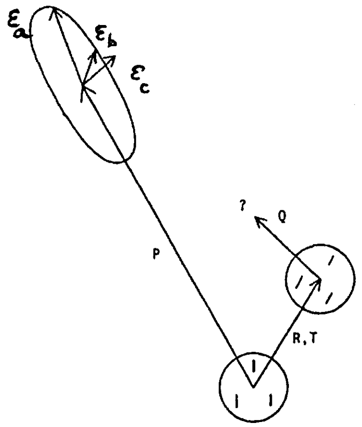

Figure 4: Interpretation of weight matrix

Generalizing this method to handle rotation is complicated by the fact that the equations become nonlinear. The function to be optimized takes the form

$$\sum_{i=1}^{n} \varepsilon_i^T W_i \varepsilon_i \qquad (5)$$

$$\textit{with } \varepsilon_i = Q_i - R P_i - T$$
$$\textit{and } W_i = (R U_i R^T + V_i)^{-1}$$

We have not been able to find direct solutions to this problem or even to approximations in which W_i is not a function of R. Our approach has been to use the direct solution for scalar weights to get an initial approximation, then to iterate on linearizations of equation (5). Linearization methods for solving least squares problems are described in [13].

To recap, this section incorporated the error model of section 2 in an algorithm for finding the rotation and translation between two 3-D points sets. The algorithm replaces the scalar weights of equation (3) with weight matrices based on the covariances of corresponding points. When the motion is purely translational, the problem is linear and has a direct solution, but when the motion involves rotation we resort to an iterative solution. The error covariance of the motion solution will be used in the following two sections in updating the robot's local model and global position estimate.

4 Updating the local model

So far we have described how to model error in triangulation and how to solve for the motion between two successive stereo pairs. This section deals with how to process a long sequence of stereo pairs. At issue is how to average information from successive images to achieve more accurate landmark localization and consequently more accurate estimates of robot position.

An appropriate tool for this is the Kalman filter [10]. In filtering terminology the quantity to be estimated is called the "state", and when a measurement is taken the filter updates the current estimate of the state. Kalman filters incorporate known statistical properties of the measurements into the update process and produce error covariances for the state estimate. They are widely used in terrestrial and aerospace navigation and guidance applications [10, 26]. In computer vision they have been used in object recognition [3], tracking of known objects with monocular image sequences [5, 12], and for robot navigation and object tracking with sonar data [15].

In our application, the state consists of the locations of the landmark points in the local model. A question arises as to whether the landmarks should be represented in a global, stationary frame of reference or in a local, moving, robot-centered frame. In either case, the update involves transforming coordinates from one frame to the other and applying the filter. If a fixed number of landmarks are being tracked, there is no difference in cost between the two. There will be a difference in the uncertainty of the resulting model; this difference depends on the relative uncertainties of the old model, the new measurements, and the intervening motion. We have not completed an analysis of this situation, but are currently keeping the landmark model in robot-centered coordinates.

The update involves transforming the old local model to the current coordinate frame, inflating its uncertainty to account for the uncertainty of the transformation, and filtering the old model with the new measurements to create the updated model. Let P_{t-1} be the coordinate vector of a single point in the old local model at time $(t-1)$ and let V_{t-1} be its covariance. For purely translational motion, P_{t-1} is transformed to the current frame by

$$\mathcal{P}_{t-1} = P_{t-1} + T \qquad (6)$$

where T is the translation from time $(t-1)$ to time t. The translation has an error covariance matrix V_T, so the transformed point has covariance

$$\mathcal{V}_{t-1} = V_{t-1} + V_T \qquad (7)$$

where V_T is the error covariance of the translation. Equation (6) introduces some correlation between points that is not accounted for in (7), but we assume this is small enough to ignore. To extend this to rotation, we rewrite equation (6) as

$$\mathcal{P}_{t-1} = R P_{t-1} + T \tag{8}$$

This is nonlinear, so to compute $\mathcal{V}_{t-1}$ we proceed by analogy to equation (2); that is, we pre-multiply the covariance of R, T, and P_{t-1} by the Jacobian of the transformation and post-multiply by the Jacobian transposed. Since we treat P_{t-1} as uncorrelated with R and T, this leads to

$$\mathcal{V}_{t-1} = J_m V_m J_m^{\ T} + R V_{t-1} R^T$$

where J_m contains the derivatives of (8) with respect to the motion parameters and V_m is the covariance of the motion parameters.

Now let Q_t be the measurement of the same point at time t and let U_t be the covariance of this measurement. Some manipulation of the basic Kalman filter equations leads to the following estimates of the updated point location and covariance:

$$V_t = (\mathcal{V}_{t-1}^{\ -1} + U_t^{-1})^{-1} \tag{9}$$

$$P_t = \mathcal{P}_{t-1} + V_t U_t^{-1}(Q_t - \mathcal{P}_{t-1}) \tag{10}$$

The intuition behind equation (10) is as follows. The second term takes the difference $(Q_t - \mathcal{P}_{t-1})$ of the new measurement from the old estimate, weights the difference by $V_t U_t^{-1}$, and applies the result as an update to the old estimate $\mathcal{P}_{t-1}$. Matrix U_t^{-1} will be "larger" the more precise the new measurement, giving it more weight in the update, and smaller the less precise the measurement, giving it less weight. Conversely, V_t will be small if the old estimate is precise and large otherwise. Hence if the old estimate is already good, the new measurement receives little weight; if it is poor, the new measurement receives more weight.

The procedure we have described assumes that the error in the motion estimate is uncorrelated with the error in the landmark points. When the motion estimate is obtained by using the methods of the previous section this will not be true, although if other sensors are also contributing to the motion estimate it will be approximately true. This is an issue we are investigating.

5 Updating the global robot position

By using the modules discussed in the previous sections, the robot computes estimates of its motion between successive stereo pairs. Combining these to estimate its global position is a simple matter of concatenating the transformation matrices. It may also be desirable to estimate the uncertainty of the global position, which can be done by propagating the covariance matrices of the incremental motions into a covariance of the global position. For translation this is also very simple. If the the global position at time $(t-1)$ is $T_{g_{t-1}}$ and the next incremental translation is T_t, then the next global position is

$$T_{g_t} = T_{g_{t-1}} + T_t \tag{11}$$

Since this is linear, if the incremental translation estimates have uncorrelated, zero mean gaussian errors, then T_{g_t} will also have zero mean, gaussian error with covariance given by

$$V_{g_t} = V_{g_{t-1}} + U_t$$

where $V_{g_{t-1}}$ and U_t the covariances of $T_{g_{t-1}}$ and T_t, respectively. The case of motion in the plane, there are two parameters for translation and one for rotation, has been dealt with by Smith and Cheeseman [21]. In summary, one obtains an equation analogous to (11) in which the three parameters of the global position are expressed as functions of the previous position and the incremental motion. These are nonlinear and error propagation is done by linearization. For general motion in three dimensions, this is not straightforward with the Euler angle representation of rotation we have used here. In this case other parameterizations of rotation, such as quaternions, may be preferable [9, 26]. We are exploring this further.

6 Performance

Our evaluation to date has concentrated on comparing the use of the spherical and ellipsoidal error models in the motion solving methods of section 3. Results of tests with simulated and real data are described below.

6.1 Simulations

Three sets of simulation data will be presented. The first set is a base case that compares the standard deviations of position estimates obtained with each error model for a single step of vehicle motion. That is, it considers motion between only two consecutive stereo pairs. It illustrates the difference in the variability of position estimates with each model and reveals different amounts of coupling between translation and rotation with each error model. The second set of data also considers only two consecutive stereo pairs and tests limiting performance by tracking progressively more distant points. The last set examines both long range performance over many images and the effect on performance of different stereo baselines.

The simulations were generated as follows. The "scene" consisted of random points uniformly distributed in a 3-D volume in front of the simulated cameras. Typically this volume extended 5 meters to either side of the cameras, 5 meters above and below the cameras, and from 2 to 10 meters in front of the cameras. The cameras themselves were simulated as having 512x512 pixels and a field of view of 53 degrees. The baseline for most simulations was 0.5 meters. Image coordinates were obtained by projecting the points onto the images, adding gaussian noise to the floating point image coordinates, and rounding to the nearest pixel. These coordinates were input to the triangulation and motion solving algorithms. For the ellipsoidal error model, covariance matrices were computed as described in section 2. In the scalar case, weights were derived by taking the Z variance from the covariance matrix. Scalars obtained by several other methods were tried and found to give very similar results. These include the volume and length of the major axis of the standard error ellipsoid and Moravec's half-pixel shift rule [18].

The first set of simulations determined the standard deviation of the estimated motion between two consecutive stereo pairs when the true motion was one meter. The results are shown in figures 5 and 6 plotted against the number of points used to compute the motion estimate. In both figures, the top three curves were obtained with spherical modelling and the bottom three with ellipsoid. Tilt implies rotation of the camera up or down, pan is the rotation about the vertical axis, and roll the rotation about the camera axis. The standard deviations obtained with the ellipsoidal model are considerably less than those with the spherical model. The size of this difference will vary; it will be larger when the 3-D points are further from the cameras and smaller when they are closer. This is because the spherical error model is a reasonable approximation to the triangulation error when points are close, but not when they are distant. Another thing to note is that with the spherical model roll and forward translation are estimated better

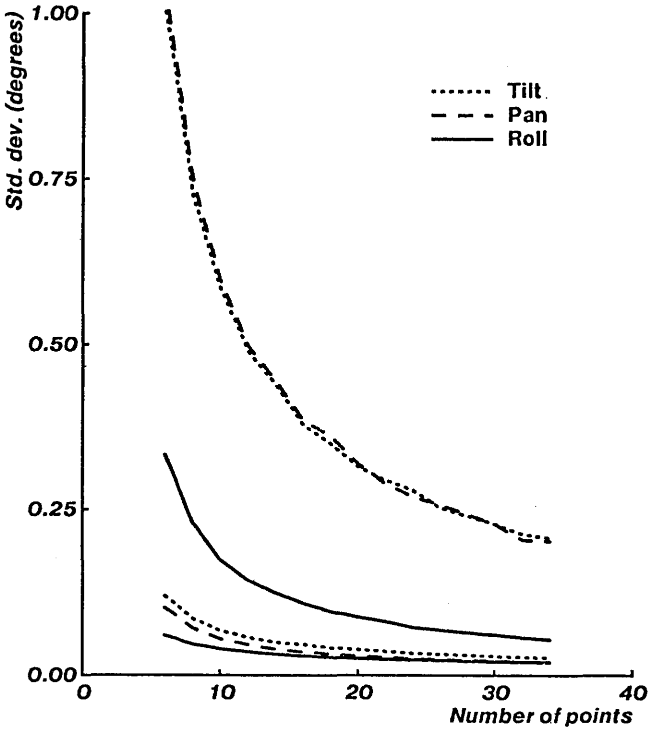

Figure 5: Simulation 1, rotations

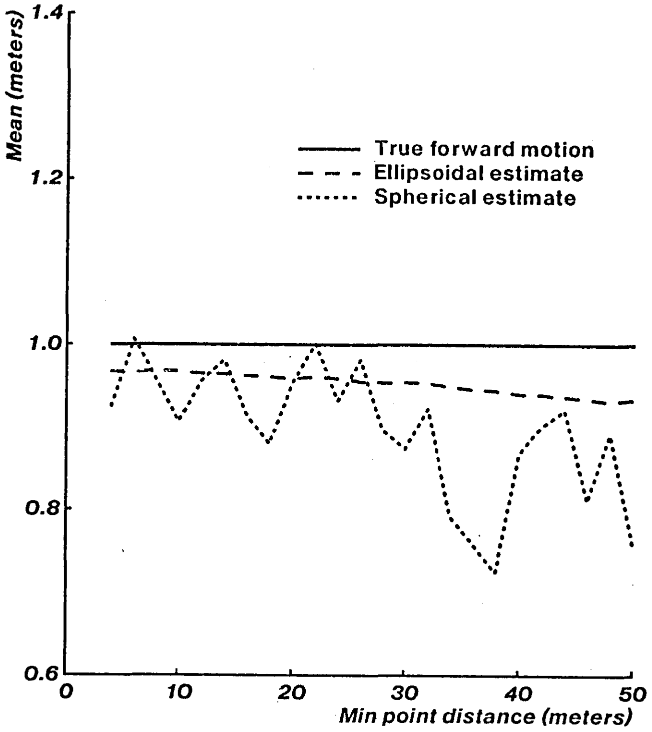

Figure 7: Simulation 2, bias

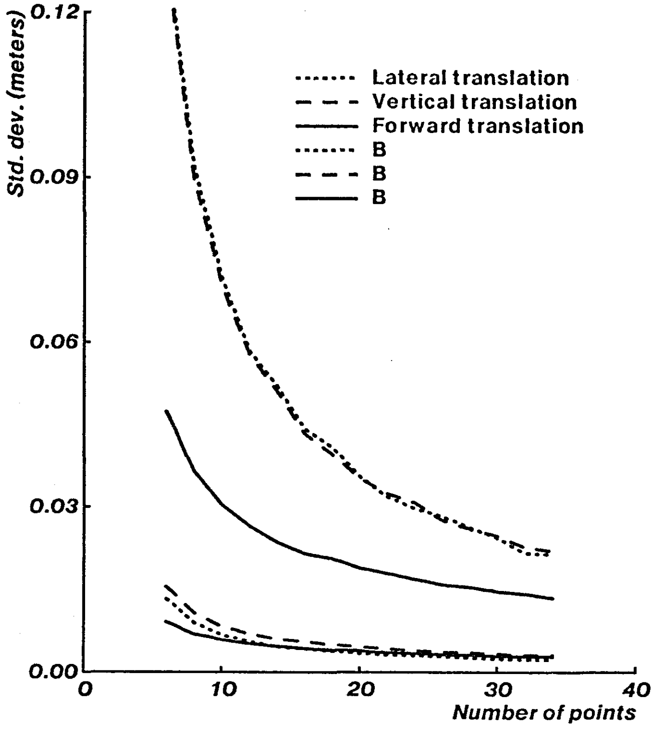

Figure 6: Simulation 1, translations

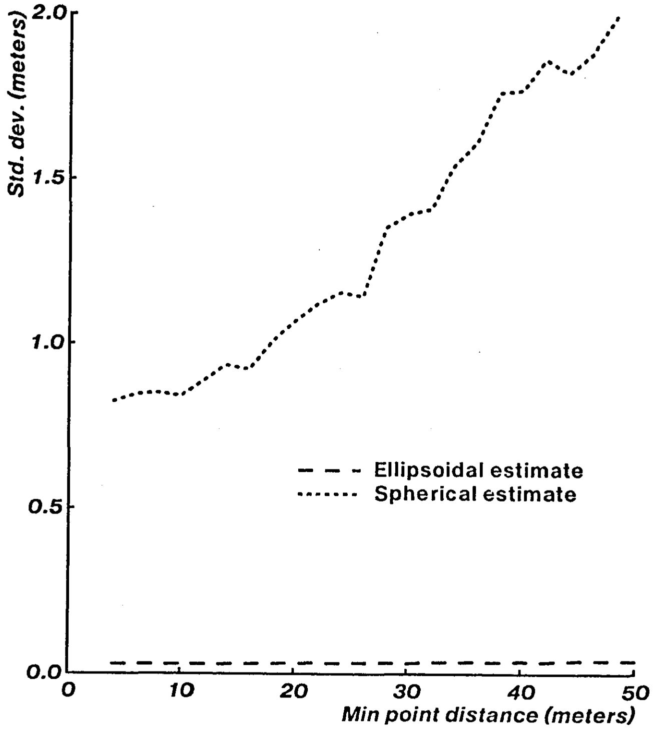

Figure 8: Simulation 2, standard deviation

than the other parameters, but with the ellipsoidal model all parameters are estimated equally well. This is because lateral translations and panning rotations have coupled effects on the errors of fit, as do vertical translations and tilting rotations. Using an ellipsoidal error model appears to reduce this coupling. Lastly, note that for a given level of performance fewer points are needed with the ellipsoidal model than the spherical, offseting the greater expense of the iterative motion solution needed in the ellipsoidal case. The exact relationship will depend on the camera configuration.

The second set of simulations also dealt with the estimated motion between just two stereo pairs. It examined the effect of increasing the distance to points in the scene, or equivalently to reducing the maximum disparity in the image. Figures 7 and 8 illustrate the results. Twenty points were generated in a volume spanning 4 to 50 meters in front of the cameras, giving disparities ranging from 2 to 32 pixels or 0.5% to 6% of image width. The volume was gradually shrunk by moving the near limit from 4 meters back until all points were 50 meters away, so that all disparities were on the order of 2 or 3 pixels. Figure 7 shows the mean value of the forward translation estimate as a function of the minimum distance to the points and figure 8 the standard deviation. The true forward motion was one meter. Looking at the means, with the ellipsoidal error model there is a consistent underestimation of the true motion that gets worse as the disparity shrinks. With the spherical error model the behavior is erratic. The jagged nature of the curve for the spherical model is due to the contribution of image quantization to the noise in the image coordinates. As a 3-D point moves smoothly away from the cameras, image quantization will lead the triangulation to alternately under- and overestimate the true distance to the point (see [22] for a good illustration). This in turn affects motion estimates based on tracking the point. Apparently the ellipsoidal model smooths out this effect. Figure 8 shows that the standard deviation of the motion estimates increases quite rapidly with shrinking disparity in the spherical case, but much less rapidly in the ellipsoidal case. On the whole, the breakdown with distance shown by the spherical error model is consistent with common experience in computer vision; this makes the stability shown with the ellipsoidal model come as quite a surprise.

Whereas the first two sets of simulations looked at motion estimates between only two consecutive stereo pairs, the last set looked at motion over a long sequence of images. There were two purposes for these simulations. The first was simply to confirm the results of the single-step simulations. The second was to test a hypothesis suggested by the previous simulation: that for equivalent performance, the ellipsoidal model may permit the use of a shorter stereo baseline than the spherical. This is an important consideration, because length of the baseline directly affects the difficulty of stereo matching. Figure 9 shows the standard deviation of the estimated distance as a function of the true distance. Here the simulated travel between images was 0.64 meters, so the figure represents about 90 simulated images. It shows curves for a 0.5 meter baseline with the spherical model and 0.125, 0.25, and 0.5 meter baselines for the ellipsoidal model. Comparing the curves for 0.5 meter baselines, the ellipsoidal model does outperform the spherical. It appears that the curves may eventually run parallel, so that the difference between the methods would be an additive constant rather than multiplicative. Looking at the effects of different baselines, results with the ellipsoidal model are still better than the spherical model with a 0.25 meter baseline, though not with 0.125 meters. Based on standard deviations of position, it does appear possible to use a shorter baseline. However, another factor involved is bias of the motion estimates. As seen in figure 7, increasing the ratio of object distance to baseline tends to cause motion estimates with both error models to underestimate the true distance. In general we have found that the narrower the baseline, the more motion is underestimated. The same occurs when we increase the variance of the simulated noise in the image coordinates. This appears to result from a net underestimation of the distance to points in space. Simple compensation schemes appear to work when only the only error in image coordinates comes from quantization, but are less adequate as the noise variance grows. This requires further investigation. For the moment we just note that bias can be a problem with short baselines or non-trivial noise levels.

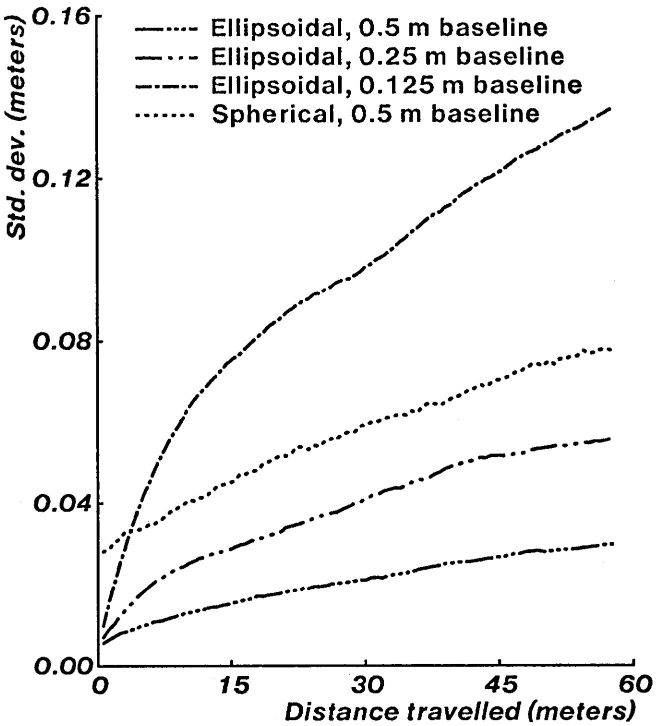

Figure 9: Simulation 3, effect of baseline

6.2 Real images

In order to verify the simulations on real images, we used both error models to estimate the position of a stereo-equipped robot travelling across the floor of our lab. The scene is pictured in figure 10. The robot was driven straight forward in 54 steps of slightly less than 10 centimeters each. The cameras were on a 20 centimeter baseline and had a 36-degree field of view. The FIDO feature-tracking system [23] was used to track points through the image sequence and the resulting set of matched image coordinates were input to the algorithms described earlier to estimte the robot's position at each step. We will briefly describe the operation of FIDO before discussing the results of the experiment.

FIDO uses the Moravec interest operator and coarse-to-fine correlation algorithm to pick and match point features in stereo pairs. The interest operator is applied to one image of a stereo pair to pick points in where intensity varies in all directions; typically these are sharp corners or intersections of lines. The correlator finds these points in the other image of the stereo pair. To find the same points in subsequent stereo pairs, an *a priori* motion estimate is used to predict the location of the point into the new images, a

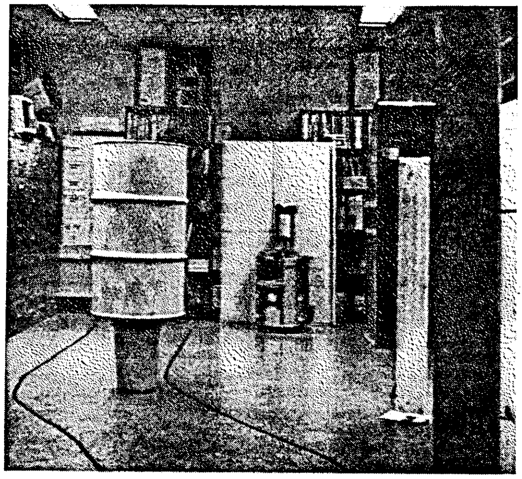

Figure 10: One image from lab sequence.

constraint window is defined around the predicted location based on the the uncertainty of the motion estimate, and the correlator is applied to find the position of best match within the constraint window. Incorrect matches are culled with a threshold on the correlation coefficient and with a 3-D error heuristic called the "3-D prune" stage. This heuristic uses the fact that under rigid motion the distance between two 3-D points does not change over time. Points which appear to violate this condition are discarded. The advantage of this test is that it does not require knowledge of the motion between stereo pairs. Points that survive this test become input to the motion solving algorithms. In the experiments to follow, between 30 and 40 points usually remained.

Figure 11 compares the true motion to the position estimates obtained with the spherical and ellipsoidal error models. For this figure a "planar" motion solver was used that solved only for the parameters of motion in the plane, that is two degrees of translation and one of rotation. The line of heavy dots shows the true position at every step, the path marked with circles shows the positions estimated with the spherical model, and the path marked with diamonds shows the same for the ellipsoidal model. The final position estimated with the ellipsoidal model was correct to within 2% of the distance and one degree of orientation. With the spherical model the corresponding figures are 8% and seven degrees.

In order to gauge the effect of noisier image matches, we adjusted the threshold of the prune stage so that progressivly fewer points were discarded. The general effect was to increasingly underestimate the distance travelled, which is consistent with the results of increasing the random noise level in the simulations. Figure 12 shows what happened when the prune stage was entirely disabled, leaving only the correlation threshold to detect matching errors. Estimates with the spherical model are initially very bad. We attribute this to matching errors caused by large depth discontinuities around the foreground objects. When these objects fall out of view, the estimates are better behaved. The behavior with the ellipsoidal model is much less erratic, though biased.

Finally, we repeated the first experiment (ie. clean data) with the algorithm that computes all six degrees of freedom of motion. The results were in accord with the planar case, with roughly the same levels of error in the final position estimate. It was notable that with the spherical model the error in roll was less than a degree, while in the other rotations it was between five and twelve degrees. This is consistent with the observation made from the first simulation about coupled rotation and translation.

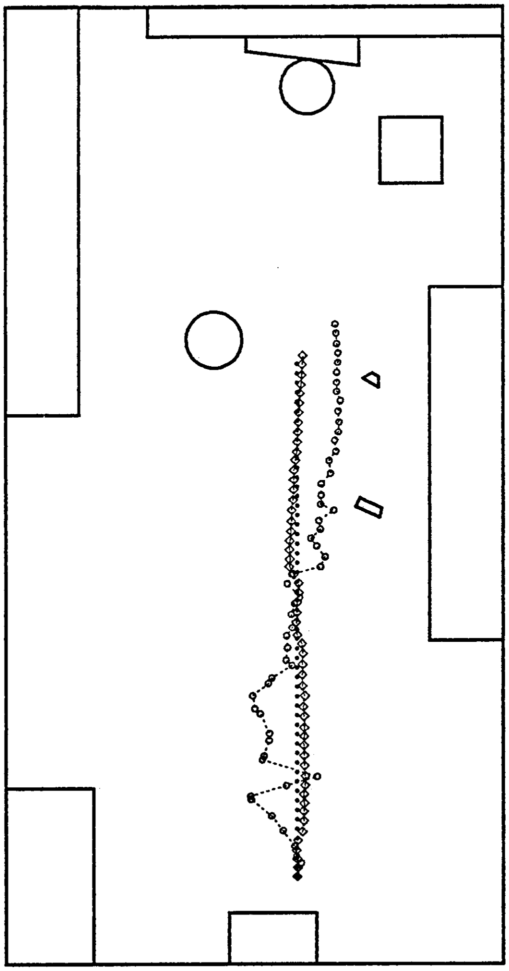

Figure 11: Results with clean data

7 Conclusions

Comparing motion estimates obtained with the spherical (scalar) and ellipsoidal (3-D gaussian) error models, under the relatively long object distance to baseline ratios we examined there is no question that the ellipsoidal model is preferred. Simulations showed that position estimates with the ellipsoidal model had less variance and live trials confirmed that they were more accurate and less influenced by matching errors. With short object distance to baseline ratios this distinction will diminish, and applications that can engineer this situation may be able to obtain satisfactory performance with the cheaper scalar error model. We suspect that many applications will be such that the 3-D gaussian model will be valuable.

A caveat to the results we have described is the possibility of bias leading to underestimation of position. This results from high noise levels in image match coordinates and from large distances to objects. We attribute this effect to the non-gaussian nature of the true error distribution in these situations. This can be dealt with either by ensuring that the noise level is low or by explicitly modelling the non-gaussian error. The low noise level can probably be achieved in many situations with the use of matching constraints, calculating match coordinates to sub-pixel resolution, and effective error detection methods. Where this cannot be achieved, better modelling is an area for further research.

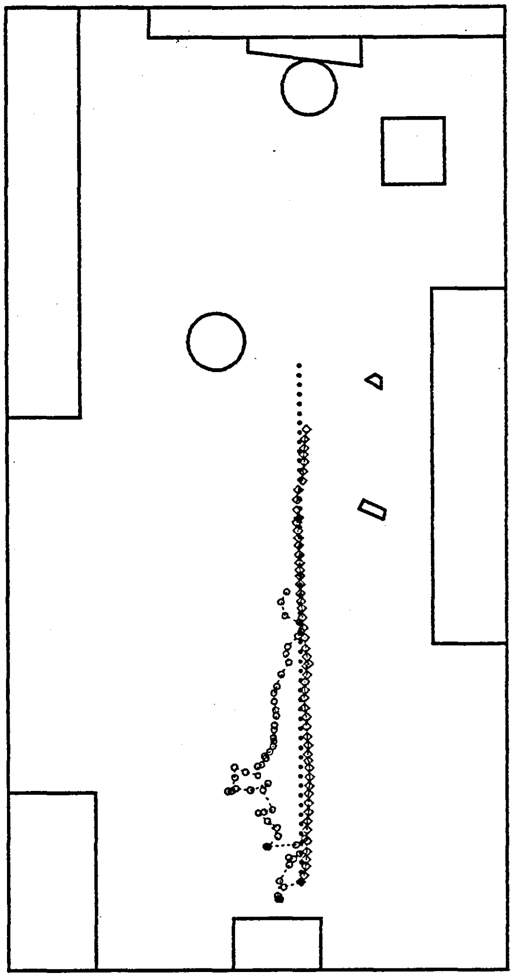

Figure 12: Results with noisy data.

There remains the question of whether use of ellipsoidal error models tolerates shorter baselines than use of spherical error models. To date we have only tested this in simulation. Based on variance of the position estimates, a shorter baseline is possible. However, the bias issue is unresolved.

Perhaps the most valuable result is demonstrating that accurate position estimates can be achieved in a fully automatic system when an adequate error model is used. The true motion in the examples we showed was pure translation, but we believe that the results will hold for general motion and preliminary simulations bear this out. With matching to sub-pixel resolution, matching of extended features instead of points, and more sophisticated error detection, it may be possible to obtain much better performance than that quoted here. Another interpretation of our results is that they show the importance of error modelling in stereo and probably other aspects of vision. One area we plan to explore this is in shape from stereo, beginning with the local update paradigm of section 5.

Acknowledgments

We are indebted to Hans Moravec for making us aware of Kalman filters, Peter Highnam for introducing us to Schonemann's algorithm, and Takeo Kanade for pointing out the possibility of using a shorter baseline.

AUTOMATIC GRASP PLANNING: AN OPERATION SPACE APPROACH

Matthew T. Mason
Randy C. Brost

Computer Science Department
Carnegie-Mellon University

ABSTRACT

During grasping motions, frictional forces and geometric constraint can combine to eliminate uncertainty in the location of the object. This paper incorporates the mechanics of friction and constraint in automatic planning of grasping motions. Our approach to automatic planning is centered on the use of *operation space*, which can be constructed for any parameterized class of operations. This approach was applied by Brost [1986] to plan planar parallel-jaw grasping motions. We extend Brost's work to include the finite dimensions of the fingers and the finite lengths of the motions. We explore the conditions for a successful grasp, and derive constraints in the operation space. An operation satisfying all of the constraints should produce the required result.

I. INTRODUCTION

An important aspect of a grasping operation is how it deals with uncertainty in the initial location of the object. In many applications, the orientation and position of an object will vary slightly from predicted values. At the least, a grasping operation should succeed despite such uncertainty. At best, we may be able to construct a grasping operation that eliminates the uncertainty. This paper focuses on grasping operations that eliminate the uncertainty mechanically, by the aligning and centering motions that occur when an object is pushed and squeezed between two fingers.

To plan grasping motions, we adopt the operation–space approach of Brost [1986], and extend it to address a broader set of issues. Brost explored the conditions for stability and convergence of object orientation, assuming that the fingers are wide enough, and approach from a great enough distance. To address the finite width and stroke of the fingers, we must construct bounds on the translations of the object, and incorporate these bounds in the planning process.

The central planning mechanism is the *operation space*. For any parameterized class of operations, we can define the operation space to be the space whose dimensions correspond to the parameters of the class. Each point in the space corresponds to a particular operation. A typical operation space constructed by Brost is shown in figure 1. For this diagram, the fingers are modeled as infinite half–planes, and the duration and speed of motions are not addressed. A two–parameter operation results, which can be viewed as a mapping from parameter values to final object configurations. This mapping is represented explicitly in the operation space, simplifying the choice of an appropriate pair of parameter values to obtain a desired outcome.

The operation–space approach involves three steps:

1) Define a parameterized operation. Each parameter defines a dimension of the operation space.

2) Develop the mechanics of the operation, combining models of the task and the operation.

3) Express the results as a mapping from the operation space to task outcomes. For any desired outcome, select a parameter value–set from the region that maps to that outcome.

Some forms of uncertainty are easily incorporated. For example, if uncertainty in one of the parameters is present, we can simply select a point that is not too close to the limits of the feasible region. This is equivalent to shrinking the feasible region before selecting a point. Other forms of uncertainty must be included in the mechanics of the operation.

Brost modeled the fingers as infinitely wide half–planes, approaching from infinity—planning the initial position was not an issue. In this paper, we assume that the two fingers have a finite width, and an initial position must be planned. Figure 2 shows part of the resulting four–dimensional operation space. As we shall see, the constraining relations among the parameters are not as simple as Brost's, but they are still fairly simple.

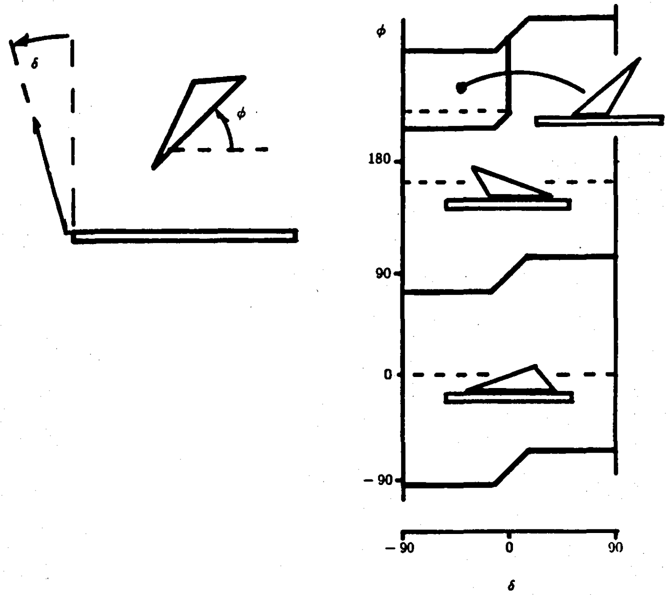

Figure 1. A two-parameter operation space for pushing, from Brost [1986]. The diagram shows the mapping from combinations of finger angle (ϕ) and pushing direction (δ) to resultant configurations of a triangle.

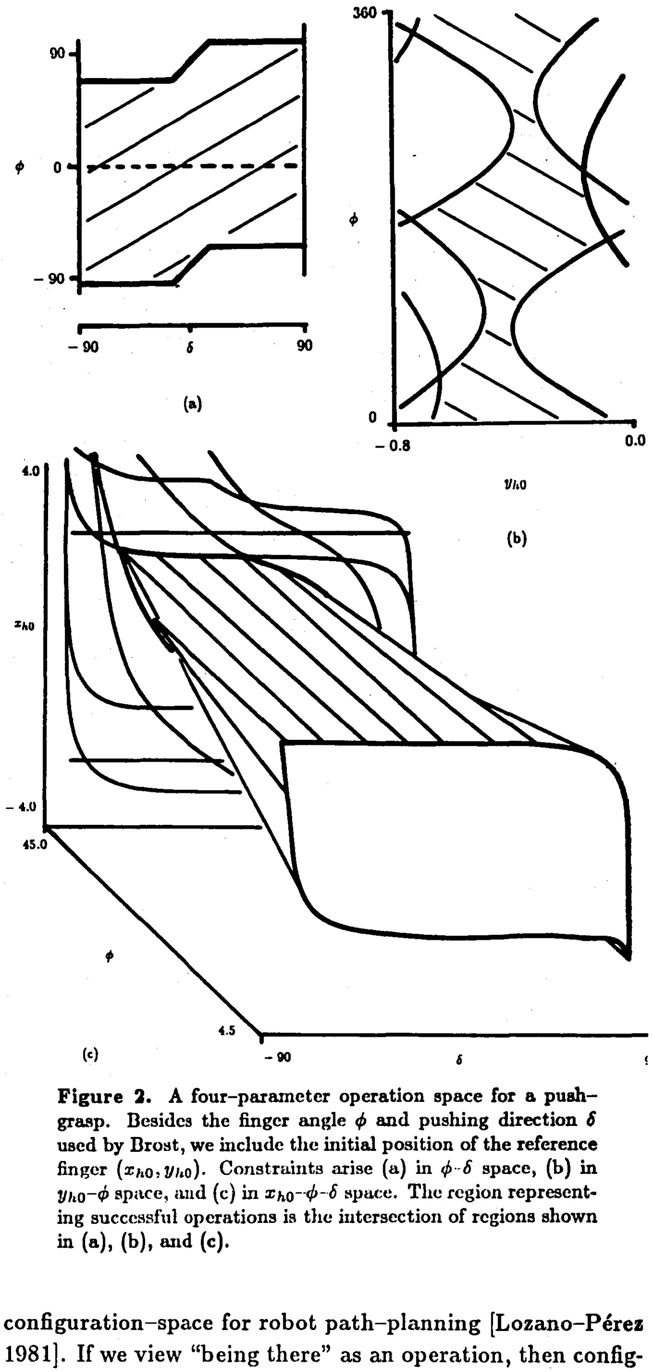

Figure 2. A four-parameter operation space for a push-grasp. Besides the finger angle ϕ and pushing direction δ used by Brost, we include the initial position of the reference finger (x_{h0}, y_{h0}). Constraints arise (a) in ϕ-δ space, (b) in y_{h0}-ϕ space, and (c) in x_{h0}-ϕ-δ space. The region representing successful operations is the intersection of regions shown in (a), (b), and (c).

I.A. Previous work

This paper draws primarily on research in the mechanics of pushing, and planning of pushing and squeezing motions. Mason [1982, 1986] explored the mechanics of pushing, and demonstrated automatic planning of push-grasp operations. Fearing [1984] incorporates the mechanics of pushing, and explores acquisition and stability of grasping with point fingers. Mani and Wilson [1985] address planning of a sequence of pushes to orient objects, and construct an operation space for pushing. Brost [1985, 1986] constructed operation spaces for three different grasping operations. Peshkin and Sanderson [1986] improved on Mason's analysis of pushing.

A number of other issues arise in the context of grasping, including control of a grasped object, mechanical properties of grasp configurations, and finding feasible grasp configurations. A short survey of this area should include Hanafusa and Asada [1977], Lozano-Pérez [1976, 1981], Salisbury [1982], Cutkosky [1985], Asada and By [1985], Kerr and Roth [1986], Abel, Holzmann, and McCarthy [1985].

There are a number of precedents in the use of operation space. Our operation space is a direct extension of the spaces constructed by Brost [1986]. Mani and Wilson [1985] independently constructed a pushing space. Kerr and Roth [1986] defines a space whose dimensions are the magnitudes of internal forces in a grasp; and the jamming and wedging diagrams of Simunovic [1975] and Whitney [1982] have the same character.

The operation space approach is similar to the use of configuration-space for robot path-planning [Lozano-Pérez 1981]. If we view "being there" as an operation, then configuration space is the corresponding operation space. A more useful operation is a straight-line motion, which is characterized by the initial and final configurations. The operation space would be $C \times C$, where C is the configuration space.

Similarities also hold with recent work in fine-motion planning [Lozano-Pérez, Mason, and Taylor 1984, Mason 1984, Erdmann 1984]. Assuming a simple, fixed, model of compliance, and a known task geometry, the robot path for a single motion command is completely characterized by an initial configuration and a nominal velocity.

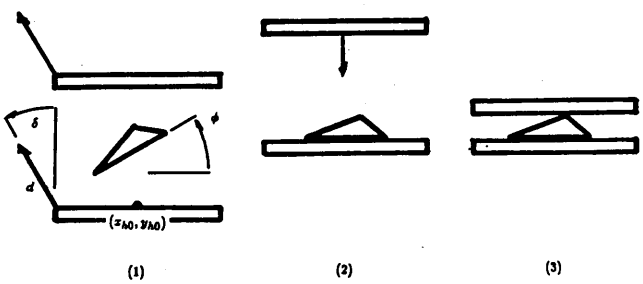

Figure 3. The push–grasp. The first finger pushes a distance d in direction δ, until the object is aligned with the finger. Then the second finger squeezes the object.

II. ANALYSIS OF THE OPERATION

Brost [1986] addresses three operations: push–grasp, squeeze-grasp, and offset–grasp. We will extend his results for the push–grasp, then briefly consider variations required for the other two operations. The push–grasp (see figure 3) pushes the object until it is stably aligned with the finger, then squeezes the object with the second finger. The general form is:

1) Move the hand to an initial position (x_{h0}, y_{h0}) and orientation ϕ, above the object;
2) Move down close to the table;
3) Translate the hand in direction δ for a distance d with velocity v;
4) Close the fingers, and translate the hand to hold the reference finger still.

We will treat the push–grasp as a four–parameter operation $(x_{h0}, y_{h0}, \phi, \delta)$. A lower bound for the pushing distance d arises as a by–product of our analysis. See Mason [1985] for an approach to producing bounds on the pushing velocity v. The initial position and orientation of the hand are expressed in a coordinate system fixed in the object, i.e. they represent *relative* position and orientation. Uncertainty in the object's initial location are equivalent to uncertainty in the parameters of the operation.

We will require the planner to verify that the following necessary conditions are satisfied:

- *geometrical conditions:* fingers clear object at initial position and orientation;
- *convergence and stability:* object converges to desired orientation relative to the fingers, and is stable in the final orientation; and
- *finite motion limits:* object does not roll or slide past the face of a finger.

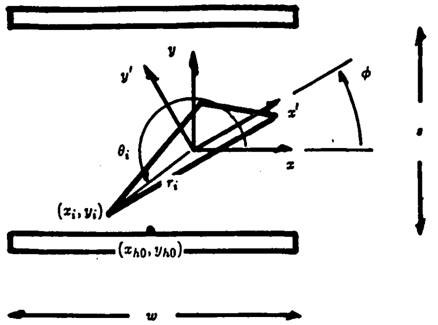

Figure 4. Notation for the push–grasp. Two coordinate frames are located at the object center of gravity. The x'–y' frame is fixed with respect to the object. The x–y frame is aligned with the fingers.

II.A. Geometrical conditions

First we address the problem of preventing undesired collisions, and producing the desired collision, between the fingers and the object. For this problem, the operation–space reduces to configuration–space. Using the notation of figure 4, the constraints are:

$$r_i \sin(\theta_i + \phi) - s < y_{h0} < r_i \sin(\theta_i + \phi)$$

for all i. This means that y_{h0} must fall between two sets of sine waves, as shown in figure 2(b).

II.B. Convergence and stability of orientation

This is precisely the problem addressed by Brost [1986], based on the earlier work of Mason [1982, 1986]. Assuming negligible inertial forces and Coulomb friction, the direction of rotation is determined by the coefficient of friction, the center of gravity, the direction of the finger motion, and the contact geometry. Stability and convergence are obtained for any operation inside the simple constraints shown in figure 2(a).

II.C. Finite fingers and finite pushing distance

The finite translations of the object are important in two respects. First, if our previous analysis is to be valid, we must ensure that each finite–width finger has the effect of an infinite half–plane. This means that the object must never make contact with an edge of the finger–face. Second, we must have an upper bound on the distance traveled during the rotation, so we know how far to push.

The primary complication is indeterminacy. We do not expect to know the distribution of support forces between the object and the table. Although the rotation direction is determined, the rotation rate, and the translational components of the motion, are not determined. Our first require-

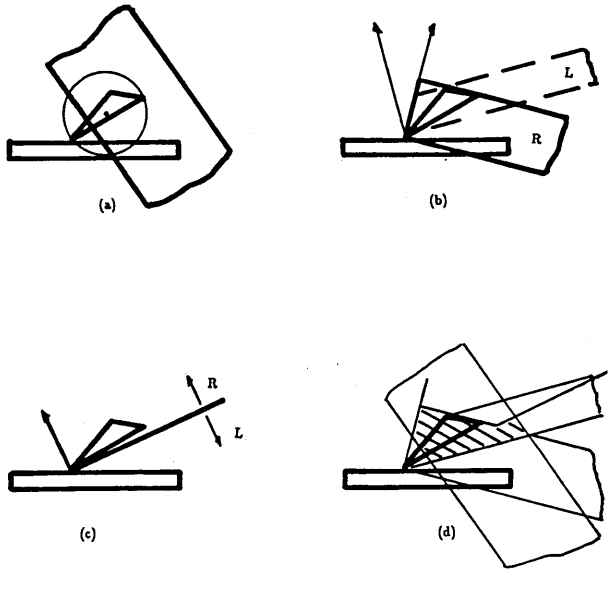

Figure 5. In order to bound the translational motion of the object, we require bounds on the instantaneous rotation center. We will use bounds arising from a variety of considerations. (a) shows the rotation center cannot fall inside the perpendicular bisector of the line connecting the contact point with the center of gravity. Nor can it fall outside a parallel line of distance $\frac{(p+r)^2}{p}$ from the contact, where r is the radius of a circle circumscribed about the support, and p is the distance from the contact to the center of gravity. (Peshkin and Sanderson [1986] have improved this bound close to $p + \frac{r^2}{p}$.) For a fixed ϕ, this defines a band—for ϕ varying over some interval, this defines a "bow-tie". Constraint (b) arises from considering the angle of force at the contact. Assume that the force is in the direction γ_R, a rotation center outside band R would give rise to net forces in a direction orthogonal to the hypothesized direction of force. If the contact force can actually lie anywhere inside the friction cone, we sweep the band to obtain another bow-tie. (b) also includes the result from [Mason 1982] that the rotation center cannot fall inside the friction cone. For constraint (c), we construct a line perpendicular to the finger velocity. Rotation centers above that line must be in region R of (b), and rotation centers below the line must be in region L of (b). (d) shows an example combining the constraints for a fixed δ.

ment, then, is to obtain at least some bounds on the possible motions. Figure 5 shows the bounds that we will use.

Given some bound on the possible rotation centers, we can proceed as follows. Circumscribe a rectangle, aligned with the finger face, about the set of possible rotation centers. Let the coordinates of the rectangle edges be x_r^+, x_r^-, y_r^+, y_r^-. It is easily shown that

$$y_r^- \le \frac{dx}{d\phi} \le y_r^+,$$
$$-x_r^+ \le \frac{dy}{d\phi} \le -x_r^-$$

where (x, y) describes the trajectory of the object vertex. If we compute these bounds for some fixed δ, letting ϕ vary over some interval, we can bound the variations in x and y:

$$y_r^+ \,\Delta\phi \le \Delta x \le y_r^- \,\Delta\phi,$$
$$-x_r^- \,\Delta\phi \le \Delta y \le -x_r^+ \,\Delta\phi.$$

for $\Delta\phi < 0$, as in the example. Let the origin be placed at the initial location of the contact vertex, then the final location is in the bounding rectangle $[x^-, x^+] \times [y^-, y^+]$, where

$$x^- = y_r^+ \,\Delta\phi,$$
$$x^+ = y_r^- \,\Delta\phi,$$
$$y^- = -x_r^- \,\Delta\phi,$$
$$y^+ = -x_r^+ \,\Delta\phi.$$

for $\Delta\phi < 0$. Although the details are not presented here, the bounds on the rotation center, y_r^- etc., are simple trigonometric functions of δ. Hence the bounds on the contact vertex, x^- etc., are trigonometric functions of δ, and linear in ϕ.

We can be confident of $\Delta\phi$ rotation by pushing at least as far as y^+ in the y-direction. However, it is almost certain that the rotation will be completed *before* the motion is complete, so we must also consider the pure translation of the object after rotation ceases. It is easily shown that if $|\delta| \le \alpha$, where $\alpha = \tan^{-1}\mu$, the object will translate in direction δ, otherwise it will translate in direction α.

These observations are summarized in figure 6. The path of the contact vertex, and the contact edge after rotation is complete, is bounded by a polygonal region of the plane. Letting (x_i, y_i) be a vertex of the bounding polygon, we can write

$$x_i - w < x_{h0} + y_i \tan\delta < x_i + w.$$

The x_i are 0, x^-, or $x^+ + l$, where l is the length of the edge, and the y_i are 0, y^-, or y^+. These are all simple trigonometric functions of δ, and linear in ϕ. In general, we obtain constraints of the form,

$$f_i(\delta)\,\Delta\phi + c_i - w < x_{h0} < f_i(\delta)\,\Delta\phi + c_i + w$$

where the $f_i(\delta)$ are trigonometric functions, and the c_i are constants. Figure 2(c) shows an example of these constraints plotted in the operation-space.

This analysis suffices for simple push grasps involving rotation about a single contact vertex. A more general anal-

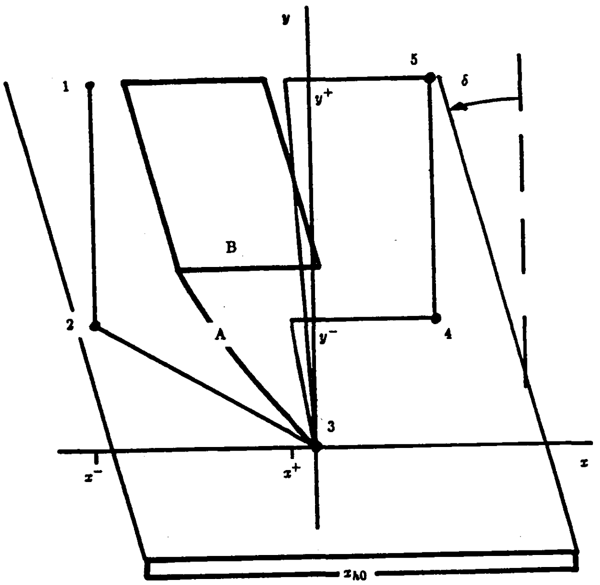

Figure 6. The region 12345 bounds the possible locations of contact of the object with the finger. A sufficient condition is that the area swept by the finger include this region. Also shown is the contact region for a typical motion. *A* shows the locus of the contact vertex as the object rotates, and *B* shows the region of contact after the rotation is complete.

ysis is required for complex grasps where the object may roll from one vertex to the next. The basic idea would be to repeat the above analysis for each vertex, and splice the envelopes together.

II.D. Related operations: squeeze–grasp and offset–grasp

The analysis of the push–grasp almost encompasses two similar operations, the squeeze–grasp and the offset–grasp. Both motions dispense with the preliminary pushing motion, and rely on pure squeezing for alignment and centering of the object. The offset–grasp requires that the reference finger makes first contact with the object, while the squeeze–grasp is indifferent to which finger hits first. The main difference in constructing the operation spaces is that a different set of rotation center bounds are required. Rotation center bounds for an example problem proved to be somewhat simpler than the bounds described in figure 5.

Constructing Stable Force-Closure Grasps

Van-Duc Nguyen [1]

Artificial Intelligence Laboratory
Massachusetts Institute of Technology
Cambridge, MA 02139

Abstract

This paper addresses the problem of synthesizing planar grasps that are force-closure and stable, with point contacts with friction. The synthesis of force-closure grasps constructs independent regions of contact for the fingertips, such that the motion of the grasped object is totally constrained. The synthesis of stable grasps constructs virtual springs at the contacts, such that the grasped object is stable, and has a desired stiffness matrix about its stable equilibrium.

A force-closure grasp implies equilibrium grasps exist. In the reverse direction, we prove that non-marginal equilibrium grasps with at least two point contacts with friction are also force-closure grasps. Next, we prove that all force-closure grasps can be made stable, by using either active or passive springs at the contacts.

The paper presents fast and simple algorithms for directly constructing stable force-closure grasps based on the shape of the grasped object. It develops a simple geometric relation between the stiffness of the grasp and the spatial configuration of the virtual springs at the contacts. The stiffness of the grasp depends also on whether the points of contact stick, or slide without friction on the edges of the object.

This report describes research done at the Artificial Intelligence Laboratory of the Massachusetts Institute of Technology. Support for the Laboratory's Artificial Intelligence research is provided in part by the System Development Foundation, and in part by the Advanced Research Projects Agency of the Department of Defense, under Office of Naval Researchcontacts N00014-85-K-0124.

1 Introduction

Robot end effectors have evolved from simple parallel grippers to multi-finger hands to provide greater flexibility and dexterity in manipulation and assembly operations. Robot hands come in many shapes, but they all have in common the ability of being programmed and servoed from a computer. To take full advantage of the dexterity offered by multi-purpose hands, we need to be able to not only *analyze* a grasp but *synthesize* it. In other words, we would like to *construct* grasps that have such features as feasibility, reachability, force-closure, equilibrium, stability, compliance, etc...

This paper addresses the problem of synthesizing grasps that are force-closure, equilibrium, stable, and compliant. Synthesizing a force-closure grasp is equivalent to finding places to put the contacts, such that these contacts totally constrain the motion of the grasped object. The contacts between the fingertips and the object are modeled as point contacts with friction. Constructing an equilibrium grasp is synthesizing the forces and moments at the contacts, such that the object is in equilibrium. Constructing a stable grasp is finding the independent virtual springs at the contacts, such that the grasp has a positive definite stiffness matrix. Constructing a compliant grasp is maping the desired stiffness matrix at the grasped object into the stiffness matrices at the fingertips and at the finger joints. The compliance model used is a generalized spring. We also explore how slip affects the force-closure and stability properties of the grasp.

1.1 A Grasp Planner

A Grasp Planner can construct a stable grasp G on a set of n edges or faces as follows:

- Synthesize a set of grasp points $\{P_1, \ldots, P_n\}$ for which the grasp G at these grasp points is force-closure. Better yet, we find the optimal set of independent regions of contact $\{s_1, \ldots, s_n\}$ for the given n grasping edges or faces. The regions are independent from each other, in the sense that as long as we pick grasp point P_i in region s_i the resulting grasp $G = \{P_1, \ldots, P_n\}$ is always force-closure. The set is optimal in the sense that the set of independent regions has the largest miminum radius for the given set of grasping edges or faces. We then pick the mid point of the region s_i as the optimal grasp point P_i.
- Synthesize a corresponding set of virtual springs, such that grasp G'is stable. Each virtual spring has stiffness k_i and compression σ_{io}. We prove that the stiffnesses k_i's and compressions σ_{io}'s of the virtual springs can always be chosen so as to make the grasp stable. We can also construct the set of virtual springs such that the grasp has some desired compliance center and stiffness matrix.

[1] The author is currently with General Electric Corporate Research and Development Center, in Schenectady, New York.

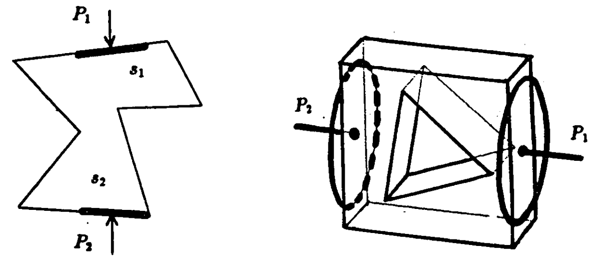

Figure 1: Examples of force-closure grasps found by the synthesis.

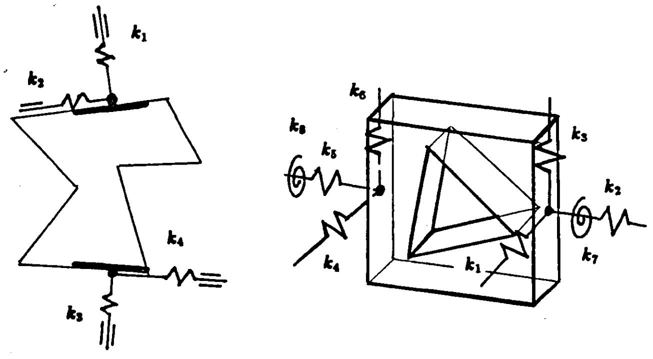

Figure 2: Examples of stable grasps found by the synthesis.

Figure 1 shows examples of force-closure grasps found by the algorithms. The independent regions of contact are highlighted with bold segments and circles. The grasp is force-closure no matter where the finger tips are placed in these regions. This flexibility is of great importance in manipulation since we always have positioning errors and many other uncertainties.

Figure 2 shows examples of stable grasps constructed by the algorithms. The stiffness matrix at the grasped object is mapped into the virtual springs at the contacts. These virtual springs are responsible for generating restoring forces and moments whenever the grasped object is displaced from its stable equilibrium.

1.2 Other Related Works

Related works can be grouped as follows:

- Feasible and reachable grasps. — Feasibility and reachability problems can be solved using the Configuration Space approach (Lozano-Pérez 1983), which grows the grasped object into a configuration obstacle in higher dimensional space, and inversely shrinks the fingers into a configuration point. The two problems become a search respectively for a feasible configuration point, and a path to that feasible point, such that the path does not intersect the configuration obstacle (Lozano-Pérez 1976, 1983).
- Force-closure grasps — Force-closure and total freedom capture the main constraint between the fingers and the grasped object. Ohwovoriole analyzed the geometry of the different repelling screw systems, and use the results to analyze systems of contacting bodies such as an object grasped by a set of fingers, or a pin being inserted into a hole (Ohwovoriole 1980, 1984). Related to force-closure is the solution of systems of linear inequalities (Kuhn and Tucker 1956).
- Form-closure grasps — A grasp is form-closure if the grasped object is totally constrained by the set of contacts, irrespective of the magnitude of the contact forces. Reuleaux (1875) proved that a 2D grasp needs at least four point contacts for form-closure. Lakshminarayana (1978) showed that a 3D grasp needs at least seven point contacts. Form-closure can be viewed as force-closure with frictionless contacts only.
- Equilibrium grasps — There are many works on analyzing the equilibrium of forces in a grasp with different types of contact (Salisbury 1982), with flexible contacts (Cutkosky 1984), or with friction (Abel, Holzmann and McCarthy 1985). Finding a good grasp is often formalized as a search of the space of all grasps with some goal function, such as optimum for internal forces (Kerr 1984), or security of grasp (Jameson 1985).
- Stable grasps — A stable prehension of a planar hand on a polygon can be found by centering the hand on the center of mass, and check for grasps that are stable with respect to rotation, then stable with respect to translation (Hanafusa and Asada 1977), (Asada 1979). Baker, Fortune and Grosse (1985) proved that stable grasps on a convex polygon exist, and presented efficient algorithms that require no incremental search.
- Compliant grasps — We can have active stiffness control of the fingers and the grasped object by using the Grip and Jacobian matrices as in (Salisbury and Craig 1981), (Salisbury 1984, 1982), or build in some proximity damping as in (Jacobsen, Wood, Knutti and Biggers 1985). Grasps can be achieved easily with active compliance and bounded slip at the fingers as in (Fearing 1984), or by exploiting the friction and passive compliance of the object with the fingers and the environment as in (Mason 1982, Brost 1986). Grasping a peg and inserting it into a hole is currently done best with a passive compliance wrist known as the Remote Center of Compliance (Whitney 1982).

2 Constructing Force-Closure Grasps

2.1 Representing Contacts and Grasps

Figure 3 depicts the different types of planar contacts with friction. The first column describes the physical contact with the finger on top and the grasped object below it. The second and third columns describe respectively the wrench convex, representing the range of forces that can be applied to the object, and the twist convex, representing the total freedom of the object. Each convex is represented by a minimal set of generating vectors. The twist convex is computed by taking the dual of the wrench convex.

a. *Point contact with friction* — The friction cone at the point of contact shows the range of pure force that can be applied through the point contact. The wrench convex has two wrenches which are along the two extreme rays of the friction cone. Any force pointing inside this friction cone can be written uniquely as a positive combination of the these two wrenches. The twist convex has two unisense translations, each reciprocal to one wrench and repelling to the other. It also has a free rotation about the point of contact as above.

b. *Edge contact with friction* — It is well known that, for rigid objects, any force distribution along the segment of contact is equivalent to a unique force at some point inside the segment. This unique force is mathematically the positive combination of two ranges of force at the two ends of the segment of contact. Specifically, the wrench convex of an edge contact with friction is equivalent to the convex sum of two wrench convexes, each represents a point contact with friction at one end of the edge of contact.

c. *Soft finger contact* — From a force-closure point of view, a soft finger contacting an edge is the same as an edge contact with friction. The pressure distribution is irrelevant to our current focus, which is concerned with whether the object can be constrained

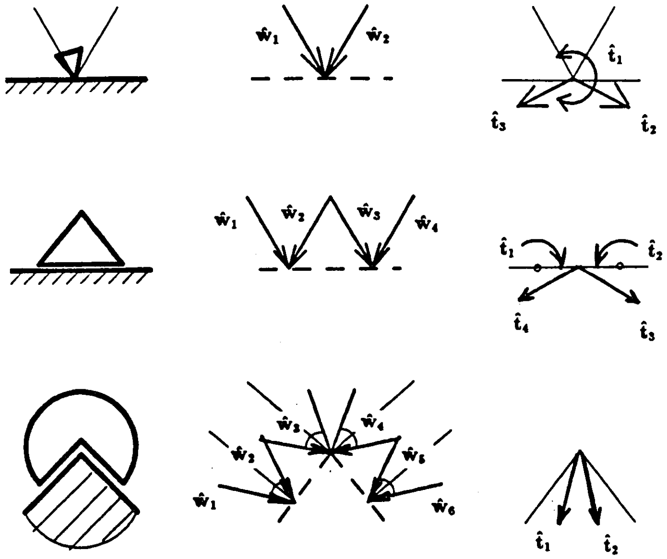

Figure 3: Planar contacts with friction and their twist and wrench convexes.

with the given contacts, rather than how much force should the fingers apply to the object.

A soft finger becomes more useful when it contacts on the inside or outside of a corner. Figure 3.c shows a soft finger contacting on the outside of a corner. The wrench convex is the convex addition of two convexes, each describes the edge contact with friction on one side of the corner. This wrench convex can be approximated by a much larger friction cone.

Gravity is not a contact, but it does play a role in constraining the total freedom of the object. For example, a box is immobile on a table because the force of gravity is holding it down to the table. We can view the box as being grasped, or more exactly constrained, by two contacts: a plane contact between the bottom of the box and the table, and an imaginary point contact at the center of gravity of the box.

Twist and wrench convexes are two dual representations for contacts. We can add wrench convexes from all the contacts or intersect the corresponding twist convexes to find the resulting wrench or twist convex of the grasp. We have two dual view points:

- A constraint view point. — Wrench convex describes the set of forces and moments which constrain the object. A total wrench convex means we can arbitrarily apply any force and moment on the object, and so we can grasp it, instantaneously rotate or translate it in any way we want.
- A freedom view point. — Twist convex describes the total freedom of the object. A total twist convex means the object can freely move relative to the fingers. A null twist convex means the object cannot break contact without external work against the contact forces exerted by the fingers.

For planning grasps, wrench convexes are definitely more efficient since generating wrenches can be deduced readily from the type of contact, and we can just take the union of all the generating wrenches to describe the grasp. The twist convex representation is more efficient for describing the total freedom at the end effectors of linked manipulators. The infinitesimal motions and the velocities of the end effector due to each joint are 'added'. The end effector can have arbitrary motion if the twist convexes of all the joints 'add up' to a total convex.

2.2 Resisting Translation and Rotation

The force closure problem can be formulated as solving a system of linear inequalities:

$$W^T \hat{t}^S \geq 0 \qquad (1)$$

where the columns of W are generating wrenches collected from all the contacts of the grasp. We can design a generate-and-test algorithm which enumerates all the possible grasps, and test each grasp by solving the above system of linear inequalities. We get a force-closure grasp if and only if there is no non-zero solution to the above system, i.e. zero total freedom. There are two main objections to this scheme: first, the set of possible grasps is infinite; second, the grasp synthesis uses an analytical formulation which does not exploit the geometry of the domain.

Polygonal objects have straight edges; contacts on straight edges have wrench convexes whose representations can be split into a convex set for the point contact, and a convex cone for the range of force directions. This property applies only to polygonal and polyhedral objects. A force (resp. infinitesimal rotation) is a line vector while a torque (resp. infinitesimal translation) is a free vector which does not depend on the point of contact. Our key contribution is to make the force-closure constraint explicit for polygonal objects.

Theorem 1 *A set of wrenches W can generate force in any direction if and only if there exists a three-tuple of wrenches $(\hat{w}_1, \hat{w}_2, \hat{w}_3)$ whose respective force directions f_1, f_2, f_3 satisfy:*

- *Two of the three directions f_1, f_2, f_3 are independent.*
- *A strictly positive combination of the three directions is zero.*

$$\alpha f_1 + \beta f_2 + \gamma f_3 = 0$$

The first (resp. second) condition corresponds to no homogeneous (resp. particular) solutions to the system $W^T \hat{t}^S \geq 0$, where twist $\hat{t} = (0, d_x, d_y)^T$ is an infinitesimal translation of the object. For detailed proofs the reader is referred to (Nguyen 1985a, 1986). Theorem 1 can be captured in a more suggestive and compact way, Figure 4, as follows:

Corollary 1 *A set of wrenches W can generate forces in any arbitrary direction if and only if there exists a three-tuple of force-direction vectors (f_1, f_2, f_3) whose end points draw a nonzero triangle that includes their common starting point.*

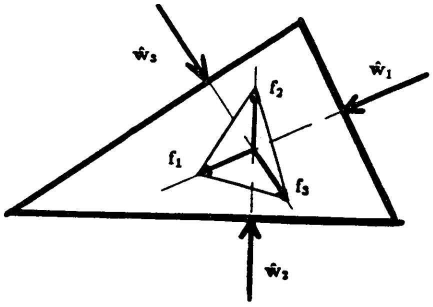

Figure 4: A geometrical view of force-direction closure.

Torque closure can be achieved easily by creating enough friction on some axis of rotation of the object. The friction between the rotating object and its supporting axis will create a torque which resists any clockwise or counter-clockwise rotation of the object. Unfortunately, in most grasp configurations, we have only point contacts, and through a point contact, a finger can exert only a pure force on the object and not torque. The more interesting problem is to achieve torque closure with only pure forces.

Theorem 2 *A set of planar forces W can generate clockwise and counter-clockwise torques if and only if there exists a four-tuple of forces $(\hat{\mathbf{w}}_1, \hat{\mathbf{w}}_2, \hat{\mathbf{w}}_3, \hat{\mathbf{w}}_4)$ such that:*

- *Three of the four forces have lines of action that do not intersect at a common point or at infinity.*
- *Let $\mathbf{f}_1, \ldots, \mathbf{f}_4$ be the force directions of $\hat{\mathbf{w}}_1, \ldots, \hat{\mathbf{w}}_4$. Let $\mathbf{p}_{12}$ (resp. $\mathbf{p}_{34}$) be the point where the lines of action of $\hat{\mathbf{w}}_1$ and $\hat{\mathbf{w}}_2$ (resp. $\hat{\mathbf{w}}_3$, and $\hat{\mathbf{w}}_4$) intersect. There exist $\alpha, \beta, \gamma, \delta$ all greater than zero, such that:*

$$\begin{aligned} \mathbf{p}_{34} - \mathbf{p}_{12} &= \pm(\alpha \mathbf{f}_1 + \beta \mathbf{f}_2) \\ &= \mp(\gamma \mathbf{f}_3 + \delta \mathbf{f}_4) \end{aligned}$$

The first (resp. second) condition corresponds to no homogenous (resp. particular) solutions to system $W^T \hat{\mathbf{t}}^S \geq \mathbf{0}$, where twist $\hat{\mathbf{t}} = (\delta_z, d_x, d_y)^T$ is an infinitesimal rotation of the object. For detailed proofs the reader is referred to (Nguyen 1986). Theorem 2 can be formulated in more geometrical terms, Figure 5, as follows:

Corollary 2 *A set of planar forces W can generate clockwise and counter-clockwise torques if and only if there exists a four-tuple of forces $(\hat{\mathbf{w}}_1, \hat{\mathbf{w}}_2, \hat{\mathbf{w}}_3, \hat{\mathbf{w}}_4)$ such that the segment $P_{12}P_{34}$, or $P_{34}P_{12}$, points out of and into the 2 cones $C_{12}^{\lessgtr}$, $C_{34}^{\lessgtr}$, formed by the two pairs $(\hat{\mathbf{w}}_1, \hat{\mathbf{w}}_2)$, and $(\hat{\mathbf{w}}_3, \hat{\mathbf{w}}_4)$.*

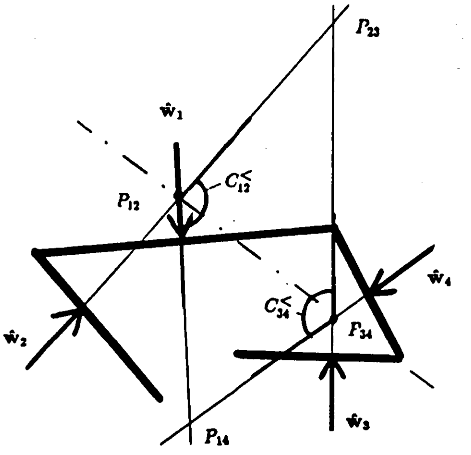

Figure 5: A geometrical view of torque closure.

2.3 Finding All Force Closure Grasps

The convex addition of the convex of all force directions $\mathrm{co}[f_x, f_y]$ and the convex of all torques $\mathrm{co}[m_z]$ is the convex of all planar forces $\mathrm{co}[f_x, f_y, m_z]$. So, the necessary and sufficient condition for force closure is contained in both Theorems 1 and 2. If we assume that through any contact we can only exert force and not torque, then Theorem 2 subsumes Theorem 1. A translation can be viewed as a rotation with point of rotation at the infinity. So, if there is no free rotation for the grasped object constrained by a set of contact forces, then there exists also no free translation. Thus Corollary 2 describes the geometrical necessary and sufficient condition for force closure with planar forces only.

Corollary 3 *Two point contacts with friction at P and Q form a force closure grasp if and only if the segment PQ, or QP, points strictly into and out of the two friction cones respectively at P and Q.*

Proof: This is a well known fact of planar mechanics. Let's however prove the above corollary using a reduction to Corollary 2. A friction cone at P (resp. Q) is equivalent to two forces $\hat{\mathbf{w}}_1, \hat{\mathbf{w}}_2$ (resp. $\hat{\mathbf{w}}_3, \hat{\mathbf{w}}_4$) along the edge of friction cone and going through P (resp. Q), Figure 6. We recognize that point P (resp. Q) is nothing more than the point P_{12} (resp. P_{34}). ∎

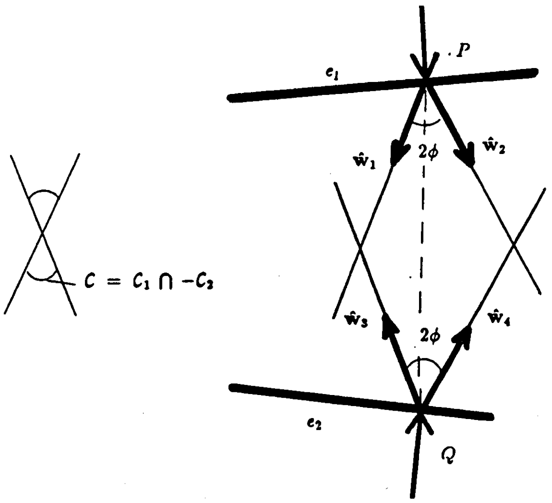

Figure 6: Finding grasps with friction on two edges.

Lemma 1 *The set of all possible grasps with friction on two edges e_1, e_2, denoted $\mathcal{G}(e_1, e_2)$, is completely described by the two edges e_1, e_2, and the counter-overlapping sector $C = C_1 \cap -C_2$ of the two friction cones resp. from edge e_1 and e_2.*

We have seen that a soft finger contacting at a vertex can be approximated as a point contact with a much wider friction cone. From Corollary 3, the larger the friction cones at the points of contacts, the greater is the likelihood that they counteroverlap, or that the grasp is force closure. So a soft finger gives us more flexibility than a point contact with friction. This partially explains why people grasp objects at edges and corners, and also why the contacting surface of human fingers had better be soft than hard like the finger nails.

By definition, a force-closure grasp is a set of contacts which allows us to exert arbitrary force and moment on the object by pushing at the contacts. So, we can exert zero force and moment, i.e. have an equilibrium grasp. In the other direction, it turns out that most equilibrium grasps with point contacts with friction are also force-closure grasps:

Corollary 4 *Let G be a grasp with at least two distinct point contacts with friction. G is a force closure grasp if it is an equilibrium grasp, and has contact forces pointing strictly within their friction cones.*

Proof: The two friction cones gives three lines of force which are not all parallel because the friction cones are not null. These three lines of forces do not all intersect at the same point because the two points of contact are distinct. So, we have three planar wrenches with independent spatial vectors. The set of contact wrenches is also force-closure, or vector-closure, if there exists a strictly positive combination of four contact wrenches that results in the zero wrench, or equilibrium. (The theorem for vector-closure has the same form as Theorem 1, except that we need at least $n+1$ vectors for an n-dimensional space.) The coefficients of the contact wrenches must be strictly positive, i.e. the contact forces must point strictly inside their respective friction cones. ∎

2.4 Finding Independent Regions of Contact

In task planning, we are interested in finding grasps that require as little accuracy as possible. One aspect of that goal is to have grasps such that the fingers can be positioned independently from each other, not at discrete points, but within large regions of the edges. Corollary 3 allows us to cast the problem of finding the independent regions of contact on two edges into a problem of fitting a two-sided cone cutting these two edges into two segments of largest minimum length, Figure 7.

Algorithm 1 *The independent regions of contact on two edges e_1 and e_2 can be constructed as follows:*

1. Find the two-sided cone $C^{\times}$ (I_1, $\pm C$) that cuts all of edge e_1 and very little or none of edge e_2. We get a triangle Δ_1 formed by edge e_1 and vertex I_1. This triangle represents the set of vertices I, where the two-sided cone $C^{\times}$ (I, $\pm C$) monotonically cuts larger segment e'_1 and smaller segment e'_2 as we move from edge e_1 to e_2. Similarly, we find the two-sided cone $C^{\times}$ (I_2, $\pm C$) such that this later cuts exactly the edge e_2 and very little or none of edge e_1. We get a triangle Δ_2 formed by edge e_2 and vertex I_2.

2. Find the trade-off region for vertex I by intersecting the triangle Δ_1 with Δ_2. The trade-off region describes the locus of vertex I, for which the two-sided cone $C^{\times}$ (I, $\pm C$) cuts both edges e_1 and e_2 into segments e'_1 and e'_2. The length of the independent segments e'_1 and e'_2 is proportional to the distance from vertex I of the two-sided cone to the respective edges.

3. We cut the trade-off region with the bisector of the two edges e_1, and e_2. The intersection is the locus of vertex I for which the two segments e'_1 and e'_2 have the same length. The optimal vertex I^* is at one of the two endpoints of the intersecting segment, or anywhere on this segment, depending on the angle between the two edges. If no intersecting segment exists, then the optimal vertex is the point of the trade-off region which is nearest to the bisector.

4. From the optimal vertex I^*, the independent regions of contact s_1 and s_2 are found by cutting the two-sided cone $C^{\times}$ (I^*, $\pm C$) with the grasping edges e_1 and e_2.

The computation of the optimum independent regions of contact for two point contacts with friction on two edges takes about 0.05 seconds. The code is written in Zeta Lisp, compiled and run on a Symbolics machine.

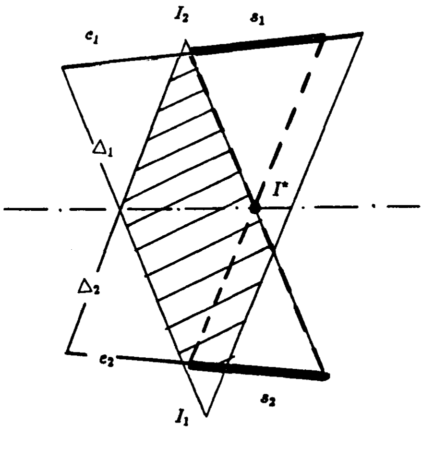

Figure 7: Finding the independent regions of contact on two edges.

3 Constructing Stable Grasps

3.1 Potential Function of the Grasp

Figure 8 shows a finger F_i contacting with friction at point P_i. The softness of the fingertip, the stiffness of the tendons attached to the finger, and/or the active control of the finger joints are all modeled by two virtual springs with linear stiffness k_i, k_j. The linear spring k_i has fixed line of action, with direction $\mathbf{k}_i = (\cos\alpha_i, \sin\alpha_i)^T$, and moment $\mu_i = \mathbf{p}_i \times \mathbf{k}_i$, about the origin O. (The cross product of two 2-dimensional vector is a scalar, which is the product of the two vector magnitudes and the sin of the angle between the two vectors.)

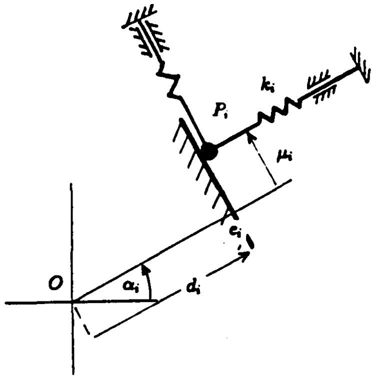

Figure 8: A fingertip which sticks is modeled by two linear springs.

We assume that there is no dissipation of potential energy in grasp, so the fingertips do not slide on the object. As the object is displaced by (x, y, θ), the point P_i is mapped into its new position P'_i given by:

$$\mathbf{p}'_i = \begin{bmatrix} C\theta & -S\theta \\ S\theta & C\theta \end{bmatrix} \mathbf{p}_i + \begin{bmatrix} x \\ y \end{bmatrix} \tag{2}$$

The linear spring k_i is compressed by an amount equal to the projection of the displacement $P_iP'_i$ onto the line of action of spring k_i:

$$\begin{aligned} \sigma_i(x, y, \theta) &= \sigma_{io} + (\mathbf{p}'_i - \mathbf{p}_i) \cdot \mathbf{k}_i \\ &= \sigma_{io} + \big((C\theta - 1)p_{ix} - S\theta p_{iy} + x\big)\ C_i \\ &\quad + \big(S\theta p_{ix} - (C\theta - 1)p_{iy} + y\big)\ S_i \end{aligned} \tag{3}$$

The potential function of grasp G is equal to the sum of the potentials of all its springs (Hanafusa and Asada 1977):

$$U(x, y, \theta) = \sum_{i=1}^{n} \frac{1}{2} k_i \sigma_i^2(x, y, \theta) \tag{4}$$

3.2 Grasp Equilibrium

Theorem 3 *A grasp G composed of n virtual springs is in equilibrium if and only if:*

$$\left\{ \begin{array}{lcll} \left.\frac{\partial U}{\partial x}\right|_{(0,0,0)} & = & \sum_{i=1}^{n} k_i\sigma_{io}\cos\alpha_i & = 0 \\ \left.\frac{\partial U}{\partial y}\right|_{(0,0,0)} & = & \sum_{i=1}^{n} k_i\sigma_{io}\sin\alpha_i & = 0 \\ \left.\frac{\partial U}{\partial \theta}\right|_{(0,0,0)} & = & \sum_{i=1}^{n} k_i\sigma_{io}\,\mu_i & = 0 \end{array} \right. \tag{5}$$

In the above columns, we recognize the spatial vectors $\hat{\mathbf{k}}_i = (\cos\alpha_i, \sin\alpha_i, \mu_i)^T$, describing the lines of action of the linear springs k_i, or as the unit wrenches describing the frictionless point contacts P_i. The above system of equations can be rewriten in a force-closure form:

$$\sum_{i=1}^{n} f_{io}\,\hat{\mathbf{k}}_i \;=\; \hat{\mathbf{0}}, \qquad f_{io} \geq 0 \tag{6}$$

where $f_{io} = k_i\sigma_{io}$. The force-closure condition is sufficient but not necessary for the existence of force equilibrium:

Corollary 5 *If grasp G is force-closure, then we can always find a set of positive contact forces at the points of contact, such that G is in equilibrium.*

3.2.1 Grasp Stability

The grasp G is stable if and only if the potential function $U(x,y,\theta)$ of G reaches a local minimum. The Taylor expansion of the potential function $U(x,y,\theta)$ about the equilibrium as follows:

$$U\,(x,y,\theta) \;=\; \sum_{i=1}^{n} \frac{1}{2}k_i\sigma_{io}^2 + \mathbf{x}^T\nabla\, U|_{(0,0,0)} + \frac{1}{2}\mathbf{x}^T\, H|_{(0,0,0)}\,\mathbf{x} + \ldots \tag{7}$$

where $\mathbf{x} = (x,y,\theta)^T$, and $H|_{(0,0,0)}$ is the Hessian matrix of the potential function at the equilibrium grasp configuration. A multivariable function reaches a local minimum if 1) the first partial derivatives are all zero, and 2) the Hessian matrix of the second partial derivatives is positive definite.

Theorem 4 *A grasp G composed of n virtual springs is in stable equilibrium if both of the following hold:*

- *The gradient $\nabla\, U|_{(0,0,0)}$ is zero.*
- *The Hessian matrix $H|_{(0,0,0)}$ of the potential function $U(x,y,\theta)$ is positive definite.*

$$H_O \;=\; \begin{pmatrix} \frac{\partial^2 U}{\partial x^2} & \frac{\partial^2 U}{\partial x\partial y} & \frac{\partial^2 U}{\partial x\partial\theta} \\ \frac{\partial^2 U}{\partial y\partial x} & \frac{\partial^2 U}{\partial y^2} & \frac{\partial^2 U}{\partial y\partial\theta} \\ \frac{\partial^2 U}{\partial\theta\partial x} & \frac{\partial^2 U}{\partial\theta\partial y} & \frac{\partial^2 U}{\partial\theta^2} \end{pmatrix} \qquad at\ (x,y,\theta) \;=\; (0,0,0)$$

$$= \begin{pmatrix} \sum k_i\cos^2\alpha_i & \sum k_i\sin\alpha_i\cos\alpha_i & \sum k_i\mu_i\cos\alpha_i \\ \sum k_i\sin\alpha_i\cos\alpha_i & \sum k_i\sin^2\alpha_i & \sum k_i\mu_i\sin\alpha_i \\ \sum k_i\mu_i\cos\alpha_i & \sum k_i\mu_i\sin\alpha_i & \sum k_i\mu_i^2 \;-\; \sum f_{io}d_i \end{pmatrix} \tag{8}$$

3.3 Stiffness Matrix of the Grasp

The stiffness matrix K of the grasp is equal to the Hessian matrix H_O about the stable equilibrium of the grasped object. The stiffness matrix K can be written as a sum of two matrices:

$$\begin{aligned} K \;&=\; K_S \;+\; K_P \\ K_S \;&=\; S\;K\;S^T \\ &=\; \begin{pmatrix} C_1 & \cdots & C_n \\ S_1 & \cdots & S_n \\ \mu_1 & \cdots & \mu_n \end{pmatrix} \begin{pmatrix} k_1 & & \\ & \ddots & \\ & & k_n \end{pmatrix} \begin{pmatrix} C_1 & S_1 & \mu_1 \\ \vdots & \vdots & \vdots \\ C_n & S_n & \mu_n \end{pmatrix} \\ K_P \;&=\; -\textstyle\sum_{i=1}^{n} k_i\sigma_{io}d_i \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix} \end{aligned} \tag{9}$$

The first matrix K_S is a product of three matrices SKS^T. S is an $3 \times n$ rectangular matrix, whose columns are the spatial vectors of the linear springs. The matrix S is called the *spatial configuration matrix* of the linear springs. K is an $n \times n$ diagonal matrix with positive stiffnesses of the springs on its diagonal. The product SKS^T is nothing more than the sum of the stiffness matrices of the individual springs expressed in the global frame of the hand.

The second matrix K_P comes from the second order variation of the compressions as the object rotates, $\partial^2\sigma_i/\partial\theta^2$. A more general expression of the position-dependent stiffness matrix K_P is:

$$K_P \;=\; \pm\sum_{i=1}^{n} f_{io}\,(\mathbf{p}_i\cdot\mathbf{k}_i)\begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix} \tag{10}$$

The sign is + (resp. −) if the fingers slide (resp. stick) on the grasping edges. The reader is referred to (Nguyen 1985b, 1986) for proofs. This sign makes outside-in grasps ~~more~~ less stable than inside-out grasps when there is friction and the fingers stick. The reverse holds for frictionless point contacts.

A force closure grasp implies that the set of contact wrenches spans the whole wrench space. If each contact wrench is generated by a linear spring, then the set of linear springs has spatial vectors that span the whole vector space. The spatial configuration matrix of the linear springs S has full row, and $K_S = SKS^T$ is positive definite. The compressions σ_{io} can be chosen small compared to the size of the grasped object, and $\sum k_i\sigma_{io}d_i$ is small compared to $\sum k_i\mu_i^2$. The stiffness matrix K of the grasp is approximatively equal to K_S, and is therefore positive definite. In other words, a force-closure grasp implies a stable grasp exists.

Corollary 6 *If grasp G is force closure, then we can always synthesize a set of linear springs at the points of contact, such that G is in stable equibrium.*

3.4 Compliance Center of the Grasp

The center of compliance of a planar grasp is the point about which the stiffness matrix K is diagonalized into two blocks. The grasped object behaves as though there are two linear and one angular springs attached to it. Figure 9.

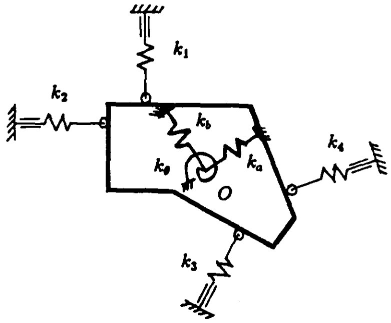

Figure 9: Compliance of the grasped object about its stable equilibrium.

The stiffness matrix K is diagonalizable with independent linear and angular springs if and only if:

$$\sum_{i=1}^{n} \mu_i k_i\,\mathbf{k}_i \;=\; \sum_{i=1}^{n} |\mu_i k_i|\;(sign(\mu_i)\,\mathbf{k}_i) \;=\; \mathbf{0} \tag{11}$$

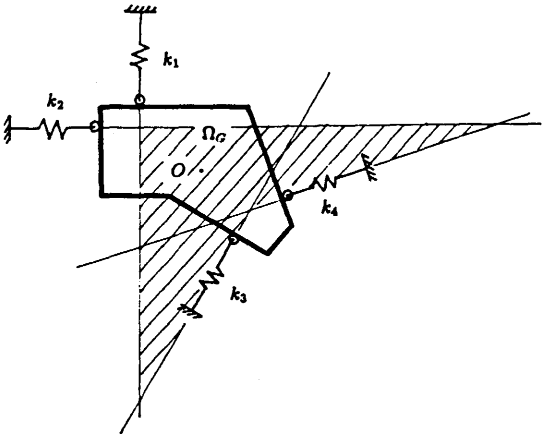

Figure 10: Compliance polygon of a grasp.

This condition is equivalent to the compliance center being inside a polygon delimited by the lines of action of the linear springs. Figure 10 shows the *compliance polygon* Ω_G within which the compliance center of grasp G must be.

We prove that if the grasp is force-closure then the compliance polygon always exists, and so equation (11) can be satisfied. Note that if grasp G is force-closure then the two cones generated by $(-\mathbf{k}_1, -\mathbf{k}_2)$ and $(-\mathbf{k}_3, -\mathbf{k}_4)$ counter-overlap in a non-zero convex polygon C_G, Figure 10. If we pick the compliance center O inside this convex polygon, then the springs k_1 and k_3, resp. k_2 and k_4, have negative, resp. positive, moments about O. One can check that there exists a positive linear combination of $-\mathbf{k}_1, \mathbf{k}_2, -\mathbf{k}_3, \mathbf{k}_4$ such that one walks counter-clock-wise along the boundary of the convex polygon bounded by the lines of action of the springs.

Corollary 7 *If grasp G is force-closure then the compliance polygon of grasp G, denoted Ω_G, is non empty. The compliance polygon Ω_G has boundary supports the lines of action of the linear springs.*

3.5 Finding Virtual Springs at the Fingertips

Figure 11 shows an interesting comparison between compliant fingertips that have passive and active stiffness. Examples of passive stiffness are real physical springs, like fingertips covered with rubber, or the Remote Center Compliance. With two fingers covered with rubber, the compliance center is not only fixed, but can only be inside a compliance rectangle with two diagonal corners at the two points of contact. The rectangle comes from the normal and tangential springs which model the rubber at the points of contact. The Remote Center of Compliance is a wrist built with fixed passive springs. The springs are designed such that the center of compliance is at the tip of the pin.

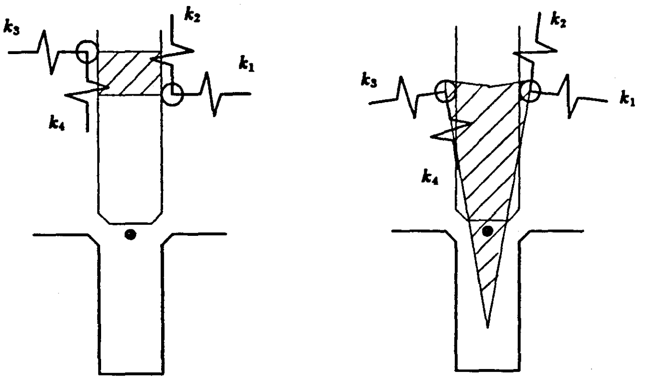

Figure 11: Pin and hole insertion with passive and active stiffness.

Active stiffness comes from stiffness control at the fingertips or at the joints. If the fingers have active compliance, then we can place and orient the virtual springs at the fingertips such that the compliance polygon overlaps the desired compliance center. So, we can not only make a force closure grasp stable, but also synthesize a compliance center for the grasp. The four virtual springs of a 2D grasp are typically computed in about 0.2 seconds on a Symbolics machine.

Algorithm 2 *Let G be a force-closure grasp with a desired compliance center O inside the compliance polygon Ω_G, defined by the lines of action of the n virtual springs. The n virtual springs at the points of contact can be synthesized so that G is stable as follows:*

1. Find a set of contact forces $(f_{1o}, \ldots, f_{no})$ such that force equilibrium is achieved. This is equivalent to solving a system of six equations with n unknowns.

2. From the desired compliance center O, find a set of positive spring constants $(k_1, \ldots, k_n)$ such that:

$$\sum_{i=1}^{n} \mu_i k_i \mathbf{k}_i \;=\; 0$$

where $\mathbf{k}_i$ and μ_i are respectively the direction and moment of the virtual spring k_i about the compliance center O. This is solving a system of two equations in n unknowns.

3. Check that the angular stiffness k_θ of grasp G is strictly positive:

$$k_\theta \;=\; \sum_{i=1}^{n} k_i \left(\mu_i^2 - \sigma_{io} d_i\right)$$

If not scale up the set of spring constants $(k_1, \ldots, k_n)$ and reduce the set of compressions $(\sigma_{1o}, \ldots, \sigma_{no})$, keeping the set of contact forces $(f_{1o}, \ldots, f_{no})$ unchanged, until k_θ is greater than zero.

4. Find the virtual compressions at equilibrium:

$$\sigma_{io} \;=\; \frac{1}{k_i} f_{io}$$

5. Output the set of spring constants $(k_i, \ldots, k_n)$, and the respective set of compressions $(\sigma_{1o}, \ldots, \sigma_{no})$ which model the set of virtual springs at the fingertips.

3.6 Controlling a Compliant Grasp

Figure 12 shows the relationships between force and instantaneous displacement at three different levels:

1. At the grasped object, we want to choose a compliance center and a stiffness matrix for grasp G such that the grasped object is stable and have restoring wrenches as follows:

$$\mathcal{F} \;=\; K_G \, d\chi$$

2. From the desired compliance at the grasped object, we would like to deduce the corresponding set of spring constants and compressions at the fingertips:

$$F \;=\; K_F \, dx$$

3. From the virtual springs at the fingertips, we then would like to derive the stiffness at all of its joints:

$$T \;=\; K_J \, d\theta$$

We can go further and derive the gains in the control loop of each joint, such that the above joint compliance is enforced. Or we can assume that each joint has a stiffness control loop with programmable stiffness.

From the kinematics of the grasp, the external and internal forces applied at the grasped object relate with the fingertip forces by the grasp matrix G^{-T} (Salisbury 1980, Salisbury and Craig 1981, Salisbury 1982). Similarly, from the kinematics of the linked fin-

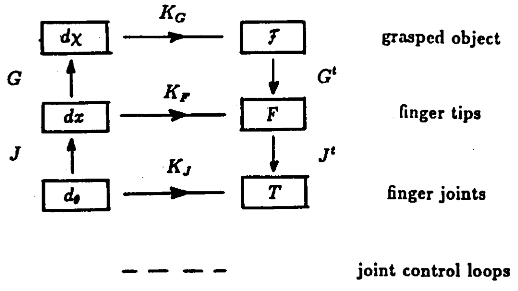

Figure 12: Linked chains and their loop equations.

gers, the force and velocity at each fingertip relate with its corresponding joint torques and velocities by the Jacobian matrices J^{-T} and J. We get loops from which we can derive easily the stiffness matrix of one level in terms of the stiffness matrix of another level. For example, given the desired compliance K_G at the grasped object, we deduce:

$$\begin{aligned} K_F &= G^T K_G G \\ K_J &= J^T G^T K_G G J \end{aligned} \qquad (12)$$

The grip matrix G^{-T} is an $n \times n$ matrix which relates the n external and internal forces applied at the grasped object to the n fingertip forces. K_G is an $n \times n$ generalized stiffness matrix at the grasped object which has the 6 linear and angular stiffnesses plus $n - 6$ internal stiffnesses. K_F is an $n \times n$ matrix which describes the springs at the fingertips, expressed in frames local to the points of contact. From the conservation of equivalent work at the object and at the fingertips, Salisbury and Craig deduced:

$$K_G = G^{-T} K_F G^{-1} \qquad (13)$$

The grip matrix G^{-T} has a $6 \times n$ block which is nothing more than the configuration matrix S. Note that S relates only the 6 external forces and moments at the grasped object to the n fingertip forces at the n springs. G^{-T} and S both capture the spatial configuration of the finger tip springs. The 6×6 stiffness matrix at the grasped object K, is a block of the generalized stiffnesss matrix K_G. The stiffness matrix K describes only the 6 linear and angular stiffnesses of the grasped object. We have shown that the stiffness matrix K of the grasped object is the sum of two matrices K_S and K_P:

$$\begin{aligned} K &= K_S + K_P \\ K_S &= S\, K\, S^T \end{aligned} \qquad (14)$$

$K = K_F$ if the local frames at the points of contact are oriented with the linear springs at the fingertips. So the grip matrix G^{-T} and the configuration matrix S both are only a first order approximation of the linkages between the grasped object and the fingertips. S is first order because its columns are spatial vectors $\hat{\mathbf{k}}_i$ which come from $\nabla \sigma_i$.

The second order approximation of the linkages between the grasped object and fingertips shows up as a position-dependent stiffness matrix K_P, which comes from the terms $\partial^2 \sigma_i / \partial \theta^2$. Our derivation of the stiffness matrix, Equations (9) and (10) is more accurate. The stiffnesses at the grasped object and at the fingertips are related not only by the conservation of total energy in the system, but also by the geometry about the grasp points. The geometry here is the point contacts which either stick or slide without friction on straight edges.

4 Grasping with Slip

4.1 Where Will The Fingers Slip To?

We need to find the direction towards which the fingers will slip, and calculate bounds on the places where the fingers will stick at, after slipping. A fingertip can be seen as being pulled by a virtual spring with the following stiffness behavior:

$$\begin{aligned} \mathbf{f} &= K(\mathbf{p}_o - \mathbf{p}) \\ \begin{bmatrix} f_n \\ f_t \end{bmatrix} &= \begin{pmatrix} k_n & 0 \\ 0 & k_t \end{pmatrix} \begin{bmatrix} \sigma_n \\ \sigma_t \end{bmatrix} \end{aligned} \qquad (15)$$

Figure 13 shows the regions where the fingertip will slip, stick, or loose contact. The stick region is a cone with angle $2\phi\frac{k_n}{k_t}$. It is defined as the region of the fingertip P where the contact force $\mathbf{f}$, generated by the virtual spring, points into the friction cone at the point of contact. The finger will slip towards the stick cone, and is pulled towards its bias position $\mathbf{p}_o$, which is fixed not relative to the grasped object, but relative to the base of the hand. When the object is displaced in the hand, the finger will stick and move with the point of contact, until it reaches one of the edges of the stick cone, then it slips.

The finger is guaranteed to stick inside the edge of contact, if the stick cone cuts in the interior of the edge of contact. This condition can be satisfied by a proper positioning of the bias position $\mathbf{p}_o$, and a proper ratio between the normal and tangential stiffnesses. The finger will not loose contact with the object, if the normal compression σ_{no} is always greater than the translational displacement of the object along this normal direction.

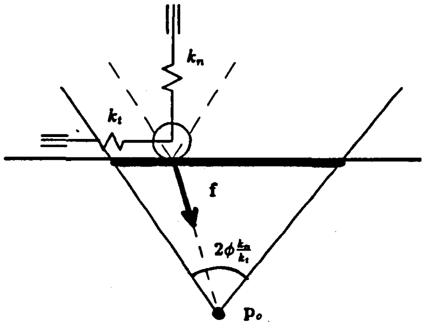

Figure 13: Stick and slip regions for the fingertip.

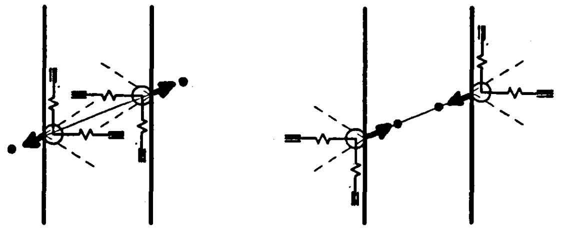

Figure 14: Places where the fingers will slip to.

Figure 14 shows two point contacts on a pair of parallel edges. Each point contact is pulled by a virtual spring towards its own bias position. As long as the stick cones intersect in the interior of the edges of contact, the fingers are guaranteed to stick on the contact edges. Better yet, the virtual springs can be synthesized such that the fingertips will stick inside the independent regions of contact. The bias positions of the virtual springs are constrained by the the equilibrium grasp condition, and so the compressions can only be scaled.

4.2 Effect of Slip on Force-Closure and Stability

We've seen that we can synthesize the virtual springs at the point contacts with friction, such that the fingers, if they slip, will always stick within the edges of contact. These fingers are pulled, independently from each other, towards their own bias positions. As the fingertip slips, the point of contact changes, and so either or both the spatial configurations of the normal and tangential springs change. We have shown that an equilibrium grasp with at least two point contacts with friction is also a force-closure grasp, if the contact forces point strictly inside the friction cones. In other words, if the fingers stick and the equilibrium is not marginal, then the grasp with friction is a force-closure grasp.

With stiffness at the contacts, a force-closure grasp implies a stable grasp, Corollary 6. So, after the fingers slip, the grasp at the points where the fingers stick is both force-closure and stable. To guarantee stability for rotations, the compressions at the linear springs must be small compared to the size of the object.

As the object slips, friction dissipates potential energy in the form of heat, and the total potential energy of the object is less. The potential energy of the object is the sum of the potential energy of the grasp, which is stored in the springs, and the gravity potential from the height of the object in the gravity field. In Figure 14.a, suppose the weight is perpendicular to the contact plane, and the fingers slips on the object, due to some impulse force with negligible work. There is no external work added into the system, and friction dissipates potential energy, so the two fingers will slide towards each other, and the grasp has a lower potential. So, as long as the contact edges are long enough, slip and disturbances make marginally stable grasp more stable.

5 Conclusion

We have presented a formal framework for analyzing and synthesizing grasps in 2D. Research is done in three areas: force-closure grasps, stable grasps, and grasps with possible slip at the contacts. The analysis and synthesis has been extended to grasps in 3D, and to curved objects. The reader is referred to (Nguyen 1986) for more details.

Acknowledgements

I would like to thank Tomás Lozano-Peréz, Kenneth Salisbury for many helpful discussions and for their constant encouragement. Part of the research on stable grasps has been done at the General Motors Research Laboratories during the summer of 1985.

OFF-LINE PLANNING FOR ON-LINE OBJECT LOCALIZATION

Tomás Lozano-Pérez
W. Eric L. Grimson

MIT Artificial Intelligence Laboratory
Cambridge, MA 02139

Abstract. Many robot applications require using sensors to locate objects whose initial pose is constrained but not exactly known. Most techniques for object localization assume that the object's pose is completely unknown. This paper describes a simple method for localizing known objects in a scene. We describe how an off-line computation that exploits constraints on the object's expected pose can be used to reduce the expected time for the on-line computation to localize the object. The objects treated here are modeled as polyhedra that, in principle, can have up to six degrees of positional freedom relative to the sensors.

0. Introduction

The problems of object recognition and localization have received a great deal of attention (see [Jain 86, Grimson and Lozano-Pérez 84,85] for reviews of the literature). Most approaches to recognition assume that the object's pose is entirely unconstrained. In most practical robotics applications, however, the uncertainty in part location is bounded to relatively small ranges. These constraints may come from knowledge of the feeding mechanisms or the physics of part stability. In most recognition systems, it is difficult to incorporate these type of constraints on the initial object pose. There have been a few systems where such information is readily incorporated, but the methods themselves have tended to be fairly complex [Bolles 76, Brooks 81, Goad 83, Baird 85, Faugeras and Hebert 83]. Nevertheless, the approach described here was significantly influenced by these previous methods, especially Goad's excellent paper. The localization algorithm described here is quite simple as is the mechanism for incorporating any available constraints on object pose. In the absence of any global constraints, the algorithm will still work, albeit more slowly.

The specific problem considered in this paper is how to locate a known object in a cluttered scene using sensors that provide dense position information. We assume that worst-case bounds on the pose of the object are available, as well as bounds on sensor measurement error. Our goal is to exploit the known bounds on object pose so as to reduce the amount of on-line computation required to localize the object. An important subgoal is that both the on-line and off-line methods should be simple enough to be easily implemented.

The method described here can be applied to both two-dimensional and three-dimensional sensing situations. In the two-dimensional case, objects have only three degrees of positional freedom relative to the sensor (two translational and one rotational). In this case, the sensors (and their pre-processors) are assumed to compute edges, that is, line segments in the scene. In the three-dimensional case, objects have up to three translational and three rotational degrees of freedom. In this case, the sensors (and their pre-processors) are assumed to compute planar patches in the scene. We do *not* deal with the general case in which only two-dimensional data is available but the object has more than three degrees of freedom. For the sake of brevity, we limit our discussion to the three-dimensional case; the specialization to two-dimensions is straightforward.

We assume that the objects of interest can be modeled as sets of planar faces. Only the individual plane equations and dimensions of the model faces are needed. No face, edge, or vertex connectivity information is required; the model faces do not even have to be connected. Because of this, the method can be applied to curved objects that are readily approximated by planar patches. Of course, such planar approximations are not adequate for all cases, for example, objects of high curvature or multiply curved surfaces.

We assume the availability of a sensor and pre-processor that can compute the planar patches present within some given rectangular sub-window of the scene. A great deal of work in computer vision has been dedicated to solving this problem of obtaining depth from two-dimensional visual data (see [Horn 86] for a representative sample). Other less computationally-intensive methods exist for obtaining the required patches, notably range sensing (see [Jarvis 83] for a review). We will not address this problem further.

In section 1, we present the basic on-line localization method. In section 2, we describe the off-line computations required for the on-line method. In section 3, we discuss the method and point out areas for further work.

1. A simple on-line localization algorithm

The process of localization is carried out in three steps:

- The first step is to identify possible assignments of sensed data to model faces consistent with a set of measurements derived from the model. This is the crucial step.
- The second step is to identify the pose of the object from each of these assignments.
- The third step is to pick the solution that best matches all the available data.

At this level of description, the method is similar to the *interpretation tree* method described in [Grimson and Lozano-Pérez 84, 85] and draws results from that earlier method. The method described in this paper differs in the first of these steps, while the earlier method does not do any hypothesis verification, the method described here goes very early into a hypothesize/verify cycle.

The current method is geared to situations where the set of possible matches of data patches to model faces can be constrained a priori. The goal is to reduce the combinatorics of the matching process in the earlier methods by exploiting the global position and orientation constraints.

1.1 Sensor Input

The on-line algorithm uses as input a list of the planar patches present in each of a set of windows specified by the off-line planner (see section 1.2). The patch must be completely within the window to be elegible. Each patch obtained by the sensor is characterized by a list of points and a plane equation in the form $\mathbf{n} \cdot \mathbf{x} = c$, where $\mathbf{n}$ is the unit normal to the plane. All the points are required to be inside the same face of the object. We represent patches by a set of points, instead of polygons, so as to simplify the processing and to accommodate a wide variety of sensors, including sparse sensors such as tactile sensors.

It is possible to use information about any patch feature, such as, size, color, reflectivity, and texture, to limit the possible model faces that a patch could match. The availability of these measurements can significantly reduce the combinatorics of the matching process. This is straightforward extension and we do not discuss it further.

1.2 Constraints from the off-line planner

The information from the off-line planner is used to reduce the combinatorics of the matching process. There are three sorts of constraints that are useful for this purpose: (1) restrictions on the data patches that can be involved in match a given model face, (2) restrictions on the model faces that can be involved in a solution, and (3) a ranked list of legal initial hypotheses. In particular, the off-line planner provides the following information for the on-line matching algorithm:

- A list of windows — each data patch is assigned to one or more rectangular windows in the scene.
- A list of matching constraints for each model face — each face requires that the patch that is matched to it be drawn from a specific window, furthermore there are constraints on the normal of the matching data patch.
- Ranges of possible measurements between pairs of model faces — these are used to check the consistency of assignments of patches to model faces.
- A list of visible face lists — these lists are indexed by the face pairs in the initial hypotheses and describe the faces visible if a particular hypothesis is correct.
- An ordered list of face pairs — these pairs are used to form initial hypotheses as to the object pose; they are ordered by size of the faces.

The windows could, in principle, be used to restrict the application of the sensor pre-processing to subsets of the scene. The windows, however, may overlap arbitrarily. In the general case, it is preferable to apply the sensor pre-processing to the whole scene and then assign the data patches to the corresponding windows. That is the strategy we have used. In simple situations where only a few windows are needed, it makes sense to limit the pre-processing to these windows. In any case, the main purpose of the windows is not to reduce the sensory pre-processing but to reduce the combinatorics of the matching process.

The key information computed by the off-line planner are the constraints on face assignments. Each face is restricted to matching a patch from a specific window. In fact, the windows are actually computed as the loci of particular model faces. The windows enforce the position constraints on faces derived from the global pose constraints. Associated with each face are constraints on the data patch normal that can match that face. This constraint is expressed as a list of cones, that is, center vectors and a minimum value for the cosine of the angle between the patch vector and the specified vector (see section 2). Also associated with each face is a window where the matching data patch must appear.

The off-line planner identifies those pairs of model faces that can appear in some view of the object consistent with the pose constraints. Of these pairs, the ones with significantly different orientation can be used to obtain an initial solution for the object's orientation. It is these pairs that drive the initial phase of the matching algorithm described in section 1.3.

The off-line planner also computes all the sets of model faces that can be simultaneously visible given the known pose constraints. These are used during the verification phase of the matching algorithm.

The object model provided by the user is described by a set of planar faces. Each face is specified by a polygon, which may be non-convex, and a plane equation. This form of the model is not particularly useful to the matcher. The off-line planner computes from this model three tables described below. Let $\mathbf{p}_i$, $\mathbf{p}_j$ and $\mathbf{n}_i$, $\mathbf{n}_j$ be respectively points on and normals to faces i and j.

- Distance — For each pair of model faces, i and j, the upper and lower bounds on distances between all possible pairs of points $\mathbf{p}_i$ and $\mathbf{p}_j$.
- Angle — For each pair of model surfaces, the angle between the face normals $\mathbf{n}_i$ and $\mathbf{n}_j$.
- Distance vector — For each pair of model surfaces, the upper and lower bound on the values $(\mathbf{p}_j - \mathbf{p}_i) \cdot \mathbf{n}_i$ and $(\mathbf{p}_j - \mathbf{p}_i) \cdot \mathbf{n}_j$, that is, the component along the face normals of vectors connecting the faces.

In each case, the values in these tables take into account the error bounds on measuring both the patch normals the positions of points. Algorithms for computing these tables are found in [Grimson and Lozano-Pérez 84]. The combination of these three types of measurements has been shown to be quite powerful in discarding invalid matches even in the presence of significant measurement error [Grimson and Lozano-Pérez 84, 85].

1.3 The matching algorithm

The matching algorithm is very simple and is based on the assumption that the set of data patches that can match a given model face is relatively small (this is up to the off-line planner to guarantee). The method works by considering each of the possible model face pairs determined by the off-line planner as suitable for constructing an initial hypothesis. The first step is to find all the pairs of data patches that can be matched to the face pair under consideration. The data patch pair must satisfy the following conditions:

- Each data patch must come from the window specified by the off-line planner for the corresponding face.
- The measured normals for the data patches must be within one of the cones associated with the corresponding face.
- The three sets of measurements (distance, angle, and distance vector) for the data patch pair must be consistent with those of the model face pair.

We could find such data pairs by looking at all combinations of patches, but that would be time consuming. It is straightforward to improve the expected performance by using hashing. Simply pre-process all pairwise combinations of data patches and place them into buckets based on the angle between their normals. Then, given a candidate pair of model faces, one can in constant time limit the data patch combinations to those whose angle is within the measurement error of the angle between the model faces. Only these data pairs need to be subjected to further testing.

Having obtained the feasible matches to a model face pair, the next stage is to use them to obtain supporting evidence for particular combinations of visible faces. Note that the match of two data patch normals $(\mathbf{n}_i, \mathbf{n}_j)$ to two independent model face normals $(\mathbf{m}_i, \mathbf{m}_j)$ determines uniquely (up to a sign) the rotation matrix R, where $R\mathbf{x} + \mathbf{p}$ is the transformation that maps points, $\mathbf{x}$, in the model coordinate system to vectors in the sensor coordinate system.

The rotation matrix R can be easily computed in the form $Rot(\mathbf{r}, \theta)$, where $\mathbf{r}$ is the axis of rotation and θ is the rotation angle. The axis of rotation is the unit vector in the direction

$$(\mathbf{m}_i - \mathbf{n}_i) \times (\mathbf{m}_j - \mathbf{n}_j)$$

and the angle of rotation can be obtained from these two relationships

$$\cos\theta = 1 - \frac{1 - (\mathbf{n}_i \cdot \mathbf{m}_i)}{1 - (\mathbf{r} \cdot \mathbf{n}_i)(\mathbf{r} \cdot \mathbf{m}_i)}$$

$$\sin\theta = \frac{(\mathbf{r} \times \mathbf{n}_i) \cdot \mathbf{m}_i}{1 - (\mathbf{r} \cdot \mathbf{n}_i)(\mathbf{r} \cdot \mathbf{m}_i)}$$

For a detailed derivation see [Grimson and Lozano-Pérez 84].

Using R we can compute for each potentially visible face on the object, the nominal data patch normal that can match that face. We must take into account measurement errors when matching the predicted normal to actual measured normals.

The match also constrains the translation vector, $\mathbf{p}$, to be on a line determined by the planes of the two measured patches. The range of values of $\mathbf{p}$ can be determined as follows: Let the equation of the patch planes be of the form $\mathbf{n}_i \cdot \mathbf{x} = c_i$ and the equation of the model planes be of the form $\mathbf{m}_i \cdot \mathbf{x} = d_i$. Then we can write $\mathbf{p}$ as a one parameter family of vectors:

$$\mathbf{p} = \alpha\mathbf{n}_i + \beta\mathbf{n}_j + \gamma(\mathbf{n}_i \times \mathbf{n}_j)$$

where γ is the free parameter and

$$\alpha = \frac{(c_i - d_i) - (\mathbf{n}_i \cdot \mathbf{n}_j)(c_j - d_j)}{1 - (\mathbf{n}_i \cdot \mathbf{n}_j)^2}$$

$$\beta = \frac{(c_j - d_j) - (\mathbf{n}_i \cdot \mathbf{n}_j)(c_i - d_i)}{1 - (\mathbf{n}_i \cdot \mathbf{n}_j)^2}$$

The parameter γ can be constrained by requiring that all the points in the data patch be mapped by the resulting transformation to be *inside* the model face. In our implementation, we compute bounds on γ by considering the set of translations that map the center of area of the patch onto each of the vertices of the face.

Let each potentially visible face have plane equation $\mathbf{m}_k \cdot \mathbf{x} = d_k$. Given the range of $\mathbf{p}$ we can compute not only the predicted normal, $R\mathbf{m}_k$, for a matching data patch but also the range of values of the offset c in the plane equation of the data patch: $c = d_k + (R\mathbf{m}_k) \cdot \mathbf{p}$, where $\mathbf{p}$ is parameterized by γ.

We also know, from the off-line computation, the window in which the data patch must appear. Thus, the initial verification process consists of checking the windows for patches satisfying the position and orientation constraints. Of course, once a third independent patch is found, the position and orientation can be determined uniquely up to the sensing error.

Once a feasible pairing of model faces and data patches, together with the corresponding object pose(s), is found there still remains a detailed verification process. This proceeds in two steps: (1) check that the patch points are all mapped to the inside of the face polygon by the computed transformation and (2) check that the patches measured in each of the windows are consistent with the computed model pose, that is, that no data patch has been measured to be *below* where the model predicts a surface to be. Note that if a data patch is above a predicted surface then this is neutral evidence, since this situation could arise from occlusion. Nevertheless, one wants to ensure that a hypothesis accounts for a sufficiently large percentage of the object's measured surface.

The matching process described above should be carried out in "depth-first" fashion, verifying each hypothesis as it is generated, rather than in "breadth-first" fashion, finding all the hypotheses and then verifying each one. Doing the matching depth-first allows us to terminate the matching once an adequate match is found. Observe that if the object were completely visible, each and every initial hypothesis should lead to a complete and correct interpretation. This points out the redundancy of examining all the initial hypotheses. In practice, face occlusion requires that we be ready to examine all the possible pairings even though we seldom will. Note that in the depth-first mode the ordering of the hypotheses by likelihood of locating the faces can significantly reduce the expected time to verify the hypothesis.

Let us quickly recap the flow of control in the on-line matcher. First, the sensing is done within a window guaranteed to contain all the faces. All the data patches are found and allocated to any windows that completely contain the patch. The matcher then proceeds through its list of legal face pairs attempting to form initial hypotheses and then verify them. Once an acceptable hypothesis is found, the matching stops. For each face pair, the matcher looks for a patch pair that has the appropriate angle between the normals. Each patch must be in the appropriate window for the matching face and satisfy the orientation constraint. Also, the assignment of the two faces to the two patches must pass all the pairwise constraints derived from the model. Only after all these test are satisfied does the matcher have a valid initial hypothesis. The next step is to verify the hypothesis. First, a potentially visible face is chosen, its orientation and range of displacements predicted and then its presence verified. If a matching patch is located, the pose of the object can be computed and all the other face predictions checked. A completeness score (based on correctly predicted area) is computed for the hypothesis.

1.4 Complexity

The matching method described above can be used with a single window and no off-line computation. In that case it has a worst-case complexity $O(n^3m^3)$ where n is the number of faces in the model and m is the number of data patches in the scene. This naive bound is simple to derive: The outer loop considers all n^2 permutations (with repetition) of the n model faces, for each such pair it tests for consistency all $m(m-1)/2$ pairwise patch combinations (without repetition). In the worst case, each pair of these $O(n^2m^2)$ combinations needs to be examined further. The further computation requires checking for each of the n faces of the model, each of the m data patches.

This bound for matcher performance is for the very worst case. The angle bucketing described above should improve the expected performance. In this version of the algorithm, one still has the $O(n^2)$ outer loop, but one expects significantly fewer than $m(m-1)/2$ data patches will have to be considered. Having found a pair of model faces and data patches, they can be tested for consistency with the distance, angle, and distance vector constraints. This will further reduce the combinatorics of the method. Of course, the actual performance will depend on the object model and the measured data. The worst performance will be for a very symmetric object such as a cube.

Thus far, we have not considered the effect of having a priori bounds on the object pose. In the absence of such bounds we are limited to using coordinate-frame independent constraints, such as angles between pairs of faces. Once we know bounds on the pose of the object, we can constrain individual matches. For example, suppose we knew that the object was in some particular stable pose on a horizontal table, then the z component of each face normal is known within the measurement error. Given a candidate model face, only data patches whose normals have z components in the appropriate range need be considered as matches. This reduces the effective number of data patches to be the expected number of data patches with the same z component.

The matching algorithm described in section 1.3 is aimed at exploiting this type of constraint. The windows enforce global position constraints and the angle cones associated with each model face enforce global orientation constraints. The purpose of these constraints is to minimize the number of data patches that can match a model face. In the ideal case, only a single patch can match each face and the whole algorithm boils down to finding three visible data patches.

These constraints, therefore, affect only the inner loop of the matcher; there still remains a potentially $O(n^2)$ outer loop. The algorithm attempts to reduce the expected number of initial hypotheses that need to be verified in two ways. The pre-processing of the pairs of model faces serves to capture other global constraints such as the fact that parallel faces cannot be used for the initial hypothesis and that not all pairs of faces can be visible simultaneously. These constraint tend to reduce the number of initial pairs well below the n^2 value. The constraints derived from the model (distance, angle, etc.) are used to prune out those initial hypotheses that remain before any detailed prediction and verification is done.

1.5 Example

Here, we consider a simple example of the matching algorithm; figure 1 outlines the stages of processing. Figure 1A shows three-dimensional depth data of a very cluttered scene obtained with a structured light range sensor, figure 1B shows the model of the target object given by the user, figure 1C shows the result of pre-processing the depth values to obtain planar patches, figure 1D schematically suggests the matching process of patches to faces, and figure 1E shows the resulting localized object superimposed on the original scene.

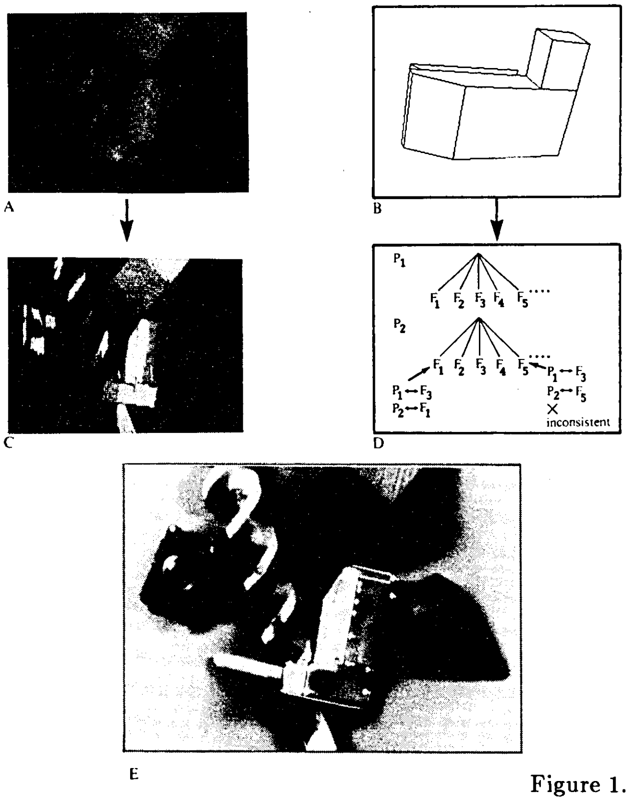

Figure 1.

Note that the matching algorithm can operate with no bounds on the pose of the input object. In that case, there is a single window within which all data patches can be found, also, there are no global constraints on the orientation of matching patches. The constraints that remain in effect are the pairwise matching constraints derived from the model, the pairwise visibility constraints, and the constraint that face pairs for the initial hypothesis have independent normals. Under those circumstances, the algorithm finds 865 legal initial hypotheses in the scene shown in figure 1. Recall that an initial hypothesis is an assignment of a pair of model faces to data patches that satisfy all the constraints. Note that for this example $n = 12$ and $m = 30$, so the worst case is 62,640 potential hypotheses. This illustrates that even in the absence of global pose constraints, the coordinate-frame independent constraints are quite powerful.

Continuing the example, assume that the target object's pose is constrained so that all the patches are within a smaller window (say with $m = 15$). This constraint reduces the number of potential initial hypotheses by roughly a factor of four (15,120). Furthermore, assume two specific faces can be constrained to smaller sub-windows (see figure 2), each with at most five patches in it ($m = 5$). Then, the upper bound on the legal number of initial hypotheses, even without considering the other geometric constraints is cut by approximately a third (10,540). We can also exploit the fact that the two front faces and two back faces can never be simultaneously visible, similarly the two top faces and the bottom face. This eliminates an additional

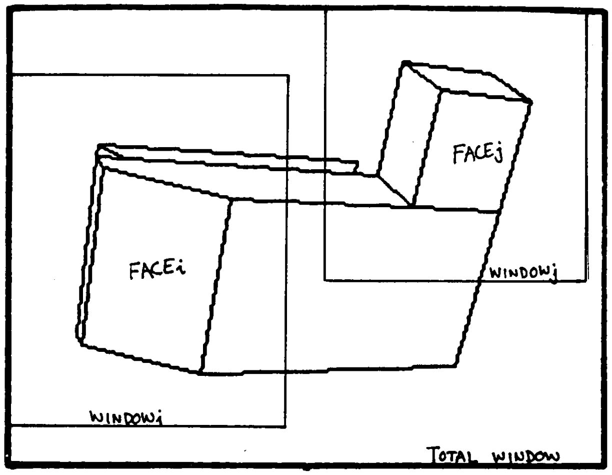

Figure 2.

1260 possible hypotheses. All of these numbers address the worst case bound; as shown above the actual number of hypotheses is typically substantially less. In the example shown above, of the 865 legal pairwise interpretations, 642 satisfy the window constraints described above.

In addition to the window constraints, there are global face orientation constraints that reduce the expected number of patches that can be assigned to the faces. These constraints will effectively reduce the value of m within the windows. As we saw above, reducing m produces large reductions in the possible number of hypotheses. For example, if the expected value of m can be uniformly reduced to 5, then the upper bound on the hypotheses (without the visibility constraint) is only 1040. The visibility constraint prunes an additional 120 potential hypotheses. The actual implementation actually had to consider 266 initial hypotheses.

2. The off-line planner

The efficiency of the off-line planner is not as crucial as that of the matching algorithm. Accuracy is not essential either; the only requirement is that the bounds be conservative. Therefore, we have adopted essentially brute-force sampling techniques for all the computations of the off-line planner.

2.1 Windows for the faces

Windows can be computed as rectangular bounds on the loci of the face's vertices over the range of legal poses. That is, the legal orientations of the object are sampled and the position of each face's vertices are computed. An enclosing rectangle is computed for the vertices of each face and updated so as to include all the point positions. This rectangle is then swept over the range of legal x, y translations of the object (also a rectangular range).

This computation generates a rectangular window for each face. Windows that overlap by some large fraction of their area are merged to form a single window. This is done to reduce the amount of computation that the sensory pre-processor needs to do when it assigns patches to windows. A window that contains all the other windows is also computed; this window bounds the area where sensor processing needs to be done.

2.2 Face orientation constraints

The global orientation constraints on the faces are represented as a set of cones for ease of testing. This can also be computed while sampling the range of object orientations. We proceed by tesselating the Gaussian sphere into the faces of an icosahedron. This gives us twenty uniformly distributed orientation buckets, represented as cones whose center vectors are the normals of the iscosahedron's faces. As we sample the orientations of the object, we keep track of which of these buckets the normal of each face falls in. This list of buckets is a conservative representation of the constraint on the orientation of the data patch that can match a face.

2.3 Visible faces

Potential visibility is determined by examining the sign of the component of the face normal along the sensing direction. This is what is known in graphics as "back face" elimination, rather than a full visible surface computation. The combinations of visible faces are also computed as the orientations of the object are sampled.

2.4 Face pairs

The planner constructs the list of all pairs of simultaneously visible faces whose normals make an angle greater than a predefined threshold ($\pi/6$ in our case). The list is ordered so that pairs involving large faces are at the front of the list. These are the most likely faces to be visible in spite of occlusion.

2.5 Pairwise geometric constraints

See [Grimson and Lozano-Pérez 84] for a description of how these constraints can be computed for polyhedral models.

3. Discussion

The algorithm presented in this paper is primarily based on a prediction/verification style: predicting the orientation and positions of faces in the model and verifying the presence of consistent data patches. The hypotheses are driven off of pairwise matches of faces to patches and it is the number of possible matches at this level that determines the performance of the method. In the unconstrained case, the algorithm needs to examine a large number of initial hypotheses. By considering some simple constraints arising from global constraints on the object pose, the number of legal initial hypothesis is significantly reduced to a manageable number. Recall that the actual prediction and verification process is already reasonably efficient so that hundreds of hypotheses can be evaluated in a matter of seconds.

Initial indications are that the method performs extremely well when the pose of the object is tightly constrained. As the range of possible poses grows, the performance reaches a plateau dictated by the performance of the algorithm in the absence of constraints. Of course, this limiting performance is a non-linear function of the number of faces and number of data patches. Future work will attempt to derive better expected bounds on the performance of the algorithm.

The main advantage of the method described here is its simplicity. The major limitation of the algorithm is its reliance on planar face approximations; extending the approach to curved objects would not be straightforward. Another disadvantage is the relatively weak coupling between the sensor processing stage and the matching. In principle, a tighter coupling could be implemented so that the amount of sensor processing could be reduced. On the other hand, the simplicity of the algorithm is due largely to the fact that the pre-processing is simple and uniform.

The on-line matching algorithm described in section 1 has been implemented on a Symbolics Lisp Machine; the off-line planner is currently being implemented. The testing of the on-line method has been done with simple window and orientation constraints specified by the user.

Acknowledgments

We thank Philippe Brou for kindly providing the laser ranging system with which we obtained the data reported in figure 1. Abstract

AML/X is a modern general purpose high level programming language, aimed at applications in manufacturing and computer aided design. It includes features for both conventional and object-oriented programming. The AML/X interpreter is implemented in C and has been ported to IBM 370, Motorola 68000, and IBM PC hardware, running under CMS, UNIX, XENIX, and DOS. This paper describes the rationale for AML/X and gives an overview of the language itself.

1.0 Introduction

Architects of industrial automation systems make a trade-off between two goals: ease of use and flexibility. A decade ago, when computers were far more expensive, these goals were seen as competing alternatives.

Historically, many industrial automation systems limited their flexibility to the minimum requirements of some (hopefully) large class of users, but no more. Those users then specified applications with a minimal language, which was simple and easy to learn. An example of this approach in robot programming was teaching by showing, in which the user manually moves a robot through a sequence of motions, recording them for later replay[1]. The disadvantage is the lack of a growth path: once the user's needs exceed the flexibility provided, the system becomes ineffective.

Clearly, there is significant benefit in providing systems with much greater flexibility. Generally, this flexibility is achieved by deferring certain choices until as late as possible. For example, a robot achieves more flexibility than fixed automation by deferring the choice of motions from the time the equipment is designed until it is actually used.

Flexibility gained by deferring choices implies the need for a much richer *language* in which to specify the choices to be made. The challenge for the system architect is to layer this language so that ease of use is not sacrificed. As computers decline in cost, this approach of layering is becoming an increasingly practical means of combining flexibility with ease of use.

One begins at the bottom layer with as much flexibility as one can afford (more on this later) and a language for specifying the remaining choices. The language must be expressive enough to allow the most sophisticated users to take advantage of the flexibility included. Perhaps less obvious, but equally important, the language must provide mechanisms for composing higher layers, each essentially a new language, with less flexibility and fewer remaining choices than the preceding layer. The highest layers, those with the least flexibility, provide ease of use for unsophisticated users along with potential growth to lower, more flexible layers.

This is the context in which we have designed AML/X, a general purpose programming language tailored for use in manufacturing and computer aided design. Its roots are in AML[2], a programming language originally developed for use in a research robot system[3] and subsequently made available as the programming language of the IBM 7565 Manufacturing System. AML also saw use as the base language for AML/V, an industrial machine vision programming system built as an extension to the research robot system[4]. AML/X is the result of a major redesign of AML and is part of the programming environment for our research activities in robotics[5], machine vision, and computer aided design. As such, it is likely to continue to evolve. It is also the basis for AML/2, the programming language for IBM's new 7575 and 7576 Manufacturing Systems.

This paper describes the rationale for the design and implementation of AML/X, provides a brief overview of the language, and illustrates its use. For brevity and clarity this paper emphasizes the use of AML/X in robotics; however, AML/X is actively used in our research in machine vision, workcell layout, and computer aided design. The next section outlines our objectives and their influence on the design of AML/X. This is followed by an overview of the basic structure and facilities of AML/X, just enough to provide the flavor of the language and to be able to follow subsequent examples. (A detailed description of AML/X is available in [6].)

2.0 Design Rationale

2.1 Guiding Principles

Designing a programming language requires balancing the many conflicting requirements of the anticipated user community. To help achieve this balance we have tried to follow a few broad, general principles, against which specific design decisions could be evaluated.

First among these is Hoare's dictum[7] that the language designer's task is one of "consolidation, not innovation." In keeping with that principle, we have not introduced any radically new constructs in AML/X. Instead, we have chosen from

CH2345-7/86/0000/0145$01.00 © 1986 IEEE

among constructs and ideas that have been tested in other languages and have tried to integrate them into a consistent, coherent whole. LISP, APL, and SMALLTALK have had an especially strong influence.

The second guiding principle is to prefer general purpose constructs to those meeting specific, limited, application needs. A corollary is that it must then be easy to provide layers that adapt general purpose features to meet the specific needs. For example, AML/X's interactive debugging tools are a small extension of a very general exception handling mechanism. These principles keep the language a coherent whole, rather than an accumulation of features. In practice, this has been very difficult. When an important user requests a specific new feature, it is hard to say no.

The third principle is orthogonality, which demands that separate features be separate, that is, that the legality and meaning of the use of a construct should be independent of its use in combination with some other construct. Orthogonality aids in achieving generality, but also makes it easier to write obscure programs. It can also be difficult to achieve in a practical implementation. For these reasons, we have occasionally violated orthogonality, but not without careful thought.

These three principles are helpful, but they do not substitute for an understanding of the anticipated applications of the language.

2.2 Language Design Criteria

We have designed AML/X keeping in mind three major areas of use: robot programming, machine vision programming, and computer-aided design (primarily of mechanical objects and assemblies, see e.g. [8]). An analysis of the requirements of robot programming and a survey of existing robot programming systems appears in [9]. Requirements for machine vision programming and an abstract language for vision programming (which could be embodied in many ways) are described in [10]. Some issues in programming languages for CAD systems and a particular language design are discussed in [11].

In all three areas, flexibility has historically been sacrificed, primarily to achieve ease of use. As a consequence, existing systems rarely exploit the intrinsic similarities between these domains. For example, all three domains deal with mechanical objects, assemblies, geometric algorithms, and transformations in 2 and 3 dimensions.

In the future, applications will expand in all three domains, and there will be increased need in industry to integrate them. It is therefore desirable to have a single language that can effectively deal with robotics, vision, and CAD.

In the following subsections we discuss the implications of the intended uses of AML/X.

Classes of Users: Roughly speaking, we anticipate three classes of users. *End users*, such as manufacturing engineers or mechanical designers, are the people who specify the operations to be carried out by the automation or CAD system. They typically have little programming skill, but need to be able to "chain together" sequences of pre-existing, relatively high-level commands, possibly including some simple control flow. *Application developers* write application packages, programs that provide facilities for use by a small class of end users. In a sense, an application package decreases generality while increasing ease of use for a particular class of users. Application developers typically have some programming skill and a deep knowledge of the application area. Often they produce new application packages by building a layer on top of an existing, more general program. *Application development environment developers* write the (typically) large systems application developers use. Robot programming and CAD systems are examples. They need both very high programming skill and a reasonably deep knowledge of the application area. This mix of users and the way they work has had an important influence on the language design.

Most significantly, the language must be a modern, general purpose language well-suited to developing large, layered systems. It must support the definition and use of abstract data types and have facilities for manipulating strings, complex data structures, and symbolic information. A general exception handling mechanism is essential so that an application can "catch" exceptions from lower layers, thus avoiding the incomprehensible error messages to end users that would otherwise result.

At the same time, the language must be simple, or at least have simple subsets, so that it is accessible to end users. However, as Hoare has observed[7], subsetting is simpler said than done, because an errant program can invoke some language feature outside of the subset. It is therefore important to be able to selectively disable or hide portions of the language. Moreover, the use of subsets increases the need for consistency and lack of special cases to provide an easy growth path for users who become more sophisticated over time.

Robot Programming: Our experience with several generations of robot system[3, 12, 13] has confirmed that specification of manipulator motion represents only a small, though very important, proportion of the total code required for a working robot application. Other components include I/O for auxiliary devices and communications, operator interfaces, calibration and setup routines, bookkeeping, access to manufacturing data bases, etc. The failure of special-purpose manipulation languages such as AL [14] to provide adequate support for these other components has led to renewed interest [e.g., 15] in the use of standard general-purpose languages for robot programming. The approach in AML, carried over to AML/X, was to design a new general-purpose language whose design trade-offs make it convenient for automation programming.

Robotic applications *do* have many special characteristics. Manipulator motion specifications and calibration packages rely heavily on geometric calculations, and means must be provided for expressing these conveniently. Most applications require some level of concurrency. Application programs are usually debugged (and often written) "on-line" and are hard to restart, thus making support for interactive programming especially important.

The structure of programs is often rather different from that found in other, more "algorithmic" domains. Generally, the main line of an application program is quite straightforward, and consists of little more than a sequence of commands, with most of the useful work being done as a "side effect". Unfortunately, the vagaries of the physical world [16] cannot be ignored. Our experience has been that robust programs can easily have three to five times as much error testing and recovery as main line code. Often, the error recovery actions are both context dependent and safety related. For example, it may be appropriate to freeze manipulator motion if a gripper feedback sensor fails *unless* the hand happens to be in a furnace at the time. These considerations have led us to place special emphasis on powerful exception handling mechanisms.

Machine Vision: Many of the considerations for robot programming also apply to machine vision [4, 10]. Indeed, one of our objectives was to promote better integration of robot and vision programs. The large amount of data that must be handled in many vision programs means that it is especially important to provide data representations and execution primitives with efficient low-level implementations while still providing great expressive power at higher levels. Beyond this, the language should permit suitable interfaces to special-purpose computational hardware.

Computer-aided Design: The requirements for computer-aided design overlap those for robotics and vision. We require good support for layering, support for interaction at high levels, efficient low-level code execution, and extensibility. Requirements that are especially acute in CAD applications include support for self-describing objects, efficient and accurate numerical computation, and the ability to build up extremely complex data structures.

Other criteria: Since we were generally pleased with our experience with AML, we decided early in our design effort to maintain its general flavor, but not to require strict upward compatibility. The result is that most nontrivial AML programs will not run unaltered on AML/X. One reason for this decision was to enable us to make several changes for future compilabilty.

Although we wanted to take advantage of object-oriented language constructs to provide language extensibility, "layering", and support for modular programming, we also wanted to preserve the procedural style that many of our users were accustomed to. We also felt that it was essential to provide good interfaces to other languages to provide "maturity" (e.g., mathematical subroutine packages), to allow for efficient low-level execution (our first implementation is an interpreter), and to allow us to integrate large and diverse subsystems.

3.0 Language Description

This section describes the basic entities and operations available to the AML/X programmer. We begin with some definitions:

objects These are the entities that can be directly manipulated by AML/X.

values The value of an object is the interpretation of its contents; it is meaningful to distinguish between an object and its value, since the value of an object can be changed.

types Each AML/X object has a type, which defines the set of values that that object can have. AML/X includes several numeric types (INT, REAL, etc.), types for character- and bit- strings, and more complicated types.

variables These are symbolic names (e.g., Foo, VAR_NAME, x) by which a programmer can refer to objects in AML/X; the object to which a variable refers is called its *binding*. We also speak of the "type" and "value" of a variable, by which we mean the type and value of its binding.

As in most other programming languages, variables are a key feature of AML/X. They can be manipulated in several ways:

evaluation Retrieving the binding of a variable, that is, the object to which it refers symbolically.

assignment Changing the value of the object bound to a variable. Since the type of an object is fixed, assignment cannot change the type of a variable.

binding Changing the binding of a variable, that is, causing it to be bound to a new object. Unlike assignment, there is no restriction about the type of the new object to which the variable is bound.

Expressions are combinations of variables, constants, and operators that are *evaluated* to produce new objects and, in the case of assignment, to change the values of existing objects. AML/X is a so-called *expression-oriented* language, in that all program execution can be described as expression evaluation.

3.1 Data Objects and Operators

AML/X has the usual complement of basic data objects and operators necessary for "language-hood". These, and a few other objects and operators are described cursorily in this section. All AML/X code is written in THIS TYPE FONT so that it stands out from the rest of the text without resorting to the use of various awkward quote marks. In code examples, we have used upper case for usage that is required (e.g., reserved words) and lower case elsewhere (e.g., identifier names).

Numeric Objects and Operators: AML/X has four kinds of numeric objects: INT and LONG_INT, which correspond to 16- and 32-bit integers, and REAL and LONG_REAL, which correspond to single- and double-precision floating point numbers respectively. The usual binary arithmetic operations addition (+), subtraction (-), multiplication (*), division (DIV), and exponentiation (**) are provided.

String Objects and Operators: AML/X provides both BIT and CHAR strings, consisting of zero or more bits or bytes, which can be manipulated collectively or individually. The usual operations for manipulating both CHAR and BIT strings, including current and maximum length, lexicographic comparison, concatenation, and selection, are provided. The standard bitwise logical operations AND, OR, XOR, logical and arithmetic shifts, rotate, and (unary) NOT are provided for BIT strings.

Boolean Objects and Operators: BOOLEAN objects can have two values, which are denoted by the reserved words TRUE and FALSE. The standard Boolean operations AND, OR, XOR, and (unary) NOT are available in AML/X. There are also two "short-circuit" Boolean operators, CAND and COR, which do not evaluate their right operands unless it is necessary. Thus, if x is

#	Concatenate two aggregates to form a new aggregate
OF	Replicate an aggregate a specified number of times
IOTA	Make an aggregate containing a sequence of integers
ISAGG	Is an object an aggregate?
AGGSIZE	Number of elements in an aggregate?
MAP	Distribute an operator or subroutine over arguments
REDUCE	"Place" an operator between successive elements of an aggregate and evaluate
SCAN	Like REDUCE but return an aggregate of partial results
ANY	Are any elements of an aggregate TRUE?
ALL	Are all elements of an aggregate TRUE?
EQUAL	Are the arguments equal in both structure and value?
COMPRESS	Select elements of an aggregate using an aggregate of BOOLEANs as a mask
AGGLOC	Locate a target aggregate within another aggregate

Figure 1. Aggregate built-in operators and subroutines.

zero, `x NE 0 CAND y / x GT 10` evaluates to FALSE and does not divide by zero.

Symbol Objects: SYMBOL objects are variables that are not evaluated (like quoted atoms in LISP) and can therefore be used as names. The notation $name defines a SYMBOL object.

Reference Objects: An object of type REF "points at" an AML/X object, which is called the *referand* of the REF. REF objects can be created by either using the & operator or by calling REF. The referand of a REF object is obtained by using the dereferencing operator (!).

DEFAULT: The AML/X object DEFAULT is used in situations where an object is needed but no particular one is required. For example, the return value of a function called only for its side effects is DEFAULT.

Type Objects and Operators: All AML/X objects have a type, which can be determined using the typeof operator (?). For example, the result of the expression ?3 is the type INT.

3.2 Aggregate Data Objects

Aggregates are one of the most important features of AML/X since they are its most basic data grouping mechanism. An *aggregate* is exactly what its name implies: a collection of objects that can be treated as one. An AML/X object that is not an aggregate, such as an INT or CHAR, is called a *scalar* object.

Creating Aggregates: Aggregates are created using the *aggregation operator* pair, < >, to form a single AML/X object from an explicit list of other AML/X objects. The general form

```
< e1, ..., ek, ..., en >
```

creates an n-element aggregate containing the elements ek. The important points to note are that: (1) any AML/X object can be an aggregate element; (2) elements of an aggregate need not all be the same type; and (3) each element is the object that is the result of evaluating an (arbitrary) expression that specifies the element. Once an aggregate is created, its size cannot be changed. Figure 1 lists some of the operators and built-in subroutines for working with aggregates.

Aggregate Subscripts: Individual aggregate elements can be referred to by numeric indices or *subscripts*. If a is an aggregate, the expression a(s) is a *subscripted aggregate reference*; we also say that a is being *applied* to s. Elements of multi-dimensional aggregates (where some elements are themselves aggregates) can be referenced by multiple subscripts. For example, a(3)(2) refers to the second element of the third element of a. Since this syntax is awkward, multiple subscripts can be elided, so that a(3)(2) can be written as a(3, 2).

The most general case of subscripting occurs with multi-dimensional aggregates subscripted by arbitrary combinations of scalar and aggregate subscripts. The rules are simple. Suppose

a	is an arbitrary aggregate
i	is a positive integer
s	is an aggregate of positive integers or aggregates
..rest..	denotes the "rest" of a list of subscripts (possibly empty).

Then, the meaning of any subscript can be determined by applying the following rules recursively until all subscripts are reduced to scalar values:

Expression	*Equivalent*
a(i,..rest..)	(a(i)) (..rest..)
a(s,..rest..)	<...,a(s(k),..rest..),...>
a(DEFAULT,..rest..)	<...,a(k,..rest..),...>

A few examples will help to give an intuitive understanding of what these rules mean. We'll start with the 3×4 matrix m defined by

```
m: NEW < < 1,  2,  3,  4 >,
         < 5,  6,  7,  8 >,
         < 9, 10, 11, 12 > >;
```

The NEW keyword indicates that this is a variable declaration.

It is simple to use aggregate subscripts to refer to rows and columns of m. If i is a scalar, then m(i) refers to the i-th row of m and m(DEFAULT, i) refers to the i-th column of m. The latter can be written more succinctly as m(, i). In general, any "missing" subscript is treated as if DEFAULT had been specified. The "missing" subscript notation is convenient for denoting entire rows or columns. Selected rows or columns can be referred to by using aggregate subscripts, as illustrated below:

```
m(<1, 3>)          ## 1st and third rows
m(, IOTA(2,4))     ## 2nd through 4th cols
m(, <4, 1>)        ## 4th and 1st columns
m(<1,2>, <1,2>)    ## Upper left 2x2
```

- IF cond THEN e1 [ELSE e2]
  evaluates e1 if cond is TRUE and to e2 otherwise; if e2 is ommitted, DEFAULT is used
- WHILE cond DO expr
  continues to evaluate expr while cond is TRUE; the result is the result of the last evaluation of expr, or DEFAULT if none
- WHILE cond DO COLLECT expr
  continues to evaluate expr while cond is TRUE; the result is an aggregate of the successive results of evaluating expr, or the empty aggregate if none
- REPEAT expr UNTIL cont
  continues to evaluate expr until cond becomes TRUE; the result is the result of the last evaluation of expr, or DEFAULT if none
- REPEAT COLLECT expr UNTIL cont
  continues to evaluate expr until cond becomes TRUE; the result is an aggregate of the successive results of evaluating expr, or the empty aggregate if none
- BEGIN e1; ... ek; END
  the expressions ei are successively evaluated; the result is the result of evaluating ek.
- SELECT expr CASE c1 THEN e1 ... CASE ck THEN ek [OTHERWISE oexpr] END
  The result of evaluating expr is compared against successive ei; if there is a match, the result is ci; if no match the result is oexpr if present, and DEFAULT otherwise

Figure 2. Control Operators

Operator Mapping: Operators extend to aggregate operands through a set of *mapping rules* (adopted with slight alteration from AML[2]) which are an abstract form of the distributive law of arithmetic. Suppose

s	is any scalar object
<u1,...,un>	is an n-element aggregate
<v1,...,vn>	is an n-element aggregate
op	is an AML/X operator

Then, the operator mapping rules are:

Expression	*Equivalent*
op <u1,...,un>	<op u1,...,op un>
s op <v1,...,vn>	<s op v1,...,s op vn>
<u1,...,un> op s	<u1 op s,...,un op s>
<u1,...,un> op <v1,...,vn>	<u1 op v1,...,un op vn>

These mapping rules apply recursively to multi-dimensional aggregates.

A key point about the mapping rules is that they work in a uniform way for most AML/X operators. In particular, "parallel assignment" can be written in the form <v1,...,vk> = expression.

3.3 Control Operators

AML/X supports control flow constructs typical of a structured programming language. These are summarized in Figure 2. Since AML/X is an expression-oriented language, all control flow constructs are operators that yield a result like any other operator, as illustrated by the expression

```
move(WHILE ask('More?') DO COLLECT teach())
```

which creates an aggregate of (presumably) points returned by successive calls to teach and passes it to the subroutine move.

3.4 Expression Evaluation

AML/X is an *expression-oriented* language, which means that *every* AML/X program construct is an expression. Thus, expression evaluation is the fundamental computational process in AML/X.

Before an expression is evaluated, it is parsed into a tree of subexpressions based on the usual sort of precedence rules found in most languages. Then it is evaluated by applying operators to objects according to two evaluation rules, one for ordinary operators and one for *special form* operators. To evaluate an expression,

1. If the operator is not a special form, first evaluate the operator's subexpressions (left-to-right), then apply the operator to the resulting objects;
2. If the operator is a special form, the operator is applied without prior evaluation of its subexpressions; the operator may cause any or all of its subexpressions to be evaluated.

The rules are applied recursively and must be augmented by two additional rules which are the basis of the recursion:

1. A constant (e.g., 1, 2.3D5, 'FOO') evaluates to itself.
2. A simple variable (e.g., a, arm, current_speed) evaluates to its binding (not a copy).

The details of the evaluation rule are only relevant when evaluation of a subexpression causes a *side effect*, i.e., when the value of some variable is changed during the course of evaluating the subexpression. We will consider several examples.

Example: <a, b> = <1, 2>
This expression assigns 1 to a and 2 to b. The left-hand-side evaluates to an aggregate of the bindings of a and b (not copies of the bindings); the right-hand-side evaluates to the aggregate <1,2>. The usual mapping rules then cause the assignment operator to be "distributed" over the corresponding aggregate elements.

There are some circumstances where such behavior is not desired. For those cases, AML/X has a *copy operator*, denoted by %. An expression of the form %expr evaluates to a *copy* of

```
diagonal:  SUBR ( m );
   ## Returns the diagonal elements of the n x n matrix m
   n:  NEW AGGSIZE ( m );   ## Number of rows (cols) in m
   i:  NEW 0;               ## Index over rows/cols
   RETURN ( WHILE ++i LE n DO COLLECT m(i, i) );
END;

id: NEW 3 OF 3 OF 0.;    ## Make a 3 by 3 matrix of zeros
diagonal(id) = 1.;       ## Set diagonal elements to 1
```

Figure 3. The subroutine diagonal returns the diagonal elements of a square matrix represented as a nested aggregate. Its use is illustrated by constructing the 3 by 3 identity matrix id.

the result of evaluating expr. Its use is illustrated in the following example.

Example: <a, b> = <b, a>
This expression might be written (incorrectly) to swap two variable values. Each side of the assignment evaluates to an aggregate of the bindings of a and b, but in different order. Applying the mapping rule, the expression is equivalent to <a = b, b = a>. Since these are evaluated left-to-right, the value of a will be "lost". The copy operator, used in the expression <a, b> = %<b, a>, causes a copy of the original values to be made before any of the assignments are done, thus achieving the desired effect.

Example: diagonal(m) = 1
The subroutine shown in Figure 3 uses WHILE..DO..COLLECT to construct an aggregate of the bindings of the diagonal elements of the matrix m. Since diagonal(a) evaluates to an aggregate of the bindings of the diagonal elements, diagonal(a) = 1 has the effect of setting all diagonal elements of a to 1. Again, the key point is that variables in AML/X evaluate to their bindings, *not* copies of those bindings, and the WHILE..DO..COLLECT operator aggregates but does not copy the successive values of the loop expression.

3.5 Subroutines

This section describes AML/X subroutines and variable declarations. A subroutine is defined by a statement of the form

```
subrname: SUBR(...formal_arguments...)
   declarations
   ...
   statements
END;
```

This statement really consists of two parts, the subroutine expression itself (SUBR...END) and the variable name subrname. The statement defines a subroutine and makes it the binding of the variable subrname. There may be any number of formal arguments, including zero. The *body* of the subroutine consists of any number (including zero) of *local variable declarations* followed by any number (including zero) AML/X statements.

A subroutine is called when a subroutine object is *applied* to an argument list, as follows:

```
subrexpr(actual_arg_1,...,actual_arg_n)
```

The subroutine to which the expression subrexpr evaluates is called with the specified actual arguments.

Local Variables and Declarations: Local variables are variables whose names are known only within the extent of a particular subroutine. A local variable is defined by being *declared* at the beginning of a subroutine. Variable declarations (except labels and internal subroutines) are of the form

```
varname: declarator init_expr;
```

where varname is the name of the variable being declared, declarator specifies various properties of the local variable, and init_expr is an arbitrary AML/X expression that defines the variable's type and initial value. The effect of a variable declaration is to associate a variable name with the storage that holds its binding, as defined by four attributes:

> **Memory space:** Determines which memory space the binding is stored in. If the binding is in the stack, it will be discarded when the subroutine terminates.
> **Constant:** Determines whether or not the value of the binding can be altered once it is initialized.
> **Copy:** Determines whether the result or a copy of the result of evaluating the initialization expression becomes the binding.
> **Persistent:** The binding is created when the subroutine is loaded and is reestablished each time the subroutine is invoked.

Possible declarators and their attributes are shown in F';ure 4.

A subroutine definition contained in another subroutine is an *internal subroutine* and can only be called from within the containing subroutine. Free variables in internal subroutines are bound lexically. Labels are declared by prefixing any statement by a name, as in

```
labname: stmt;
```

Internal subroutines and labels are two exceptions of the rule that declarations appear at the beginning of a subroutine. In this case, ease-of-use seemed to outweigh consistency.

Arguments: A simple formal argument is a variable name, implicitly declared as a BIND declaration, and bound to the corresponding actual argument when the subroutine is called. In effect, arguments are passed by reference. The caller can specify that an argument be passed by value by preceding the actual argument with the copy operator (%). The formal argument can also be preceded by the copy operator, in which case the argument is passed by value regardless of how the actual argument is passed. This is illustrated in the following example:

Declarator	Memory Space	Constant	Copy	Persistent
NEW	Stack	No	Yes	No
NEW CONSTANT	Stack	Yes	Yes	No
CONSTANT	Stack	Yes	Yes	No
STATIC	Heap	No	Yes	Yes
STATIC CONSTANT	Heap	Yes	Yes	Yes
BIND	—	—	No	No
STATIC BIND	—	—	No	Yes

Figure 4. Variable declarators

```
fact: SUBR(%i)
  ## Returns i factorial (i GE 1)
  f: NEW i;
  WHILE --i GT 1 DO f *= i;
  RETURN(f);
END;
```

AML/X provides a way to specify values for missing arguments. If the formal argument has the form

```
formal_arg DEFAULT expr
```

and the corresponding actual argument is supplied, then formal_arg is processed as described above. However, if the corresponding actual argument is missing, or if its value is DEFAULT, then expr is evaluated and its result becomes the binding of formal_arg. Thus in the code

```
s: SUBR(p, tol DEFAULT 1.0e-6)
...
END;
s(3);
s(3, 1.0e-8);
```

tol is bound to 1.0e-6 the first time s is called and to 1.0e-8 the second time.

Subroutines can also access excess actual arguments using the predefined variable ACTUAL_ARGS, which is bound to an aggregate of the actual arguments.

It is easy to write *generic subroutines* in AML/X because it is not necessary to declare the type of formal arguments. This is often convenient, especially for small programs, but can lead to programming errors and make it very difficult to compile efficient code for the subroutine. In keeping with our philosophy of letting the user make the trade-off between flexibility and efficiency, AML/X allows optional type declarations for formal arguments. A formal argument (possibly including a DEFAULT clause) can be followed by a type specification of the form

```
MUSTBE type_spec
```

where type_spec is an aggregate of types. If the corresponding actual argument is not one of the specified types, an exception is raised.

Exiting from Subroutines: Any AML/X object can be returned as the result of a subroutine call by passing the object to the RETURN built-in subroutine. The object returned is not copied unless it would be destroyed by termination of the subroutine (e.g., a NEW variable). Therefore a variable binding can be returned and a subroutine call can be used on the left-hand side of an assignment, as illustrated in Figure 3.

The built-in subroutine CLEANUP can be called while executing a subroutine to request an action when the subroutine terminates. For example, suppose a subroutine which opens a file should always close it, even if the subroutine terminates because of some error condition. This can be done by the code shown in Figure 5.

3.6 Exception Handling

When an error is detected during program execution an *exception* is *raised.* The action taken by a program when an exception is raised is determined by the *exception handler* defined for that particular exception. The design of AML/X's exception handling is described in [18].

Each possible exception has a name, which is represented by a SYMBOL. When an exception is raised, either by the system or by the user through the RAISE_EXCEPTION built-in subroutine, AML/X finds the most recent activation of a block containing a variable of that name which was declared as a HANDLER. If none is found and a variable of the appropriate name exists at top-level, it is used. The binding of that variable is the exception handler used.

The type of the binding determines what kind of action is taken, as follows:

EXPR: The EXPR is evaluated and the result becomes the result of the exception handler.

SUBROUTINE: The SUBROUTINE is called. The arguments passed provide the SUBROUTINE with detailed information about the exception that occurred. The result of the subroutine call becomes the result of the exception handler.

LABEL: The LABEL is branched to. The exception handler has no result.

BOOLEAN: The BOOLEAN object is set to TRUE and the result of the exception handler is TRUE.

SYMBOL: The value of the SYMBOL is used as the name of another exception to raise. This allows exceptions to be grouped hierarchically into exception groups, each consisting of several exceptions all handled by the same exception handler.

```
file_update: SUBR()
   c: NEW OPEN('file.name','w'); ## Open file
   CLEANUP( $(CLOSE(c)) );       ## Request cleanup action
   ...                           ## Processing code
END;
```

Figure 5. An example of a subroutine cleanup action: The expression $(CLOSE(c)) passed to CLEANUP is an (unevaluated) expression object which will be evaluated when file_update terminates.

A program can use the EXCP_BINDING built-in subroutine to determine the current exception handler for a specified exception. In this way, a subroutine can decide to let an exception be handled by its caller if its caller has an appropriate handler, or can handle the exception itself if the caller doesn't provide a handler. For example, in the code in Figure 6, the subroutine default_handle_set is used in foo to bind EXCP_ZERODIV to the caller's handler if it exists, or to a boolean flag if it doesn't exist.

Most system-defined exceptions are *continuable*, meaning that execution continues from where the exception was raised and the result of the exception handler becomes the result of the operator that caused the exception. The operation is not "retried", although the exception handler is free to retry the operation or provide a reasonable result, as in

```
EXCP_ZERODIV: HANDLER SUBR()
   ## Return largest possible number
   RETURN(MAXVAL(LONG_REAL));
END;
```

User exceptions can be either continuable or non-continuable.

3.7 Object-oriented Programming

The use of abstraction is a very powerful tool for building large programs. Powerful or complicated abstractions can be implemented by using simpler ones so that each implementation is small and (presumably) easy to understand. AML/X supports abstraction by providing *classes*, a mechanism for defining new objects and operations on them. A class defines a new type in the language; a *class instance* is a particular object derived from a class. This is analogous to built-in types and instances of the built-in types: for example the number 2 is an instance of the type INT. Thus, if one writes a class definition for complex numbers, each instance of that class would correspond to a particular complex number. The data for each instance is held in its *instance variables*, which are accessible only from within the class unless access elsewhere is granted explicitly.

Class Definitions: A class definition is defined by a statement of the form

```
classname: CLASS(...formal_arguments...)
   IVARS
      instance variable declarations
   END;
   declarations
   initialization statements
   methods
END;
```

This statement defines a TYPE and makes it the binding of classname. Each declaration in the IVARS section defines an instance variable. All of the non-STATIC declarators shown in Figure 4 can be used. Figure 7 shows part of a simple class definition for vectors.

Class Instantiation: A class instance is created (the "class is instantiated") by calling the class definition as one would a subroutine, the only difference being that a class returns an instance containing the current bindings of the class' instance variables. Thus, vector(1,2,3) would return an instance of vector with instance variables 1E0, 2E0, and 3E0.

Methods and Operator Overloading: Classes are only useful if there is a way to do something to class instances. A *method* is a special kind of internal subroutine that (1) is contained in a class definition but can be called from outside of the class definition, and (2) has access to the instance variables of an instance of the class. A method is invoked by executing an expression of the form

```
obj_exp.method_name(...formal_argumens...)
```

where obj_exp is an expression that evaluates to a class instance and method_name is the name of a method. The method executes exactly like an ordinary subroutine except that the instance variables are bound to the values of the instance variables contained in the instance instead of to the result of evaluating their initialization expressions. Also, the predefined variable SELF is bound to the class instance itself.

AML/X operators can be extended to class instances, or *overloaded*, on a class-by-class basis by associating a method with the operator. This is done simply by having in the class a method whose "name" is a literal form of the operator to be overloaded. If the left operand of an operator is a class instance, the corresponding operator method in the appropriate class definition is invoked with the right operand as actual argument; if the left operand is an instance of a built-in type but the right operand is a class instance, the corresponding *modifier method* is invoked passing the left operand as actual argument. This allows non-commutative operators to be overloaded.

Exposed Instance Variables: Ordinarily, instance variables are not accessible except within the class definition or through method calls. Direct access to instance variables can be explicitly granted by declaring them to be EXPOSED as in

```
IVARS
   x: EXPOSED NEW REAL();
END;
```

An exposed instance variable is referenced by an expression of the form:

```
instance.inst_var_name
```

Note that a class definition containing only exposed instance variables is equivalent to C's structures and PASCAL's records.

Exposed instance variables were added to the language in response to user's complaints that they often had to write a method just to access a single instance variable. However, because they expose the data representation used by a class, they

```
default_handle_set: SUBR(ex_name, new_handler)
  ## If the caller of the caller of this routine does not
  ## have an exception handler for the exception named
  ## ex_name, return the specified new handler; otherwise,
  ## return the existing handler.

  existing_handler: BIND EXCP_BINDING(ex_name, CALLER(CALLER()));

  RETURN( IF existing_handler NE UNBOUND THEN existing_handler
                                         ELSE new_handler      );
END;

foo: SUBR()
    ## Set up handler for EXCP_ZERODIV
    EXCP_ZERODIV: HANDLER BIND
      default_handle_set($EXCP_ZERODIV, FALSE);
    ...
END;
```

Figure 6. Providing a default exception handler: The subroutine foo binds the result of calling default_handle_set to EXCP_ZERODIV, thus making it the exception handler for dividing by zero. The subroutine default_handle_set first determines the exception handler binding in its caller's caller (i.e., foo's caller). If there is one, it is returned for use; otherwise the new_handler is returned for use as the exception handler.

violate the abstraction that classes were intended to provide. PRIVATE EXPOSED instance variables, which only allow direct access to instance variables from within the class definition, were introduced so that data representation could be exposed inside the class definition but remain hidden from outside view.

4.0 Examples

4.1 Cartesian Data Types

Data types for vectors, rotations, and coordinate transformations are often provided in special-purpose languages for robotics and CAD [e.g., 14, 15, 19, 20]. The conciseness and consistency checking provided by such types, compared to the subroutine libraries providing comparable functions for general-purpose languages, significantly improves programmer productivity and program readability. Unfortunately, users of special-purpose languages are often stuck with whatever internal representation and function set the system implementers have chosen to provide.

This section illustrates the use of AML/X classes and operator overloading to implement these data types in a way that provides both expressive power and easy customizing.

Vectors: Vectors are represented by three real numbers, stored in EXPOSED instance variables x, y, z. Methods overloading the normal arithmetic operators can be provided for vector addition, subtraction, and scaling. "Multiplication" of two vectors is used for vector inner product and "exponentiation" is used for cross product. A method for assignment can also be provided. A sketch of such a class definition is given and several standard constant vectors are declared in Figure 7.

Rotations: Rotations are commonly represented as 3x3 orthogonal matrices. This representation is easily understood and is computationally efficient if many vectors are to be rotated. On the other hand, it is wasteful of storage, subject to numerical inconsistencies, and computationally expensive for many operations, including composition and specification from angles.

As an alternative, we have sketched in Figure 8 a class definition for rotations that uses quaternions[21, 22] as the underlying representation. In this case, EXPOSED PRIVATE instance variables are used in order to hide implementation details while permitting efficient execution within methods. Two "class" methods,

```
r = rotation.polar(axis_vector, angle);
r = rotation.euler(abt_z_1,abt_y,abt_z_2);
```

permit rotations to be specified either as a right-handed twist about a specified axis or as a sequence of rotations about cardinal axes. Multiplication is overloaded to provide for composition of two rotations and rotation of a vector and division is overloaded to provide for formation of an inverse rotation and for multiplication by the inverse.

Two methods,

```
<axis_vector,angle> = r.polar_parms();
<abt_z_1,abt_y,abt_z_2> = r.euler_parms();
```

invert the polar and euler methods, respectively. One potential problem with the latter method arises when the second angle, corresponding to rotation about the "y" axis, is zero. In this case, only the sum of the first and third angles is determined. By default, the third value will be set to zero and an exception, EXCP_degen_rot, is raised. However, the exception handler can override the default. For example, the simplified kinematic solution procedure shown in Figure 9 uses an exception handler to divide the angle sum evenly between the first and third wrist joints.

Transformations: Arbitrary coordinate transformations, consisting of rotation followed by translation, are straightforwardly implemented using the class definitions for vectors and rotations. In a typical class definition (not shown), multiplication would be overloaded to provide transformation of vectors and composition, and division would be overloaded to provide inverses and composition with inverses. A class method for co-

```
vector: CLASS(xx DEFAULT 0.0, yy default 0.0, zz DEFAULT 0.0)

  IVARS
    x: EXPOSED NEW REAL(xx);
    y: EXPOSED NEW REAL(yy);
    z: EXPOSED NEW REAL(zz);
  END;

  $*: METHOD(v)      ## Inner product and scaling
    SELECT (?v)
      CASE vector THEN RETURN(x*v.x+y*v.y+z*v.z)
      OTHERWISE RETURN(vector(x*v, y*v, z*v))
    END;
  END;
  $*: MOD_METH(s) RETURN(vector(s*x, s*y, s*z)); END;

  $**: METHOD(v MUSTBE <vector>)  ## Cross product
    RETURN(vector(y*v.z-z*v.y, z*v.x-x*v.z, x*v.y-y*v.x));
  END;

  ...

  $=: METHOD(v)
    <x, y, z> = SELECT (?v)
                  CASE vector THEN <v.x, v.y, v.z>
                  OTHERWISE v
                  END;
    RETURN(SELF);
  END;

  uvect: METHOD() RETURN(SELF/sqrt(self*self)); END;
END;

null_vector: STATIC CONSTANT vector(0, 0, 0);
x_axis:      STATIC CONSTANT vector(1, 0, 0);
y_axis:      STATIC CONSTANT vector(0, 1, 0);
z_axis:      STATIC CONSTANT vector(0, 0, 1);
```

Figure 7. Class definition for vectors: Methods that overload the addition, subtraction, and division operators have been omitted for brevity.

ercing vectors and rotations to transformations would also be useful.

4.2 Coordinate Frames and Affixment

Coordinate transformations arise naturally from part-subpart relationships in both robot and CAD programming. If the location (i.e., position and orientation) of Part A relative to the workstation is given by a transformation, frame_a, and trans_ab gives the location of a Subpart B relative to A, then the location of B relative to the workstation is given by frame_a*trans_ab. Similarly, if the location of C relative to B is given by trans_bc, then the location of C relative to the workstation is given by frame_a*trans_ab*trans_bc. In practice, these expressions become very cumbersome and tend to interfere with the readability of programs. To get around this, AL [14] introduced the concept of *affixment*, in which part-subpart relationships and similar dependencies were declared explicitly, as in

```
AFFIX part_b TO part_a AT trans_ab;
```

Programs then simply referred to part_b to get the current location of Part B. If Part A was moved or if a new value for its location was determined by sensing, then the location value for Part B was updated automatically.

One of the interesting aspects of the AL implementation of affixment [23] was that recomputation of coordinate frame values was deferred until they were needed, but the values were saved to eliminate needless recomputation. This saving can be quite important in robotic applications where parts are being moved about the workstation and where the expressions involved in recomputation may involve a long chain of affixments. An AML/X implementation of much the same idea is shown in Figure 10. Once again, classes and operator overloading are used to provide a new data type, frame, whose value corresponds to a coordinate system.

Figure 11 illustrates the use of this data type in a simple assembly application. Figure 11(a) shows a box and cover plate being delivered to an assembly station on a small tray. The coordinates of the box and cover are initially known relative to the tray. Furthermore, grasping points relative to the box and cover have been defined. The problem is to use vision to locate the tray, then use a vision routine to locate the box and cover more precisely, based on the tray location. Finally, place the cover on the box and pick up the box. A program to accomplish this is sketched in Figure 11(b).

```
rotation: CLASS(ss DEFAULT 0.0, vv DEFAULT null_vector MUSTBE <vector>)

  IVARS
    s: PRIVATE EXPOSED NEW REAL(ss);
    v: PRIVATE EXPOSED NEW vv;
  END;

  $=: METHOD(r) <s,v> = <r.s, r.v>; END;

  polar: CLASS_METH(axis MUSTBE <vector>, angle)
    RETURN(rotation(cos(angle/2), sin(angle/2)*axis.uvect()));
  END;

  euler: CLASS_METH(a, b, c)
    RETURN(rotation.polar(z_axis,a) * rotation.polar(y_axis,b) * rotation.polar(z_axis,c));
  END;

  $*: METHOD(p MUSTBE <rotation,vector>)
    SELECT (?p)
      CASE rotation THEN RETURN(rotation(s*p.s-v*p.v, p.s*v+s*p.v+v**p.v))
      CASE vector THEN RETURN((SELF*rotation(0,p)/SELF).v)
    END;
  END;

  $/: METHOD(p MUSTBE <rotation>)
    RETURN(rotation(s*p.s+v*p.v, p.s*v-s*p.v-v**p.v))
  END;

  $/: MOD_METH(p)
    IF p NE 1 THEN RAISE_EXCP($EXCP_invalid_inv,,<p,SELF>,TRUE);
    RETURN(rotation(s,-v));
  END;

  euler_parms: METHOD()
    ad:   BIND s**2 + v.z**2;
    bc:   BIND v.x**2 + v.y**2;
    beta: BIND acos((ad-bc)/(ad+bc));
    gpa:  BIND atan2(v.z, s);
    gma:  BIND IF beta NE 0 THEN atan2(v.x, v.y)
           ELSE BEGIN rslt: BIND RAISE_EXCP($EXCP_degen_rot,, gpa, TRUE);
                  IF is_3_reals(rslt) THEN RETURN(rslt) ELSE 0.0;
                END;  ## See also Figure 9
    RETURN(<gpa-gma, beta, gpa+gma>);
  END;

  polar_parms: METHOD()
    s_sqd: BIND v**2;
    RETURN(IF s_sqd EQ 0.0 THEN <z_axis, 0.0>
                            ELSE <v/sqrt(s_sqd), acos(s**2-s_sqd)>);
  END;

  is_3_reals: SUBR(val)
    RETURN( ISAGG(val) CAND AGGSIZE(VAL) EQ 3 CAND ALL(?VAL EQ REAL) );
  END;

END;

EXCP_degen_rot: BIND HANDLER FALSE;  ## Default: ignore exception
null_rot: STATIC CONSTANT rotation.polar(z_axis, 0);
```

Figure 8. Class definition for rotations

The declarations create an "affixment tree" of frames. The instance variables associated with each frame specify the parent frame, the offset of the frame relative to its parent, the present value of the frame—i.e., its transformation relative to the workstation—a "mark" counter used to determine whether the value is valid, and a flag specifying whether the affixment is "rigid". The mark counter is incremented every time a new value is saved, and a frame's value is valid if and only if its mark counter is greater than its parent's. "Rigid" affixments are those

```
hand_vector: STATIC CONSTANT vector(0,0,9);

solve_arm: SUBR( f MUSTBE <frame> )
  t: BIND f.xf();  ## Frame transformation
  cj: BIND t.v - t.r * hand_vector;
  RETURN( <cj.x, cj.y, cj.z> # (t.r).euler_parms() );

  EXCP_degen_rot: HANDLER SUBR(a, b, ang_sum);
      RETURN(<ang_sum, 0., ang_sum>/2);
  END;
END;
```

Figure 9. Simplified kinematic solution procedure for a cartesian robot such as the IBM 7535: This subroutine returns an aggregate of six real numbers giving joint values corresponding to specified hand frame. Note the use of an exception HANDLER subroutine to override the default handling of degenerate wrist rotations.

in which updates to the frame value are to cause the parent's value to be updated as well.

The initial assignment statement causes the value of tray to be updated, and its mark to be incremented. The second statement first causes the value of cover to be computed as part of the call to locate_object. Since tray has been updated, its mark counter is higher than that of cover, so the value is obtained by obtaining a valid value for tray and then composing the result with the offset stored for cover. The assignment then updates the value stored in cover a second time. The third statement repeats the process for box.

Subsequent statements call subroutines to pick up the cover, place it on the box, etc. The fragments from grasp_object and move_object illustrate the use of affixment to simplify programming. grasp_object moves the robot to the specified grasping point, closes the gripper, and then affixes the object (by assumption, the most remote rigidly affixed ancestor) to the robot. Subsequent motions of the robot will cause all location attributes of the object to be updated. move_object verifies that motion_frame is affixed to the robot and then moves the robot so that the value of motion_frame is equal to destination.

5.0 Implementation

AML/X is implemented by a portable interpreter written in C. It runs on the IBM 370 family of machines under VM/CMS, on the IBM PC under DOS and XENIX, on the IBM RT/PC under AIX, and on several other machines. Facilities exist on all machines for writing C subroutines callable from AML/X; on the VM/CMS implementation, there are also interfaces to Fortran and PL/1.

6.0 Experience and Conclusions

AML/X has now been in use for about a year in our research in robotics, computer-aided design, and machine vision. Execution speed of the interpreter has proved adequate for robotics applications. As anticipated, however, the interpreter is too slow for production use in the lowest layers of more complex systems, especially in CAD applications. We have begun work on a prototype compiler that should resolve this issue. Meanwhile, several of our researchers find AML/X sufficiently expressive that they prototype low level geometric data structures and algorithms in AML/X and recode in C where necessary for efficiency. Classes, including operator overloading, are often used in this work, and the resulting programs are both readable and modifiable.

AML/X has also been used as a programming "front-end" to a powerful geometric modelling system [17]. In this case, class definitions for geometric objects have been written in AML/X but the actual data representation is created and manipulated by the modelling system. Each class instance essentially contains a "handle" on the data maintained by the modelling system. Methods implement geometric operations by passing these "handles" to the modelling system, which then does the necessary computation. Our initial (limited) experience with this use of AML/X in the higher layers of a system is that it provides a very powerful programming environment with very reasonable performance. The drawing in Figure 11 was produced by an AML/X program running on this system.

The need for concurrency can to some extent be met by simple interfaces to operating system services. However, in response to the requirements of automation programming, we have begun to consider providing concurrency directly in the language.

Providing interfaces to other languages has allowed us quick access to a variety of existing code, ranging from mathematical subroutines, to graphics routines, to a large modelling system. We expect that AML/X will continue to be used at the highest layers of large systems built from existing components and that using it in this way will help us to integrate various automation technologies.

Acknowledgments

AML/X is a descendant of AML (A Manufacturing Language) and owes much to its developers. As early users of AML/X, Georg Maier and Vijay Srinivasan at IBM Yorktown provided especially valuable suggestions on ways to improve the language. Dave Klein of the Manufacturing Systems Program (MSP) at IBM Boca Raton designed and implemented the garbage collector. Ken Morgan, also of MSP, implemented most of the debugging facilities. Many others in the Automation Research group at IBM Yorktown and the Manufacturing Systems Program at IBM Boca Raton have also made useful comments and suggestions.

Satyr and the Nymph[†]
Software Archetype for Real Time Robotics

J. Bradley Chen, Brian S. R. Armstrong, Ronald S. Fearing and Joel W. Burdick
Stanford Artificial Intelligence Laboratory
Department of Computer Science
Stanford University

Nymph is a multiprocessor system created at Stanford University for the implementation of real time control systems. After a brief description of the nature of Nymph, the design and implementation of the system software is discussed. Software in Nymph emphasizes the benefits of abstraction in the user interface, with an awareness of limitations abstraction creates when used in excess. The distinction between latency and throughput, and its importance in the design of real time multiprocessor software is discussed, motivating use of synchronized parallel processes. Discussions of implementations of the Cosmos force control system and a control system for the Stanford/JPL hand reflect further experiences with Nymph. A general discussion of debugging a tightly coupled multiprocessor follows; what makes it unusually difficult, techniques that have been useful with Nymph, and possible hardware/software strategies for creating debugging environments in future systems.

Introduction

The architecture of multiprocessor systems for high performance real time control applications creates unusual problems for the programmer. The added complexity of parallel software design, and the fact that the programmer is working on an unusual and often unique machine architecture demand creative solutions to old problems such as communication and synchronization. In addition to difficulties inherent in the design of parallel software systems, implementation of this software is made difficult by the lack of development tools, such as debuggers, for a tightly coupled real time system.

The difficulties created by the multiprocessor architecture are enhanced by the demands and requirements of the software to be implemented. The programmers of real time control systems are aware of the performance of which the multiprocessor is capable, and they insist upon having all of the computing power available to them. Because of this, common issues of system design such as security and quality of user interface subordinate to the singular goal of computational efficiency. The challenge for the system software designer is to implement a programming environment conducive to software development without compromising performance.

Software for the Nymph system has been designed to achieve a good user interface within the requirement of minimal system overhead. The general philosophy in design is that people need the abstraction and refined user interface provided by a sophisticated operating system, but robots don't.

Additionally, for optimal utilization of hardware resources in a real time multiprocessor environment, the programmer must have a clear understanding of how parallel processes interact. Conventional knowledge of serial processing is not sufficient. Experience with and awareness of the peculiarities of parallel computing have helped us create software which allows top performance from the Nymph hardware. One significant example in which intuition will misguide the programmer without experience in parallel environments is the choice between synchronous and asynchronous processes. This issue is discussed in the Synchronization section of this paper.

The multiprocessor environment creates new problems in debugging. Beyond the new kinds of errors which occur in parallel software design, the debugging tools and techniques available in a tightly coupled environment are limited. In the Debugging section of this paper debugging problems specific to multiprocessors, and some techniques for coping with these problems are discussed.

Related Projects

The diminishing size and cost of high speed microprocessors have made multiprocessor systems a popular solution to the problem of computational architectures for real time robotic control. A general overview of the Nymph system can be found in [Chen et. al. 1986].

Researchers at the MIT AI Labs are working with a multiprocessor which uses MC68000 series computers on a common bus, linked to a VAX computer via a DMA link. This system is designed for the implementation of a control system for the Utah/MIT dexterous hand. The system utilizes a mail-box communications model and scheduling of asynchronous processes by means of a servo-loop-scheduler routine. [Siegel et. al. 1986]

Another interesting system is being worked on by the National Bureau of Standards. Theirs is a loosely coupled multiprocessor system, with a fine grained modular structure for a programming model, encouraging generic modules. [Haynes and Wavering 1986]

Members of the Manufacturing Research Department of the IBM T.J. Watson Research Center have developed a multiprocessor control system to support research in automation programming and motion control. Their system consists of a Programming System for program development and user interaction, linked by a shared memory bridge to a Real Time System, which is a tightly coupled multiprocessor. The system also utilizes a Verb structure for command syntax. [Korein et. al. 1986]

Gaglianello and Katseff of AT&T Bell Labs have done work on a distributed system for control applications called Meglos. The system is based on multiprocessor clusters linked by a high speed network, with user interaction and programming environment based on the Unix operating system. [Gaglianello and Katseff 1986]

The Nymph System

In the Nymph system (in its current configuration) eight NSC 32016 single board computers (hereafter denoted as 32k computers) provide the computing power. Each board carries 512k bytes of dual-ported RAM, a parallel port, two serial ports, and a floating point co-processor, which enables a 32k to do a floating point multiply in six microseconds.

In addition to the 32k computers, Nymph includes a MC68010 based Sun Workstation which provides the interface between Nymph and the rest of the world. The Sun communicates with server machines on a 10MB/second Ethernet to provide facilities such as file I/O and downloading of programs. Since the Sun and the 32ks reside on the same Multibus, communication between the machines is very fast. The Sun runs the V-System distributed operating system [Cheriton 1984] with the VGTS windowing system [Lantz 1984]. Using the graphics and I/O routines provided by the VGTS, interaction windows are created for each 32k processor.

Nymph also has 2.5M bytes of EDC RAM, parallel I/O boards to communicate with robot hardware, A-D converters to process force and tactile sensor data, and D-A converters to drive motors. A schematic of the Nymph system appears in Figure 1.

Software Overview

Abstraction can be defined as the removal of hardware specific detail in a communication. Clearly abstraction is useful in communications between computers and people, examples being ascii character encoding and high level languages (versus high and low voltage levels). However, in communications between machines and computers, the abstraction is only useful in as much as it makes it easier for people to control the machines' communication. It does nothing to improve the quality of interaction between machines. Additionally, abstraction tends to produce several determental side affects:

1. Inefficiency. This problem is analogous to adding bureaucracy to government. Abstraction in communications generally results in making the communication path more complicated, and therefore slower.
2. Loss of Robustness. As paths of communications become more complex, the number of possible states in the computation increases, making it less and less likely that the programmer will (or will be able to) test all the possible failure modes of the software.
3. Loss of access to the machine. In removing detail from a communications path, that detail often becomes inaccessible, along with some of the functionality/flexibility it provides.

In such a machine oriented environment as a robotics control system, these problems are precisely those which we seek to avoid. Thus, there are many cases where abstraction would be appropriate in typical computer systems, but becomes an unpleasant burden in a control system. Software for the Nymph system has been created with the problems of abstraction in mind, with a goal being to create a system that uses abstractions when clearly worthwhile, and avoiding abstraction when it seems reasonable to do without it.

In the Nymph system, these concepts about abstraction have been applied to the implementation of the Nymph run-time environment. Nymph was designed with the Sun Workstation dedicated to user interaction, and the 32k processors strictly dedicated to the real time system. Thus, abstraction abounds on the Sun, where it is useful in creating a refined user interface, but is confined to the Sun, and avoided in the 32k. On the 32ks, the real time control system gets 'the whole machine,' simplifying the implementation of time critical control. When a 32k requires some sort of operating system service, such as file I/O, it uses facilities provided by the Sun in a client-server relationship. Thus, the 32k computers can exert an interrupt on the Sun to have there system requests serviced, but the Sun can't interrupt the 32k, keeping its environment clear of unpredictable interrupts and consistently available for real time computations.

There is not a complete "operating system" which runs on the 32k processors of Nymph, but rather a collection of run-time libraries which interface the 32k processors to the Sun and V-system. This creates a convenient interaction environment for the programmer, providing a familiar procedure call interface to system facilities provided by the Sun. Also the runtime library implementation insures that the resources consumed by system overhead is limited to that which the application requires.

Nymph Windows

Due to restrictions in design and a primary concern for efficient use of hardware resources, many real time systems have a very primitive user interface. This is unfortunate, because when hardware systems are inconvenient to use, either the user's time is wasted or the system is not used at all.

The Sun Workstation of the Nymph system was selected because of the excellent user interface and abundance of software which was locally available for it. In letting operating system people develop the operating system, we have been able to concentrate our efforts on the problems relevant to real time systems.

User interaction between the programmer and the 32k processors on the Nymph system occurs on the workstation console. Through the VGTS system, I/O windows are created for each 32k processor. For each window there is an I/O handler process running on the Sun. The 32k computers communicate with the handler processes using the message passing system described in [Chen et. al. 1986]. The interaction windows are initialized by a simple procedure call from a C program, which defines **stdin**, **stdout**, and **stderr** in terms of the interaction window, as well as initializing facilities for file I/O. Figure 2 illustrates some of the mechanisms of the Nymph I/O system. In this case, abstraction has been used to the fullest extent: each 32k processor has its own output device, but the details of the communication between the 32k processor and the interaction windows are hidden to the program. However, the computational burden of the abstraction is confined to the Sun, preserving the real time environment of the 32k processors.

Figure 3. Nymph Windows.

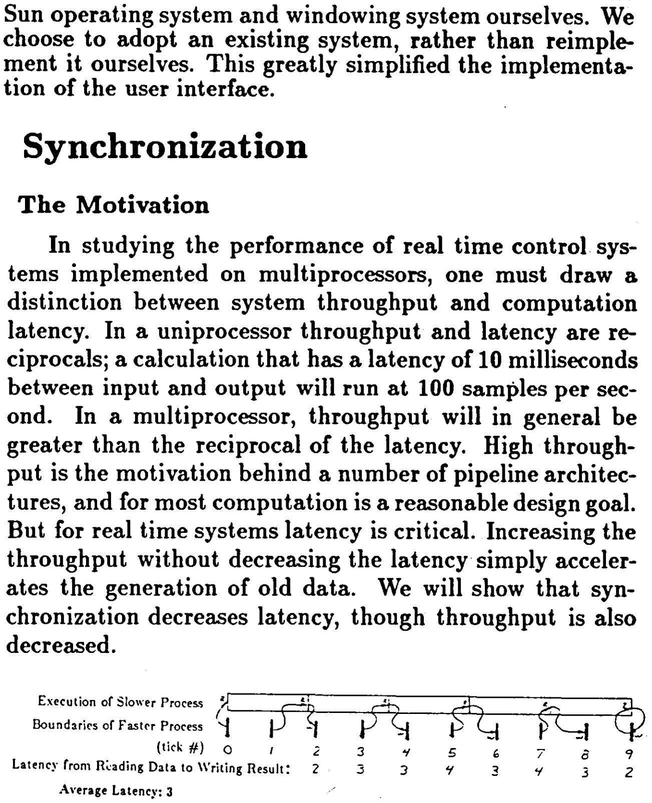
The windowing capability of the Nymph system has proven to be a great convenience in the use of the system. It allows the user to interact quickly and efficiently with all the processors, with all facilities available from the mouse and keyboard. It also allows (conceptually) simultaneous output from all processors, a feature useful in debugging. Figure 3 shows the user's view of Nymph.

It should be noted that this refined user interface would have been difficult to achieve if we had had to create the Sun operating system and windowing system ourselves. We choose to adopt an existing system, rather than reimplement it ourselves. This greatly simplified the implementation of the user interface.

Synchronization

The Motivation

In studying the performance of real time control systems implemented on multiprocessors, one must draw a distinction between system throughput and computation latency. In a uniprocessor throughput and latency are reciprocals; a calculation that has a latency of 10 milliseconds between input and output will run at 100 samples per second. In a multiprocessor, throughput will in general be greater than the reciprocal of the latency. High throughput is the motivation behind a number of pipeline architectures, and for most computation is a reasonable design goal. But for real time systems latency is critical. Increasing the throughput without decreasing the latency simply accelerates the generation of old data. We will show that synchronization decreases latency, though throughput is also decreased.



Execution of Slower Process

Latency from Reading Data to Writing Result: 2 3 3 4 3 4 3 2
Average Latency: 3

Figure 4. Asynchronous Process Communications and Latency.

In Figure 4 an example of the possible timing between two interacting processes is shown. The faster process is assumed to produce the input and consume the output of the slower process at the beginning of each faster process cycle (tick mark in the figure; we shall refer to the fast process intervals as ticks). This example might arise in a system with a high speed I/O process synchronized with external devices. The top portion of Figure 4 shows the alignment of the slower process with the faster one. We have made the favorable assumption that the process speeds are in an integer ratio, 5:9, and that the slower process lines up exactly with the faster one every nine ticks. Along the bottom of the figure are numbers to indicate how many ticks have elapsed since the reading of the data used by the slower process to compute the result used by the faster process at the tick shown. The mean of the numbers in this row is the mean latency.

Looking at the second execution of the slower process in Figure 4, one sees that it begins at $t = 1.8$, and produces its result at $t = 3.6$. When the process began, the freshest input data came from $t = 1$, and thus was 0.8 ticks old. The result of the second execution of the slower process is applied at $t = 4$ and $t = 5$, the result of the third execution of the slower process then becomes available at $t = 5.4$ and is applied at $t = 6$. At $t = 5$, the system applies a result based on the data measured at $t = 1$. The data and the result are 4 ticks old, even though the slow process requires only 1.8 ticks to execute. The mean latency for the asynchronous case is 3 ticks.

(tick #) 0 1 2 3 4 5 6 7 8 9
Latency from Reading Data to Writing Result: 2 3 2 3 2 3 2 3
Average Latency: 2.5

Figure 5. Synchronous Process Communications and Latency.

In Figure 5, the same process interactions are shown for the synchronized case. Here the slower process blocks until fresh data is available; it is synchronized with the faster process. Notice that 10% of the computing power of the slower processor is sacrificed while the process blocks for synchronization. As in Figure 4, the latencies are shown. The mean latency for the synchronized case is 2.5 ticks, a 16% reduction from the asynchronous case, even though the process ran five times in the asynchronous case and in the synchronous case only four. The asynchronous case also shows a broader range of latency than does the synchronous case.

A general analysis of asynchronous process latency can be had by assuming the phase relation between the faster and slower processes is a random variable with uniform distribution. The expected value of latency resulting from asynchronous process interactions is given by Equation 1. In the following, phase is measured in units of the ticks and ranges from 0 to 1. Equation 1 is derived from the interaction model of Figures 4 and 5 by summing the latency contribution over all possible event orders. Figure 6 shows the possible event orders for the case where $u = 1.8$ ($(u - \lfloor u \rfloor) > 1/2$). When the phase is between 0 and ϕ_i, the mean latency is $\mathrm{E}\{l_2^3\}$, which is 2.5. When the phase is between ϕ_i and ϕ_j the latency is $\mathrm{E}\{l_3^3\} = 3$. The final possibility is that the phase is greater than ϕ_j, which produces a mean latency given by $\mathrm{E}\{l_3^4\} = 3.5$.

$u = 1.8 \quad i = 2 \quad j = 4 \quad \phi_i = 0.2 \quad \phi_j = 0.4 \quad \lfloor u \rfloor = 1$

Figure 6. Possible Permutations of Event Order for two Processes of rate ratio 1.8:1, Asynchronously Interacting.

The three event orders correspond to the three product terms of the expected latency. A separate equation is needed for the case where $(u - \lfloor u \rfloor) < 1/2$ because a new permutation of events is possible and one permutation shown in Figure 6 is not possible. The two equations give identical result when $(u - \lfloor u \rfloor) = 1/2$.

If $(u - \lfloor u \rfloor) \leq 1/2$,

$$\mathrm{E}\{L\} = P_{(\phi_j - 0)} * \mathrm{E}\{l_i^{i+\lfloor u \rfloor - 1}\} + P_{(\phi_i - \phi_j)} * \mathrm{E}\{l_i^{i+\lfloor u \rfloor}\} + P_{(1-\phi_i)} * \mathrm{E}\{l_{i+1}^{i+\lfloor u \rfloor}\}$$

if $(u - \lfloor u \rfloor) > 1/2$, (1)

$$\mathrm{E}\{L\} = P_{(\phi_i - 0)} * \mathrm{E}\{l_i^{i+\lfloor u \rfloor}\} + P_{(\phi_j - \phi_i)} * \mathrm{E}\{l_{i+1}^{i+\lfloor u \rfloor}\} + P_{(1-\phi_j)} * \mathrm{E}\{l_{i+1}^{i+\lfloor u \rfloor + 1}\}$$

where $P_{(\alpha - \beta)}$ is the probability that the phase relation between the slow and fast processes lies in the region between α and β; and $\mathrm{E}\{l_m^n\}$ is the expected latency when a result of the slow process is applied from ticks m to n, where m and n are measured with respect to the tick at which the raw data of the slow calculation are taken.

$$E\{l^n_m\} = \frac{\sum_{k=m}^{n} k}{n-m+1} = \frac{n(n+1)-m(m-1)}{2*(n-m+1)}$$

When the phase relation between the slower and faster processes is uniformly distributed,

$$P_{(\alpha-\beta)} = \alpha - \beta$$

Note that the phase relation ranges from 0 to 1, not from 0 to 2π. The remaining terms in Equation 1 are defined to be:

u	is the rate ratio of the two processes;
i	is the least integer greater than u ;
j	is the least integer greater than $2u$;
ϕ_i	is $(i-u)$;
ϕ_j	is $(j-2u)$;
$\lfloor u \rfloor$	is the greatest integer less than u.

The expected latency for the asynchronous and synchronous calculations, as a function of the process rate ratio, is shown in Figure 7. The stair step shape describes the synchronous case, where latency is fixed for increasing u until a boundary is reached and one more tick is required to complete the slower calculation. Figure 7 shows that for rate ratios above 1.3:1 the synchronous case always gives less expected latency. For ratios just greater than an integer, the reduction in latency by synchronization is a few percent; for ratios just less than an integer, the reduction in latency by synchronization is more than a full tick. The expected latency for a rate ratio of 1.8:1 is 3.2 ticks. In the example of Figure 4 we assume that the asynchronous processes "line up" every nine ticks, with a lower expected latency of three ticks. The integer ratio "lining up" assumption was made to show the asynchronous construction in optimal conditions.

Latency is pure delay: the anathema of feedback control. In this final thrust to convince the unbelieving that you can throw away computer power and still improve control, we will compare the tracking of a linear first order filter by its equivalent discrete filter under four assumptions: (1) uniprocessor, (2) two asynchronous processors, (3) two synchronized processors, (4) a uniprocessor of twice the power. For this numerical exercise we will take our input signal to be 10 hertz, our desired linear filter to have a pole at 10 hertz, our uniprocessor (example 1) to have computation power sufficient to sample at 80 hertz, and our problem to be amenable to parsing in chunks with a ratio of 1.8:1. The results are shown in Table 1. The error measured is the difference between the linear filter and the digital equivalent. The digital filter has been designed with the forward integration approximation. The excess lag (excess over the linear filter lag of 45°) was measured by finding the advance that should be supplied to the digital filter to minimize the squared error. The results show that by going to two processors a substantial improvement is achieved, and that by synchronizing a further improvement is achieved. The fourth configuration, a uniprocessor of twice the power, is included to show that two processors are not twice as powerful as one.

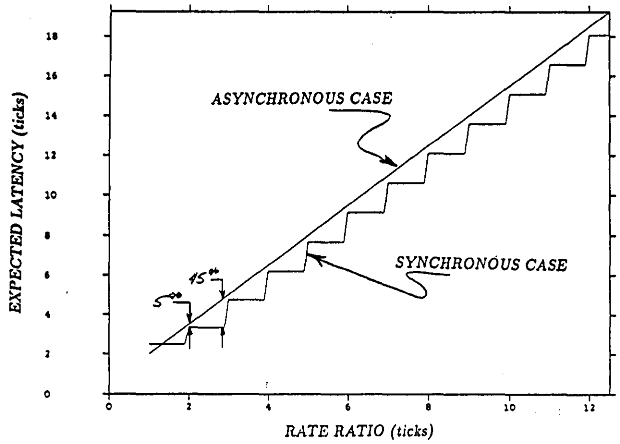

Figure 7. Expected Latency in Synchronous and Asynchronous Process Coordination.

Table 1. A Comparison of Synchronized and Unsynchronized Digital filters. The error measures are relative to a single pole linear filter with an input signal of 10 hertz.

Filter Configuration	Mean Squared Error (unit input)	Excess Delay (milliseconds)
A uniprocessor at 80 hertz	0.558	25.7
Two processors, problem split 1.8:1, fast rate: 224 hertz, slow rate: 124.4 hertz, slow process unsynchronized.	0.280	16.9
Two processors, as above, fast rate: 224, slow rate: 112, slow process synchronized. (see Figures 4 and 5)	0.235	14.3
A uniprocessor at 160 hertz.	0.156	12.6

The Implementation

The basic design of the Nymph synchronization primitives is presented in [Chen et.al 86]. Since the writing of that paper, in implementing several control systems, one lesson on is clear: Asymmetric synchronization primitives are often needed, as opposed to the symmetric synchronization primitives of the original implementation. By symmetric we mean that the behavior of the synchronization primitives, `Synch_Signal()` and `Synch_Wait()`, depends only on the order of occurrence, not on the processor upon which the commands occur. Thus if processors A and B are synchronized, B will block if it arrives at its `Synch_Wait()` first, to be awakened by A; or A will block if it arrives at its `Synch_Wait()` first, to be awakened by B.

There are cases in which one wants B to block for A, but not vice versa, or for B to block only if A is on some critical segment. In both of these scenarios A never blocks for B, and B never does any awakening. The primitives Synch_Block(n, patience) and Synch_Check(n, patience) were written for these cases. As in [Chen 86], n is an index indicating the synchronization event, and patience is a parameter indicating how long the processor is willing to sleep.

Synch_Block() is used when one or more processors must block until one processor reaches some event. It is useful for MASTER-SLAVE interactions and for synchronizing several processors to a single time base.

Synch_Check() is used for mutual exclusion of a critical section. A typical example is in I/O channels that have internal state and thus may not be used by multiple processors concurrently. The priority processor, or the one expected to be first, will execute Synch_Signal() before entering the critical section (possibly long before) and Synch_Wait() upon leaving the section. The next processor will execute Synch_Check() before entering its critical section; if the primary has completed its action, the secondary will continue; if the primary has not completed its action, the secondary processor will block. The advantage of this special construction is that Synch_Check() appears as a single if statement when the program does not block, and runs in 8 microseconds. Thus, Synch_Check() can be used liberally to ensure event order without sacrificing performance

The example shown in Figure 9 illustrates the use of Synch_Block() and Synch_Check(). Awakenings are indicated by arrows. A Synch_Block() or a Synch_Check() can only be awakened by a Synch_Wait().

Nymph for Hand Control

The Stanford/JPL hand has three fingers with three degrees of freedom each, actuated by a coupled pulley system with 4 tendons and motors for each finger, for a total of twelve motors. Each tendon has a tension sensor mounted near the finger to allow control of joint torque, and motor shaft encoders to determine motor position. This hand has some dexterity for fine motion and force control of grasped objects, and for regrasping operations where objects are reoriented within the hand [Fearing, 1986].

The previously proposed hand control structure [Chen et al 1986] has been revised to provide a high bandwidth tendon controller (see Figure 8). The system is currently running with seven processors, with a force and tendon processor for each finger. The low level tendon processor runs at 480 Hz, and the force servo on a separate processor runs at 120 Hz, and the two are tightly coupled by synchronization. The seventh processor coordinates finger actions. Three more processors wil be added for the processing of tactile data.

The three low level processors share a 12 channel motor interface, and synchronization is used to prevent collisions when accessing this device. This also reduces potential delays due to all three processors contending for the bus simultaneously if they were locked in step. The second use of synchronization is the transfer of data between the high and low servo levels. This ensures minimal latency and prevents the use of partially updated information by the two levels.

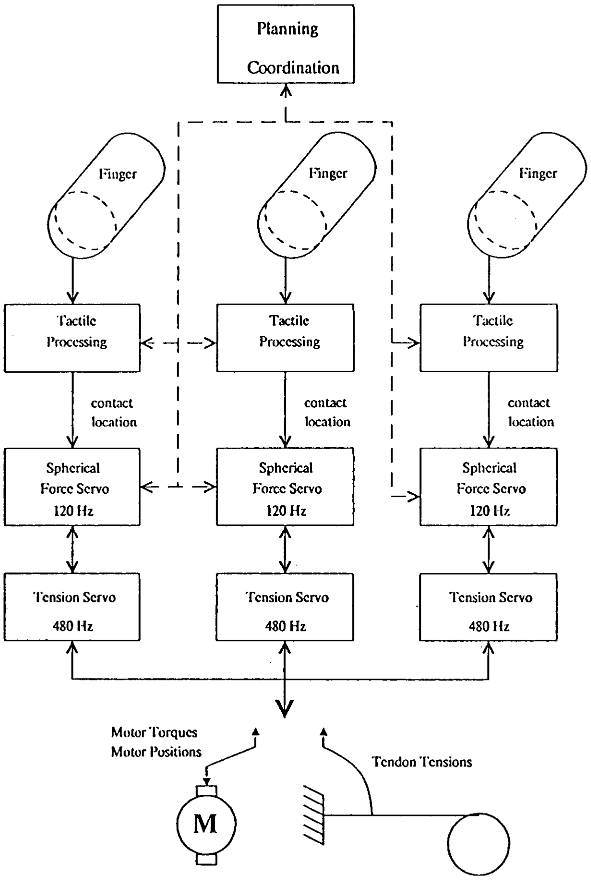

Figure 8. Multiprocessor System for the Stanford/JPL Hand.

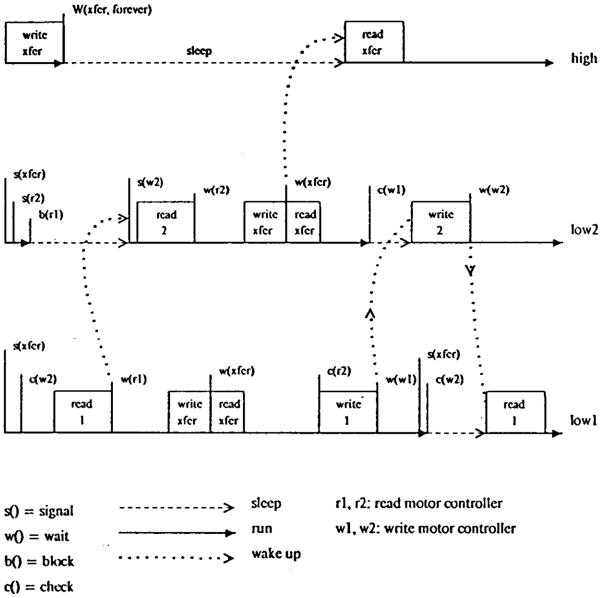

Figure 9. Synchronization of low and high level control.

Figure 9 shows a portion of the synchronization scheme. Processor "low1" is the master processor and sets the timing for the other processors. There are five separate synchronization events: two reads and two writes of the motor controller, and filling the transfer buffer between the high and low levels. The high level writes desired tendon tensions into the transfer buffer and waits `Synch_Wait(transfer, for_ever))` until all low level processors have written measured motor positions into the buffer. The high level can now proceed with correct data, and the proper servo rate.

Signals are used to protect the motor controller from accesses by other processors by forcing the other processors to "`Synch_Check()`" and thus wait until the signal is cleared by `Synch_Wait()` on the signal issuing processor.

Cosmos

COSMOS is an experimental programming system designed to facilitate experiments in manipulator position and force control. The control algorithm used in COSMOS is based on the operational space method, described in [Khatib and Burdick 1986]. Parallelism can be extracted from this algorithm by conceptually dividing the computations into two levels:

1. A "high level" system which computes the configuration dependent dynamic models at a relatively lower rate.
2. A "low level" servo system which computes the forward kinematics and servo equations at a faster rate using sensor data and the dynamic data from the "high level."

The low level system measures the manipulator position and end-effector forces, and then computes joint torques using a series of vector and matrix operations. The vector and matrix elements used in these computations are dependent on the configuration of the manipulator, and are updated by the high level. The high level requires processed sensor data from the low level in order to perform its computations. Thus, time dependent data passes in both directions between the high and low level. A third level, the "programming level" interacts with the manipulator programmer, performing run time program execution, path planning, and error checking. The computations of each of these levels can be further divided among different processors to extract more parallelism, reducing latency in the overall computation.

Because of the decomposition of the algorithm into two major levels, and the decomposition of each of these level into separate computational tasks (which are implemented on different processors) various levels of synchronization and data transfer occur in the COSMOS system. Within each level, very high speed symmetrical synchronization (on the order of a few microseconds) occurs between processors. The high level computations are asymmetrically synchronized with the low level in order to minimize the latency in the low level computations, which is the crucial latency for stability of the control algorithm. In the current COSMOS implementation on the NYMPH system, a low level kinematics and servo rate of 200 Hz and a high level dynamics computation rate of 100 Hz has been achieved.

While COSMOS uses one particular control algorithm, most advanced manipulator feedback control algorithms can be decomposed into fast and slow loops, with the minimization of the latency in the fastest loop being critical to the success of the implementation. Thus, for optimal implementation of a manipulator control algorithm on a multiprocessor, tight coupling of the processors of the fast loop, and asymmetrical coupling of the fast loop with the slower loops is necessary to minimize latency.

Debugging in a multiprocessor environment

Software development can be divided broadly into two activities, design and debugging. These activities are related in that greater complexity in design leads to more difficult debugging problems. The design of multiprocessor software is made more complex by the need to take advantage of parallelism in the computation. Genuine concurrency and inability to guarantee the order of events can lead to errors from programmers who are used to working in a serial environment. Another source of bugs is that processors share memory, and so they are able to corrupt eachothers' memory. This creates situations in which the bug in the system is not necessarily in the software which fails, but rather in another piece of software which is irresponsible in its memory activities. The result is that new sources of program bugs exist in the multiprocessor software, in addition to the errors common in serial software.

Debugging for real time robotic control applications is additionally complicated for two reasons. First, synchronization and timing within the system is critical down to the level of a few microseconds, and so debugging systems that use the single step method are useless, since the critical timing information is lost. Second, since the multiprocessor is connected to robotic hardware, much of the input to the software algorithms is sensor data, which is difficult to predict or model in a software simulator.

In the planning stages of this project it was recognized that there should be a convenient and fast (low overhead) monitoring system for keeping track of many processors simultaneously. At the speeds involved in real time control, monitoring can only be done by hardware. The hardware solution is a meter, an LED, and an input switch permanently connected to each processor for diagnostic purposes.

The meter has three primary and switchable functions: measuring bus utilization, showing the time spent waiting in synchronization, and showing the execution time for various sections of the servo loops. The meters immediately show the case where processors lose synchronization, because there will be significantly different waiting times if one processor misses a synchronization event. The meters are also useful for determining which processor amongst the various processors is responsible for "wedge" conditions. Because the meters indicate how much time each processor is idling, the applications programmer can use the meters in the early stages of software design to rebalance the computational load among processors to minimize latency. An additional meter monitors activity on the global Multibus.

The LED can be turned on and off under software control in critical sections of code, and is useful for determining the exact sequencing of events. The software readable input switch is primarily useful not so much for debugging, but as an input for application programs in which the programmer is interested in switching between different servo algorithms in real time for comparison purposes. Individual non-maskable interrupt switches are also provided for each processor. Figure 10 is a picture of the Nymph front panel.

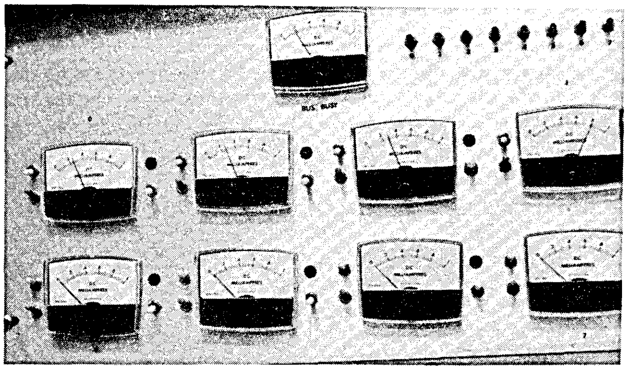

Figure 10. The Nymph Front Panel.

Another important debugging tool for the Nymph system has been the ability to make long traces of control system states without modifying servo code or introducing extra servo delay. This is made possible by having shared variables in globally accessible memory, and having extra processors available that can be dedicated to the trace task. To trace passed variables, for example the data passed from high to low level in the three finger hand control example, all that is needed is to do `Synch_Wait(xfer)` on the trace processor. This ensures that all data is captured and at the same time.

A major source of difficulty in debugging in a real time tightly coupled multiprocessor environment is that there is no central control. There is no intelligent entity on the bus which, in an error situation, is capable of preventing other devices on the bus from corrupting available state information. This makes the development of a runtime system debugger in a multiprocessor extremely difficult.

The central control which does exist is the bus, but this device is generally a slave to the processors in the system which it connects. It is not surprising that many of the more difficult debugging situations are characterized by a bus lock situation, in which some irate processor or processors monopolize the bus, making it impossible to examine state information in the memory of devices on the bus.

One plausible solution to the problem of central control would be to assign a single processor to debugging tasks, give it priority to control the bus, and somehow wake it up whenever an error situation occured. Because of the asymmetry involved, the processor would have to be dedicated to debugging and not a part of the control system, for the debugging system would be useless to debug code running on the debugging processor. The cost of a dedicated processor would be small if it was an effective debugging tool, but its effectiveness would be limited by its ability to capture and analyze the system state at the time the error was detected.

Conclusions

The Nymph system has proven to be a versatile and effective system for the implementation of real time control systems. Much of the success of Nymph can be attributed to the use of the 68k based Sun Workstation with existing software, with which the implementation of the user interface was greatly simplified.

The workstation provides a logical boundary for Nymph software. The 32k processors are dedicated to real time computations, and the Sun is dedicated to system functions. By isolating the system software on the workstation, we have been able to avoid the complications imposed by system software in the real time system, allowing simple and efficient implementations.

In a real time environment, throughput subordinates to latency as the key issue in optimal performance. The use of synchronized processes is a useful technique for minimizing latency in parallel computations.

Debugging in a multiprocessor environment is a difficult problem in which many opportunities for improvement exist. In Nymph we have attempted to provide maximum availability of system resources through user interaction windows, greatly improving the debugging environment. Real time debugging information provided by the front panel and trace processors has also proven to be a useful tool. The main limitation in improving the debugging environment is that real time debugging capabilities require hardware support.

Acknowledgements

The authors wish to gratefully acknowledge Professor Thomas O. Binford for his guidance and support. We would also like to thank Oussama Khatib for his many contributions throughout the project. Special thanks to Lance Berc and Professor Keith Lantz for making available their expertise on the V-System, and all of Stanford's Distributed Systems Group for making the V-System and VGTS available to us. This work was funded by DARPA Contract MDA903-86-K-0002, and by industrial sponsors under the Stanford Institute for Manufacturing and Automation. AT&T Bell Laboratories
Holmdel, NJ 07733

Abstract: Meglos provides a user-level programming environment for a system of interconnected processors and provides a convenient testbed for developing, testing, and running large-scale robotics applications. Meglos extends the program development and execution environment of the UNIX® Operating System with simple, powerful and efficient communications and synchronization primitives. Each processor has a priority-based preemptive scheduler, simplifying the programming of real-time applications. Meglos provides a convenient environment for writing and debugging applications that require multiple processors for their execution and allows several programmers to simultaneously run and debug their applications.

I. Introduction

As robotics applications exceed the capabilities of computers traditionally used in robotics, it becomes necessary to investigate alternative types of computing systems. An attractive candidate for such a system is one consisting of many interconnected microprocessor-based computers[1]. In addition to providing additional computational power through parallelism, a multiprocessor system exhibits many useful characteristics such as low cost, modular growth, and increased reliability through replication. To achieve these benefits, the cost of communications must be low; small enough so that the communications cost does not exceed the time savings obtained by parallel execution on the different processors. Furthermore, if time-dependent operations are to depend on communications between processors, then there must be a guaranteed maximum latency for interprocessor communications.

This paper describes the programming environment provided by Meglos[2] [3], a multiprocessor system that is well suited to robotics applications. The system consists of up to twelve processors using Motorola 68000 based Multibus computer systems. Each processor is connected to the S/NET[4] [5], a high throughput (80 Mbit/sec), low latency, message-oriented interconnect. The processors communicate by sending messages—no shared memory or other means of communications is provided. A DEC VAX computer running the UNIX operating system serves as a host processor for the system. Programs running on Meglos are controlled from the UNIX System, which provides terminal and file system access for these programs.

The satellite processors are built around the Pacific Microsystems PM-68K single-board computer[6]. This board contains a Motorola 68000 processor clocked at 10 MHz along with 256 kbytes of memory that is accessed with no processor wait-states. Each PM-68K is connected to a separate Multibus backplane. In addition to the single board computer, each backplane contains one or two additional boards with 512 kbytes of memory, a Sky Fast Floating Point Processor board[7], and an interface board that connects the processor to the S/NET interconnect. The Multibus may also contain other boards that interface to devices such as robot arm controllers, sensor interfaces, or frame-grabbers.

The addition of the Sky floating point boards to each processor is a requirement for robotics applications. Without it, all floating point calculations must be done in software. The speed of performing floating point calculations in software is so slow as to be almost useless for time critical computations such as robot arm kinematic solutions. With a Sky board, the floating point performance of a Motorola 68000 is 20 times better than with software floating point and for many applications, is 50% that of a VAX 11/780 with a floating point accelerator[8].

The initial design and implementation of Meglos was influenced by our sister Robotics Research Department. They were interested in several projects that were beyond the capabilities of a single 68000-based computer system and realized that a multiprocessor system based on the S/NET interconnect would be well suited to robotics applications with real-time requirements because the S/NET hardware guarantees that data is always transmitted within a specified time interval.

Because of their interest, many of the features of Meglos are designed to simplify the programming of robotics applications. Its interprocess communications mechanism is well suited for use in real-time applications because it has predictable and small latencies. This mechanism is based on communications paths called *channels* that permit two programs to communicate via message passing. Each channel is independently flow-controlled, so that a program may set up multiple channels to communicate simultaneously with many other programs. Channels may be set up between two programs running on the single-board computers, or between a program on an attached processor and a pro-

CH2345-7/86/0000/0169$01.00 © 1986 IEEE

gram running on the UNIX System.

Each of the attached processors runs the Meglos *kernel*, a real-time multitasking executive that oversees each processor's local resources. The kernel manages the allocation of processing cycles and communications bandwidth for programs running on the processor. For real-time response, there is a priority-based preemptive scheduler and an efficient mechanism for switching between processes. User programs may specify interrupt service routines, change the processor interrupt priority level, and directly access processor I/O space. Meglos provides a mechanism that integrates the scheduler with device interrupts and user-written device handlers. This allows users to customize the attached processors to control a variety of devices such as robot arms and video image processors.

The Meglos operating system allows several independent applications to run at the same time. One of our testbed systems has several processors connected to robot arms and other processors attached to cameras and image processors. Since Meglos makes it easy to write programs without embedded physical processor numbers, the testbed system may be shared by several researchers, each using some of the robotics equipment, without having to reserve the use of specific processors.

Since most of our users are already familiar with the UNIX system, we chose to design the Meglos programming environment as an extension of the UNIX environment. Since the single-board computers do not have disks, terminals or other standard peripherals, a satellite processing scheme is used: each time a program issues a UNIX system call, the call is passed to the UNIX System for execution. On completion of the system call, the results are sent back to the requesting program. This allows Meglos programs to access all files and other facilities on the host UNIX system in the same way as programs running on UNIX do.

II. An interesting application

An interesting robotics application that has been implemented on Meglos is a robot teaching system, MIMIC, in which a robot arm follows and mimics an operator's hand movements in real-time[9]. We refer to this application throughout the paper to illustrate how an application uses various facilities provided by Meglos. The application was motivated by the desire to overcome some of the limitations of teach boxes currently available for teaching robots a desired task. Conventional teach boxes can only teach points along a desired path. This can be difficult to convert into a trajectory. Another limitation is their inability to allow control of all joints simultaneously.

The operator moves a flat circuit board on which are mounted five LEDs in front of a camera. The three-dimensional position and orientation of the board are determined from the camera images and the actual motion is computed. The board's motion is converted into robot motion, by assuming a similar board is attached to the robot's gripper, as shown in Figure 1. The robot arm and gripper then reproduce or mimic this motion. All the calculations take place in real-time, i.e., as the operator moves the board around, the robot arm across the room performs the same movement with no noticeable delay.

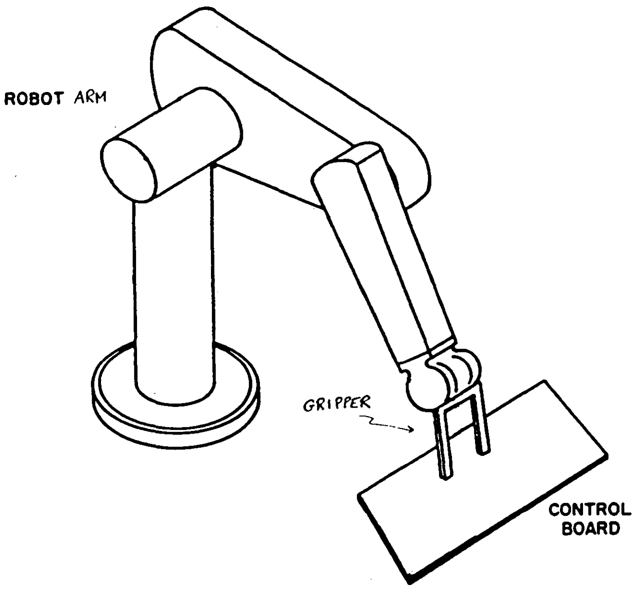

Figure 1. *Robot holding board.*

The application is broken into three modules, each of which runs on a separate processor. See Figure 2. The first module is a data acquisition system that processes data from a solid state camera that captures a frame each 17 msec. The module determines the image coordinates of each LED and sends them across a channel to the next module. Module two determines the position of the board in three space, calculates the board's motion, computes the angles through which the arm and gripper should move, and sends them to module three. This calculation requires 15 msecs. The third module, the robot controller, moves the arm and gripper in the requested fashion.

This application naturally breaks up into several modules executing on separate processors: two device handling modules and a central module that communicates with the others to coordinate their work. An advantage of partitioning the problem in this manner is that general purpose device handling routines can be designed for reuse by many applications. New applications that wish to track LEDs or control the robot need only understand the format for data sent to and from the device routines and need not concern themselves with the detail of handling the devices.

Like other robotics applications, MIMIC requires the use of customized hardware for its implementation. The data acquisition processor uses a commercially available

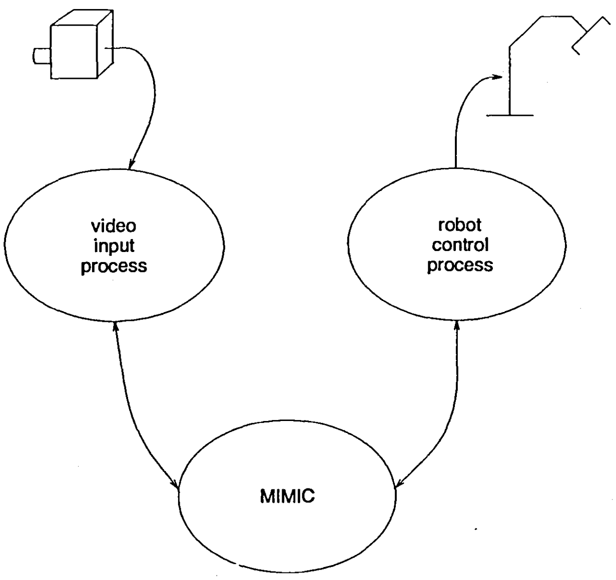

Figure 2. *Block diagram of teaching system.*

frame grabber and image processing system. The robot controller processor uses an in-house interface. Both connect directly to the Multibus. Building Meglos around an industry standard bus and allowing user-written interrupt service routines allows users the flexibility of customized processors. When a new device is to be attached, the kernel does not require being recompiled with a driver for the new device. This is another feature of Meglos that makes it useful for robotics applications.

III. Programmer interface

Like other message-based multiprocessor systems[10], applications are coded in a sequential programming language extended by primitives that provide communications and synchronization. An application typically consists of programs running on many processors that communicate amongst themselves to cooperatively perform the application. Users run and debug programs on the attached processors from terminals connected to the UNIX host. Programming is simplified because the entire "edit–compile–run" debugging cycle can be performed from a single terminal.

For example, to run a program that has previously been compiled into a file named mimic, the command:

```
tx mimic 10 20
```

is issued from the host UNIX system. It causes the file mimic to be downloaded to one of the processors, the arguments 10 20 to be passed to the program, and starts the program running on the single-board computer. If the running program executes a UNIX system call, the kernel on its processor passes the call to the tx program and tx actually executes the call. For instance, if the program issues a `write` to its standard output, the tx program responds by writing the data to its standard output. This exact emulation of the UNIX environment allows programs running under Meglos to make use of input and output redirection, pipes, and the other features of the UNIX System that contribute to its effectiveness as a program development environment[11].

For applications that make use of custom hardware such as robot arms, it is necessary that the program runs on a processor with the proper hardware. For example, the command:

```
tx3 mimic 10 20
```

causes the program to be run on processor number 3. A way to invoke an application that consists of many programs is to create a UNIX shell script[11] that starts each of the programs in the background with a separate tx command.

As an example of how these primitives are used, we show how MIMIC is run on one of our testbed Meglos systems. The data acquisition portion of MIMIC is compiled into the file trakleds and runs on processor 2, the processor with a camera, frame buffer and image processor. The robot controller, mimicarm runs on processor 5, the processor with the robot interface, and mimic, the program that does the calculations can run on any processor.

Processors are made available for use by Meglos programs with the txadd command and removed with txdrop. One typically drops a processor before powering it off, say to change a board in its Multibus. Before running MIMIC, the command

```
txadd -e 2 5
```

could be given. This causes processors 2 and 5 to be made available in the *exclusive* mode, indicating that no other users may run programs on the processors.

After the processors have been added, MIMIC may be started. A shell script that could be written to run MIMIC is as follows:

```
tx2 trakleds vision &
tx5 mimicarm 10 .3 &
tx  mimic vision &
```

This causes the trakleds and mimicarm programs to be started on the appropriate processors and mimic to be run on any processor. The mimicarm program requires two input parameters for setting internal constants within the robot controller. They are passed on the command line invoking the program. The "&" is part of the shell syntax that says to run the program in the background, concurrently with the other programs in the script.

The txstat command is used to display a list of available processors and what is running on each processor. Figure 3 shows the output of a txstat command obtained while MIMIC is running.

It indicates that user rdg is running the three programs comprising MIMIC on processors 1, 2, and 5 and that processors 3 and 4 are available for use. Other items displayed are the total memory on the processor, the memory currently available and the UNIX process id,

```
MACHINE  MEMSIZE  MEMFREE  USER       PID    MEMSIZE  PRIORITY  PROGRAM
      1    1152K    1056K

memory usage and Meglos execution priority of each program.

IV. Channels

The communications requirements for multiprocessor robotics applications differ from other types of distributed systems, such as networks of workstations, in several fundamental ways, including requirements for communications performance, naming mechanisms, access control, and fault recovery.

Workstations typically use a client-server model of computation in which a processor (or groups of processors) offer some service, such as file system access, to the other workstations in a system. In contrast, the programs of a robotics application are typically peers and the relationship of client/server or master/slave cannot conveniently be assigned to the programs. This suggests that the Meglos communications mechanisms should be symmetric both in methods for establishing communications and for sending messages between processors.

In Meglos, programs establish communications channels between each other before they communicate and each channel connects only two programs. Channels provide for the transmission of data messages from the address space of one program to the address space of another and provide synchronization between readers and writers.

Communications via channels is independent of where the two programs are executing. They may be on the same or on different single-board computers or on the host UNIX System. It is this feature of channels that allows several independent applications to run on Meglos at the same time. To establish a channel between two programs, both must first agree on a name for the channel. The two programs then issue a `copen` system call. The channel name is passed to `copen` and it returns a channel descriptor for that channel. If a program attempts to read or write a channel before a second program does a `copen` for the channel, the read or write blocks until the other program does its `copen` and the channel is set up. The first read or write call may also return an error if a problem occurs while opening the channel. Note that no indication of channel direction is passed to `copen`. This is because channels are bidirectional and thus can always be either read or written by the program.

The performance of channels is sufficient to meet the demanding real-time performance requirements of robotics applications, yet they still provide transparent and automatic recovery from faults that are likely to occur while a program is running such as receiver buffer overflow or transient communications errors. Channels provide a good match with the communications patterns of robotics applications because such applications can often be structured as a set of programs whose communications topology is either fixed or changes slowly over time.

With channels, the operating system provides flow control that allows a program that is accepting input from more than one channel to read input from the channels in whatever order is most convenient for the program. Communications mechanisms without independent flow control do not allow a program to chose which channel data is to be received from. Instead, each time a program reads data, it gets whatever message has next arrived on any of its channels, so that a program may be flooded with messages that it is not ready to deal with. We did not use a more general scheme, such as ports that allow multiple readers and writers, because the protocols for flow-control and for the detection and recovery from transient communications failures can be implemented more efficiently when the reader and writers of messages are known in advance[12].

Programs send messages on a channel by issuing a `write` call. `Write` requires three arguments: a channel descriptor (obtained from a `copen` call), a pointer to the message to be sent, and the length of the message, in bytes. When the `write` returns, the sending program is assured that the reader has received the message with no errors.

To accept data from a channel, a program issues a `read` call. `Read` requires three arguments: the channel descriptor, a pointer to a local buffer, and the size of the buffer, in bytes. If a `write` has already been issued by the program at the other end of the channel, then the message sent on the channel is placed into the local buffer and the `read` call returns. If a `write` has not been issued, then the `read` blocks waiting for one. When the `read` call completes, it returns the length of the message that was placed in the buffer.

Programs sometimes need to coordinate data originating from several channels. A mechanism provided for such programs is a multiplexed input primitive. readn, to which an array of channel descriptors is passed. When a message arrives on any one of these channels, it is placed into the buffer specified in the readn call and the channel descriptor for that channel is returned to the calling program. If input is simultaneously available on more that one channel then the channel number that occurs first in the array of descriptors is returned. By using this mechanism, a program can implement either prioritized or round-robin service for input channels. Readn provides multiplexing capabilities that are similar to those of the 4.2BSD select call[13].

To close a channel, a program issues a close call. After a program closes its end of a channel, any attempts to read or write on that channel return an error. After reading the last data sent before the close, reads by the program at the other end of the channel return an end-of-file indication. Similarly, writes to a channel that is closed indicate end-of-file.

In a message-based system, two measures of communications performance, latency and throughput, provide programmers some idea of how their application would perform, and for robotics applications with real-time requirements, indicate whether they can be implemented at all. Latency is defined as the elapsed time between when a message is sent and when the sending processor is notified that the message is received by the destination processor. Throughput is defined as the number of bytes one program can send to another in one second. Guaranteed low latencies for communications between user programs are required to satisfy the real-time requirements of robotics applications and knowing the throughput of a system is useful to determine performance when sending large amounts of data between program.

We measured the performance of the system with no other activity on the interconnect. It takes only 750 μsec to send a 2 byte message and for a 1000 byte message the latency is only 3.3 msec. In the two byte case, the actual time the message spent going across the bus is only 2 μsec. For a 1024 byte message, the time spent on the bus is only 100 μsec out of the total time of 3.3 msec. This data shows that over 95% of the cost of communications can be attributed to the Meglos software and less than 5% to the hardware. This demonstrates why it is necessary to evaluate performance at the user level to obtain meaningful results.

Because writes do not return until an acknowledgement is received from the remote end, their times include all overhead for communication protocols and context switching. The latency for access to the S/NET depends on the number of other processors already waiting to send a message and the length of the messages that they send. Because the S/NET interconnect provides first-come first-served access to its bus, it provides a guaranteed maximum response time. In the extreme worst case, when each other processor is sending a long (1000 byte) message, the maximum hardware latency is 4.4 msec. So, the worst case transmission time for a short message is 5.2 msec and a for a long message is 7.7 msec.

The second measure, throughput, is obtained by dividing the number of bytes in a message by the latency for that size message. For messages longer than 1000 bytes, the throughput exceeds 300 kbytes/sec. Even at such high rates, only 3% of the S/NET's available bandwidth is used. Thus, the S/NET is capable of supporting up to thirty pairs of processors, communicating at their maximum rates, before the S/NET's bandwidth is used up.

When comparing the measurements reported here with the performance of other systems, one should be aware that some system designers only provide speed measurements of the hardware interconnect or measurements made at the kernel level. Such measurements usually indicate significantly better performance than can actually be obtained by user programs and are not useful for determining how well an application would run on the system. All our measurements were made between user programs and were done with a high-precision timer located on the individual processor boards.

The txstat command has an option for displaying the status of all the channels currently in use. For the example, the output from txstat with the channel information displayed is shown in Figure 4.

The figure shows the five channels used by MIMIC. A channel can be in any one of three states OPENING, OPEN, and CLOSING. The first line indicates that the channel vision is OPEN and connects trakleds executing on machine 2 to mimic executing on machine 1. This channel is used to transmit the LED image coordinates to mimic so it can determine the motion of the circuit board. The channel mimic_update_message is OPEN and connects mimic to mimicarm. This channel is used bidirectionally, to send joint rotations to mimicarm and to send the current robot position back to mimic. The channel mimic_clock_message is interesting in that it connects the mimicarm executing on machine 5 to itself. The use of this channel will be discussed in the forthcoming section on subprocesses. The last channel is OPENING because only one program has issued a copen for the channel. These channels are used to change internal parameters of the robot controller from a terminal.

V. Devices

Since each of the single board computer systems has its own Multibus cage, specialized devices such as robot arms and sensors may be connected to the Multibus and be used by the processor. Meglos allows programs running on a processor to use these devices and respond to their interrupts. All Meglos programs run with the processor in user mode. Most other operating systems require that programs that control devices to run in

supervisor mode. This is potentially dangerous because a program in supervisor mode can overwrite the kernel or other programs running on a processor.

Every program running on Meglos may access Multibus I/O space. Programs access I/O registers of devices on the Multibus by reading or writing the address that corresponds to the register. Meglos allows programs to respond to device interrupts by calling a C language subroutine in the user's address space when an interrupt occurs. The name of the subroutine to call and the interrupt number are specified in the `onintrpt` call. `Onintrpt` also requires a user-written subroutine that contains code to disable the device. Meglos calls this subroutine when the program terminates either normally, or due to an exception such as a bus error. For applications using devices such as robot arms that can cause physical damage without proper program control, such a routine is required to stop the device when the program terminates abnormally because of a programming error.

There are certain limitations placed on interrupt service routines because they are not schedulable like subprocesses. This makes it impossible for an interrupt service routine to read or write on a channel or perform any UNIX system calls. A typical interrupt service routine performs the function needed by the interrupting device and then starts up a subprocess to handle any communications that may be required.

Programs that access hardware devices sometimes need a mechanism to prevent the interrupt service routine (specified in `onintrpt`) from executing during some sections of code. A program may delay the servicing of a hardware interrupt by raising the processor interrupt priority with one of the `spl` calls. The call `spl`*n* sets the interrupt priority level to *n*. It is the programmer's responsibility to return to priority level 0 with the `spl0` call at the end of the critical section of code. By default, interrupt service routines run at the hardware priority level of the interrupting device.

Mimicarm, the robot controller used by MIMIC, requires that joint angle updates occur at fixed intervals of 28 msecs. The interface board generates interrupts at this rate from the robot controller's internal 28 msec clock. This interrupt is tied to one of the Multibus's eight interrupt lines and the `onintrpt` call binds mimicarm's service routine to this interrupt. This routine need only reset the interrupt and resume the mimicarm update subprocess. This will be discussed in more detail in the next section.

Like any other device, Meglos allows programs to directly access the device registers for the S/NET interconnect. This allows programmers and language designers to experiment with communications primitives other than those provided directly by Meglos. For instance, the communications operations of the Linda language[14] and a queue-based communications scheme for the CEMU circuit simulator[15] are implemented in this fashion. Programs performing their own communications are required to send messages with a header that allows the kernel to distinguish these messages from those sent on channels. A variant of the `onintrpt` call is used to specify a handler to be called when these messages arrive at a processor. Though this general communications facility is available, all robotics applications implemented to date have found the channel mechanism to be sufficient for their needs.

The single board computers include a timer that can be set to interrupt at fixed intervals. The `maketimer` call makes use of this timer to call a C routine at a specified time interval. The timer interrupts at interrupt priority level 6 and the specified C routine runs at this priority level.

VI. Subprocesses

The portions of robotics applications that control devices often have strict real-time requirements. To simplify the design of such programs, Meglos allows a program to be subdivided into subprocesses with user-specified execution priorities. Subprocesses are a part of a user's process that may execute asynchronously with the rest of that process. Each subprocess is independently schedulable; the Meglos scheduler knows and understands that a process can contain more than one thread of execution. This can be viewed as a form of multitasking within a process. All subprocesses within a given process share the same address space and each subprocess has its own stack for storing the machine state information and its local variables.

Meglos includes a preemptive scheduler that allows execution priorities to be specified for each subprocess of a process. Since high priority subprocesses are always run in preference to those with lower priorities, strict real-time response may be assured by coding the portion of an application with real-time requirements as a high priority subprocess. The scheduler is referred to as *preemptive* because when a higher priority process becomes runnable (say, as a result of its input or output completing) while a lower priority process is running, the higher priority process preempts the execution of the lower priority process. The lower priority process will be restarted when the higher priority one terminates, blocks waiting for input or output to complete, or by issuing a `suspend` call or a `P` operation on a semaphore, Meglos does not provide time slicing between processes of the same priority, so that a subprocess that computes forever would prevent other subprocesses from executing.

Each process in Meglos consists of one or more subprocesses. All subprocesses of a process execute in the same address space, so that global variables are shared between subprocesses, Each subprocess has its own local variable stack. A process initially consists of a single subprocess and additional subprocesses may be created with the `creat_sbp` call. The name of a C subroutine that contains the code for this subprocess as well as the arguments describing the environment for the subprocess are specified in this call. `Creat_sbp` returns a subprocess number that is used to refer to the subprocess that was created. A process can temporarily stop its own execution by calling `suspend` and can restart another suspended subprocess by calling `resume` with the number of the subprocess that is to be resumed.

A subprocess is terminated when its procedure returns or can be terminated by another subprocess with `kill_sbp`. The main subprocess (i.e., the first subprocess of a process with the procedure name of `main`) should not return and no subprocess should call `exit` while other subprocesses are running. If they do, all subprocesses of the process are immediately terminated.

A subprocess that modifies a data structure shared among many subprocesses may have to prevent the other subprocesses from accessing that data structure while it is being modified. Like many other systems, Meglos provides semaphores[16] to allow programs to implement such controlled access.

For applications that consist of many subprocesses or processes on the same processor, it is important that the overhead incurred by Meglos for switching between tasks is small. The time for switching between two subprocesses within the same process is 200 μsec and the time for switching between two different processes is 250 μsec. The interrupt response time, the time that elapses between when an interrupt occurs and the user routine that services that interrupt starts to run, was measured at 50 μsec.

Two of the programs that are part of MIMIC, trakleds and mimic each consist of a single subprocess. The robot controller program, mimicarm, consists of three subprocesses and an interrupt service routine. One subprocess is used to provide synchronization and the second actually controls the robot arm. The third subprocess uses the mimicarm_info_external channel to connects to a program that reads from the user's terminal to allow changes to the internal controller parameters while the application is running. See Figure 5.

Every 28 msecs, the synchronization subprocess is resumed by the interrupt service routine and it sends a message across the mimic_clock_message channel and suspends itself awaiting another interrupt. The other subprocess is connected to both the mimic_clock_message channel and the mimic_update_message channel. Since messages arrive asynchronously on both channels, it uses `readn` to accept data from either channel.

A typical sequence of events is as follows: A joint angle update message arrives from mimic on the mimic_update_message channel. The subprocess stores the new joint angle rotation values, reads the current positions of each joint from the robot controller and sends these values back to mimic across mimic_update_message. It then blocks on the `readn` awaiting either another update message or a synchronizing message. When a synchronizing message arrives, the subprocess passes the joint angle rotation values it saved previously to the robot controller and again executes the `readn`. The system continues to function this way until the application is terminated by the operator.

VII. Debugging

The message-passing style of communications used in Meglos encourages programmers to break up their applications into functionally distinct modules with well defined communications interfaces. This often allows each program of a robotics application, like the trakleds, mimic, and mimicarm programs, to be written and debugged as separate modules in isolation from each other.

To help debug such programs, Meglos includes a symbolic debugger for C programs that allows programs to be run in an environment that can be monitored and controlled. Breakpoints can be set, either at a specified C statement, or at a machine instruction. Both C language variables and arbitrary memory locations may be displayed and modified. The debugger allows the programmer to access the program at both the C and

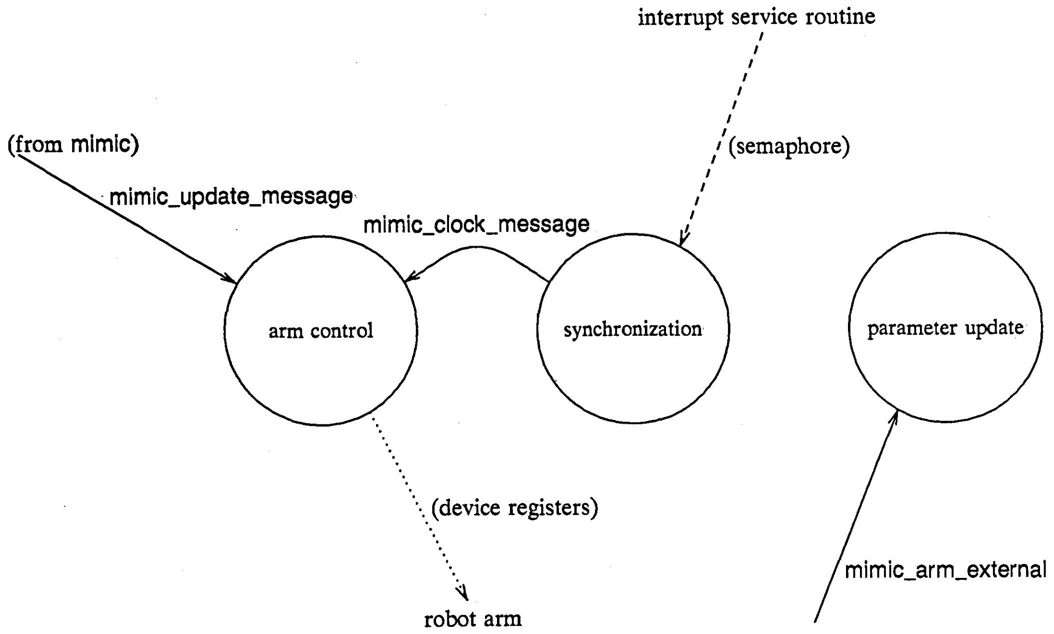

Figure 5. *Subprocesses of* mimicarm.

machine language levels and provides for easy translation between the two. The debugger's user interface is identical to that of the sdb debugger[17] which is part of the UNIX System.

If a program incurs an exception such as a bus error, Meglos aborts the program and produces a file on the host system with the contents of the program's memory and registers. The debugger is used to examine these images of aborted programs. It is also possible to abort a program at any time from the UNIX system, disable devices connected to that processor, and obtain a memory image by hitting a key on the keyboard. This is crucial when debugging robotics applications because it allows the operator to stop a robot before it crashes through a wall.

When it is necessary to simultaneously debug programs running on many processors at the same time, the windowing capabilities of a workstation or a terminal like the Teletype 5620[18] may be used. Each program of the application can be run with the debugger in a separate window, so that interactions between programs may be viewed.

The convenience of having full access to the UNIX system and good debugging facilities can be used by programs that have real-time requirements. Programs incur no extra overhead for accessing the host UNIX system except for the duration of the system call. While debugging, programs run at their normal speed until they are stopped at a breakpoint. Thus, the interactive debugger can be used to test most portions of real-time programs. For debugging time-critical sections of code, one can send debugging output to a file. If that is still too slow, debugging output can be written into memory and examined at a later time.

Far more sophisticated debugging tools that we provide would be useful in many situations. For example, a common symptom of a program bug is for an application to deadlock with all of the program of an application waiting for channel input. Examining core dumps of the programs provides little help, because they do not show how the processes got into the deadlocked state. A tool that should help in such situations is one which monitors communications and retains the last several messages sent on each channel, allowing them to be viewed by the programmer.

VIII. Conclusions

We have illustrated the user interface provided by the Meglos operating system. A real-time robot control application example was used to show some of the primitives and run-time information commands available to a user of the system.

Several prototype Meglos systems have been built and some are used to support multiprocessor robotics applications in our Robotics Research Department. The users' experiences demonstrate that Meglos is a good environment for developing and running robotics applications. The close coupling of the host UNIX System with the single-board computers allows real-time programs to access all the facilities provided by the UNIX System. The job of programming and testing an application is simplified by the availability of a source language debugger and by convenient access to the UNIX system. The primitives provided by Meglos for communications between programs, and for multitasking within a processor have proven to be easy to use and to perform adequately for robotics applications.

In the past, developers of robotics applications that require multiple processors have found it necessary to build specialized hardware and operating system software for each of their applications. We have shown that a single hardware and software system can be built to accommodate a wide range of applications, allowing robotics applications developers to concentrate their efforts on hardware and software designs specific to their applications.

A Robot Force and Motion Server

Hong Zhang and Richard P. Paul

Department of Computer and Information Science
University of Pennsylvania
Philadelphia, PA 19104

ABSTRACT

The design and implementation of a distributed robot manipulator controller based on a concurrent architecture is introduced in this paper. We consider the manipulator as a force and motion server (RFMS) to a robot system executing force and motion commands issued by the robot system coordinator. In the server, computations are distributed to a number of processors in order to minimize the time delay in responding to input requests. The "C" programming language is used for both system programming and the user interface.

1. Introduction

A robot manipulator might be considered to act as a force and motion server for a robot [1]. The robot, interpreting sensor information in terms of a task model and a task plan, issues requests to the manipulator to exert forces or move objects. The motion of the manipulator is modified by sensor feedback.

Sensors determine the state of a manipulation task in terms of their own coordinate frames. If this information is to be used to control the manipulator, it must be transformed into a common coordinate task frame where given constraints may be applied and information from various sensors integrated to form a best estimate of the task state. This information must in turn be transformed into the manipulator joint coordinates where control of the manipulator is exercised. The time delays involved in these transformations, the time from when a sensor observation is made until the time when the signal to the manipulator actuators is changed in response to the sensor observation, must not be of the same order of magnitude as the natural response time of the manipulator itself; otherwise, system instability will result. It must be either much slower, such as in welding sensor feedback, or much faster, such as in force or contact feedback. We are interested in working in the latter domain to provide a manipulator controller in which the response of the system is limited only by the manipulator itself and not by the control computer.

In order to minimize the time delay between a change in some Cartesian coordinate frame and a response at the actuator level, we perform as many calculations concurrently as possible. We do this by separating the kinematic and dynamic aspects of the computation. There is little point in utilizing a processor to perform manipulator joint control, another to perform input/output, another to perform kinematic transformations, and another to convert from accelerations to joint torques, as these processes must then be performed one after the other. This increases the rate at which the calculations may be performed but does nothing to minimize the processing time delay. In our design, we use one processor for each joint of the manipulator and perform as many operations concurrently as possible to reduce the computation time delay. In order to separate the kinematic and dynamic aspects of the task, we compute manipulator configuration dependent parameters at a rate related to change in manipulator configuration and then make use of these parameters in the control of the manipulator at the much higher control sample rate. For example, we compute the joint inertias as a kinematic process in background to simplify the conversion of joint accelerations to joint torques which must be performed at the control sample rate. This is to be contrasted to the Newton-Euler approach in which link accelerations are first computed recursively from the base out to the end effector and then torques are computed, once again recursively from the end effector back to the base, resulting in a pipelined process in which the rate of calculation may be increased but the time delay in performing the calculation is not reduced. Numerically, the worst case delay in the Newton-Euler approach corresponds to some 2000 arithmetic operations.

We are also judicious in determining those calculations that we will perform exactly, those we will approximate, and those we will ignore. We do not calculate, or take into account, centripetal acceleration or Coriolis forces as these occur only at high speed, since we are primarily interested in

the performance of the manipulator at the end of motions when the speed is low. In most cases where accurate path following at high speed is important these forces may be pre-calculated or simply learned. We make use of as much knowledge as possible; we do not try to learn the dynamics of the manipulator, as we have symbolic equations, but we do learn the mass of an object being carried. Finally we are interested in performance and not just in control formalism elegance.

We have tried to use commercially available components as much as possible in our design. Intel 86/30 single board computers are used to perform the bulk of the processing. Each 86/30 is provided with its own input/output interface to the joint in order to minimize time delays. Calculations are performed in floating point, since 16 bit integer does not have sufficient precision for manipulator control and the resulting programs are virtually unreadable. We program in "C" to facilitate program understanding and modification. While we are interested in performance, we are also interested in cost and believe that the system we are developing is economically viable for industrial robot control.

2. Background

The control of a robot manipulator deals with the relationships among objects and between the manipulator and the objects. A robot manipulator task can be defined in terms of relationships in positions and orientations from one coordinator frame to the next. These relationships may in turn be described with homogeneous transformations [4] where the operation of matrix multiplication corresponds to the composition of coordinate frames.

The robot manipulator must be able to position its end effector arbitrarily in its work space. The Cartesian position and orientation of the manipulator, commonly referred to as $\mathbf{T}_6$, is obtained as the composition of transformations describing each position in a task. Given a manipulator task as successive Cartesian positions, the control system of the robot manipulator must convert them to joint coordinates where a robot manipulator is actuated. The desired joint positions can then be used to determine joint errors to produce joint correction torques.

If force control is required, the joint torques or forces must be computed by a different method. This in general requires the computation of the Jacobian matrix and inverse Jacobian matrix corresponding to the current manipulator position. In control of a manipulator the dynamics of each joint are taken into account by computing the link gravity loading and the effective and coupling joint inertias.

Feedback from sensors is achieved by modifying an appropriate coordinate frame in the composition of transformations specifying $\mathbf{T}_6$. The sensors run concurrently with the manipulator on their own processors. The information communicated is purely geometric.

3. Classes of Processes

The computations performed by the RFMS can be classified into dynamic processes, kinematic processes, and static processes, based on their real time constraints. Dynamic processes must be performed at a rate considerably higher than the natural frequency response of the manipulator. A kinematic process is a function of the position of a manipulator; its rate of computation is dependent on the change of configuration. The execution of the kinematic process affects the control accuracy but not the stability. A static process is time independent; failure to execute a static task delays the execution of the task, as the manipulator will come to rest and wait for its completion.

In control system of a robot manipulator, the dynamic processes control the joints. These processes are performed at a sufficiently high rate to provide for stable, noise-free control of the manipulator. This rate is of the order of 250 hertz for a manipulator of approximately one meter reach. As the control rate is reduced, the sophistication of the control algorithm must be increased.

The kinematic processes in a RFMS correspond to such tasks as computing the Jacobian matrices and link inertias. When the manipulator is at rest, or when performing fine motions these processes do not need to be computed at all. The static processes, very much like the ones in a time-sharing multi-user computer system, are related to house-keeping tasks such as user interface or file creation where there is virtually no time constraint. In a control system, various processes coexist and priority of service is given in the order of dynamic, kinematic and static processes.

4. Process Definition

In general, the following processes must exist in a manipulator control system: a set-point process for position control, a force control process for joint torque generation, and a supervisor process for system coordination, although implementation details may vary from system to system and additional processes may be required. In our particular case, a communication process is also needed to communication to the robot coordinator. The tasks all these processes perform are specified in the following sections.

4.1. Set-point Process

This process generates a set of desired joint positions or set-points every servo period. Neighboring set-points are thus separated in time by one sample period, Δt. A sequence of set-points make up a position trajectory. This trajectory must meet certain continuity conditions to assure the stability of the system. Different methods exist for such a process, but we use the algorithm for trajectory generation described in [2]. This method is based on the homogeneous transformation representation of the relationships between coordinator frames and allows two fundamental modes of motion, *Cartesian* and *joint*. The amount of computation in each sample period depends on the location of the trajectory and the mode of motion. The worst case occurs when the trajectory is specified in Cartesian mode and a transition to another Cartesian motion segment needs to be computed.

A position in the robot work space is defined by a position equation that, in its simplest form, equates the $\mathbf{T}_6$ to another position as:

$$\mathbf{T}_6 = \mathbf{P} \tag{1}$$

In general more structure is needed, for example:

$$\mathbf{Z}\,\mathbf{T}_6\,\mathbf{Tool} = \mathbf{C}\,\mathbf{P}\,\mathbf{G} \tag{2}$$

which means a tool is attached to the end of last link, the base of the manipulator is **Z** from the world coordinator frame, the grasp position **G** is defined with respect to a position **P**, which is again defined relative to a reference coordinate frame **C**. In general any of these transforms can be functions of time.

Motion is defined not only by the end points but also by the manner in which it is achieved. One can specify such motion parameters as the segment time, velocity, mode of motion, etc. A mode structure, **M**, describes these parameters in detail.

The set-point process computes the set-point in two stages. First it solves for $\mathbf{T}_6$ from the current position equation $\mathbf{P}_i$ and possibly the next position equation $\mathbf{P}_{i+1}$ if transition is necessary. This requires matrix operations such as matrix inversion and multiplication. Obviously, the more complex the position equation, the more expensive this process is computationally. Eq(3) functionally defines this first stage:

$$\mathbf{T}_6 = \Gamma(\mathbf{P}_i, \mathbf{P}_{i+1}, \mathbf{M}, t) \tag{3}$$

The second stage of the set-point process is the inverse kinematics that solve for the joint positions from the $\mathbf{T}_6$. When the manipulator is simple, this can be performed symbolically, i.e., closed-form solutions exist to express the joint positions as a function of the $\mathbf{T}_6$.

$$\boldsymbol{\theta}_d = \Lambda(\mathbf{T}_6, \mathbf{M}, t) \tag{4}$$

Typically an iteration of this process requires between five to ten milliseconds on a VAX 11/780 minicomputer.

4.2. Force Control Process

This is a dynamic process responsible for computing joint torques and then driving the joints. Given the desired joint positions, $\boldsymbol{\theta}_d$, there are a number of methods of generating joint torques. A general form for torque at the *i*th joint is:

$$\tau_i = \mathbf{D}(\boldsymbol{\theta}, \dot{\boldsymbol{\theta}}, \ddot{\boldsymbol{\theta}}, \mathbf{D}_i, \mathbf{D}_{ij}, \mathbf{D}_{ijk}) + \mathbf{F}(\mathbf{f}_c, \mathbf{J}) + \mathbf{R}(\boldsymbol{\theta}_d, \mathbf{S}, \mathbf{J}) \tag{5}$$

where

D dynamics compensation due to the gravity loading $\mathbf{D}_i$, inertial acceleration $\mathbf{D}_{ij}$, and Coriolis and centripetal forces $\mathbf{D}_{ijk}$,

F joint bias force due to the Cartesian bias force $\mathbf{f}_c$, and

R the reaction torque due to joint errors $d\boldsymbol{\theta}$ with the Cartesian compliance specification S taken into consideration, where S is a 6x6 diagonal selection matrix with 1's for constrained directions and 0's for unconstrainted directions.

Eq (5) is based on [3] and reflects the general approach of all joint based force control methods such as the stiffness method and hybrid method. Note here that all the input parameters to Eq(5) are assumed to be available from the kinematic processes. This process generates joint torques in response to the joint position errors, to the compliance specification of the manipulator task, and to the requirement of dynamics compensation. In the case when there is no contact between the manipulator and the environment, the torques are simply generated from the joint position errors and dynamics compensation.

4.3. Background Process

Parameters such as the Jacobian matrix and its inverse and the dynamic constants in the dynamic equations are functions of the manipulator kinematics and are computed in a kinematic process in the background.

4.4. Communication Process

A process is provided to communicate between the force and motion server nd the robot coordinator. The robot coordinator issues messages to the RFMS and may request information such as current $\mathbf{T}_6$. The messages sent by the coordinator describe the task model and defines the task plan in terms of the following data structures: *transform* definitions, *position* definitions, *mode* definitions, and *action request*. In addition, special messages also are defined to deal with situations such as initialization and emergency. All the messages are handled by the communication process.

In *transform* definition, one can define a constant transform or a variable transform that is dependent on external signals such as sensors. If the transform is variable, a redefinition by the coordinator would result in a corresponding redefinition of its counterpart in the server. This mechanism enables a user to modify manipulator motions. A transform symbol table exists on the server and this communication process stores the transforms in this symbol table.

In a message for a *position equation*, there are two ordered lists of transforms corresponding to the left and right hand sides defining a position in the robot work space. The transforms used must have been defined prior to the position definition and, therefore, they must exist already in the transform table of the server. Using the transform symbol table, we link the transform equation on the server into a ring structure for easy operation[4] and then enter it into the position symbol table.

A *mode* structure specifies how each motion is to be made, with parameters such as segment time, acceleration time, velocity, compliance specifications, etc. One may define a number of modes in a program and associate motion segments with modes. It may sometimes be desirable to execute a motion one way in the beginning of a task and then execute the same motion later in the task with another mode specification. The definition of mode structures and their association with a motion make the programming of tasks simple and clear. When a mode message is received, the communication process stores it in a mode symbol table for later reference.

Another type of messages, *action requests*, relies on the defined data structures in the first three categories to initiate actions for the manipulator. An action request contains two pointers: one to a destination position with the current position being the default initial position, and the second pointer to a mode structure specifying how the motion is to be made. Upon receipt of an action request, the communication process stores the request in an action queue. The two pointers in an action request are identifiers to the position table and mode table. The use of action queue guarantees program synchronization.

5. Implementation

The RFMS has been constructed using Intel single board computers (SBC) to control a Unimation PUMA 260 robot manipulator. The system is illustrated in Figure 1. It contains a number of processors including one for each joint, one for the gripper, one as the supervisor, one communicating with the robot coordinator, one as the math processor, and one data channel processor. In addition, special hardware has been designed for the low level joint interface.

The system is tightly coupled by the Multibus system bus. The Multibus interface is a general purpose system bus structure providing for communication between system components. Memory on one board can be accessed by another through the Multibus; eight interrupt signals can be used to direct actions. To minimize the bus contention, Multibus usage by boards other than the supervisor is kept at the minimum in the system. The RFMS does not use an operating system but is driven by interrupts and handshaking operations.

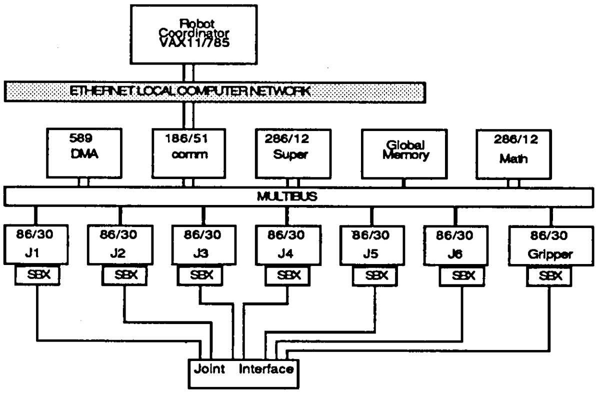

Figure 1. System Organization

5.1. Ethernet Communication

In this implementation the robot coordinator runs on a VAX 11/785 under Unix in a time-sharing environment. An Intel iSBC 186/51 communication controller in the RFMS facilitates the communication between the robot coordinator and the RFMS through the Ethernet local network. It is through this means that different agents such as sensors and RFMS in the robot system exchange information to update the world model. The speed of this communication is at the millisecond level, thus allowing the closing of a feedback loop through the Ethernet.

The communication between the coordinator and the RFMS takes place in the form of messages. The messages sent from the coordinator are first received by the communication controller, which stores the messages sequentially in a message list. Each entry of the message list contains a message identifier or index, a message type as described in Section 4.4, a flag for handshaking with the process reading the messages, and the content of the message. The communication controller appends the messages to the list to be processed by the supervisor. Depending upon the types of messages, this process can be either kinematic when handling sensor modifications or static when defining a task.

5.2. Supervisor

The supervisor runs on an Intel iSBC 86/30 with an 8087 floating point co-processor. The iSBC 86/30 contains 128K of dual-port memory accessible to both the local CPU and any other SBC on the Multibus, nine levels of interrupt control, two programmable timers, and serial and parallel I/O interfaces. The 8087 numeric co-processor executes floating point instructions at eight MHz and its instruction set provides for both arithmetic and trigonometric functions. The task of the supervisor is to maintain the global variables and control the system timing. Two separate processes run in the supervisor, one that reads the messages from the communication controller in background and one that coordinates the set-point generation in real time.

The background process reads the messages stored in the iSBC 186/51 and creates the internal data structures in terms of symbol tables and a motion queue as described in Section 4.4. The numeric values of the transformations elements are stored in the math processor memory where the matrix operations are performed.

When a position equation is processed, the two transformation lists representing the two sides of a position equation are used to create the ring structure, and a pointer to the structure is stored in a position symbol table. A mode record is treated similarly in a mode symbol table. Finally, an action request is queued in the action queue after its two pointers to a position equation and to a mode record are located in the respective symbol tables. The memory organization is summerized in Figure 2.

The real-time process on the supervisor initiates the computation of the next set-point upon a real-time clock interrupt from the programmed timer every sample period. The supervisor requests the math processor to compute the Cartesian set-point, i.e., the desired $\mathbf{T_6}$, and then requests the data channel processor to communicate $\mathbf{T_6}$ to the joint processors to compute the joint coordinates. The specific computation performed during each period depends upon the *state* of the manipulator or its trajectory. This process must finish before the next interrupt comes when another set-point must to be generated.

The most time-consuming computation in generating Cartesian set-point is the matrix multiplication required to compute $\mathbf{T_6}$. The math processor performs this operation. The math processor will eventually be replaced by a matrix multiplier device [5]. In each sample period when the matrix multiplications are needed, the supervisor simply generates a pointer list to those matrices to be multiplied, interrupts the math processor, and then continues with other operations. Upon completion of matrix multiplications, the math process interrupts the supervisor.

5.3. Joint Processors

Each joint is equipped with an iSBC 86/30 and an 8087 numeric processor. 64 kilobytes of its memory is configured global for interprocess communication. Joint processes run in parallel to control individual joints as described by Eq(4) and Eq(5). Working as slave processors to the supervisor, each of the joint processors computes its joint trajectory. The only process on a joint processor is real-time and interrupt driven. At the beginning of a sample period, it reads the current desired Cartesian position computed by the supervisor and solves for the joint position. Since the *i*th joint solution requires sines and cosines of the prior *i*-1 joints in general and this would cause considerable time delay if joints wait for solutions, we make use of the sines and cosines of joint variables computed in the last sample period so that all joints start computing simultaneously. During a transition, however, a joint process computes the coefficients of the transition polynomial and obtains solution by evaluating the polynomial. The *state* variable of the supervisor dictates the action of the joint processes.

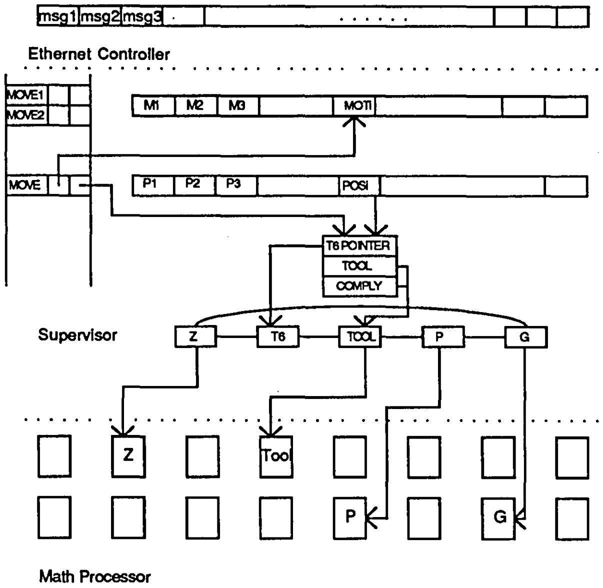

Figure 2. Memory Organization

The force control process is executed next to compute joint torque as in Eq(5). Information such as the Jacobian matrix and dynamics equation coefficients are broadcast to the joints when they are updated by the kinematic processes while the information such as errors and accelerations of other joints is collected from and distributed back to the joints as required in every sample period, all by the supervisor.

The low level interface to the joint is achieved through a specially designed hardware, iSBX multimodule board, attached to the standard SBX connector on each host 86/30. It provides the joint encoder interface and conversions between analog and digital signals. The board employs two digital to analog converters, two analog to digital converters, and an incremental encoder circuit. The first DAC outputs motor current, while the second allows us to specify a force set point to the joint. The ADCs read back the joint motor current and joint velocity, respectively. The incremental encoder tracks the position of the joint by observing the waveforms generated by the joint encoder. At the end of each sample period, the computed torque is converted to an equivalent joint current value before it is sent to the amplifier circuits to drive the joint motors.

5.4. Math Process

The math process is based on a iSBC 286/12 with an 80287 floating point co-processor. The iSBC 286/12 has 128k on board dual-port memory, a programmable interrupt controller, programmable timers, Multibus interface, and parallel and serial I/O interface, and the numeric co-processor 80287 similar to 8087 in its function. The process performs dynamics and Jacobian updates in background and, when needed, is interrupted to perform matrix operations for the set-point process.

5.5. Data Channel Processor

A DMA board iSBC 589 is added to the system to speed up the data transfer operations. Because the supervisor and the joint processors exchange information frequently in their real-time processes, this device considerably reduces the time for global memory read/write. At the time of initialization, destination and source addresses for different data transfers are stored in the parameter blocks of the DMA board. For each operation, the DMA simply needs to be written a wake-up byte and given the address of one of the parameter blocks.

5.6. Packaging

The system is housed in two connected iSBC 608 and iSBC 618 Cardcages with two iSBC 640 power supplies to provide a total of four double width and twelve single width SBC slots on the same Multibus for the system.

5.7. Performance Evaluation

The RFMS as described above has been evaluated for its real-time performance. Experiments have shown that the RFMS achieves a sufficiently high rate to update the Cartesian set-points while employing sophisticated control strategies for such applications as sensor-driven motions and force control. In order for the joint processes to evaluate joint set-points without waiting for the supervisor to finish computing T_6, th supervisor process pipelines its results to the joint processes, as is illustrated in Figure 3, where τ represents the sampling period, joints represents one of joint processes, and kinematic represents the background process computed on the math processor. By overlapping the supervisor and joint processes, we can shorten the minimum sampling period to obtain a servo rate over 250 Hz without performing any joint set-point interpolations. This servo rate is almost an order of magnitude improvement over the manipulator controllers that are being used today to control six degree of freedom manipulators.

We have achieved a throughput of 4 Kbytes per second data transmission rate through the Ethernet between the coordinator on a VAX 11/785 under normal working conditions and the RFMS. At this speed, we are able to send more than 100 transformations per second from the coordinator to the RFMS, as new observations are acquired by sensors, thus achieving real-time sensor feedback closed around the network.

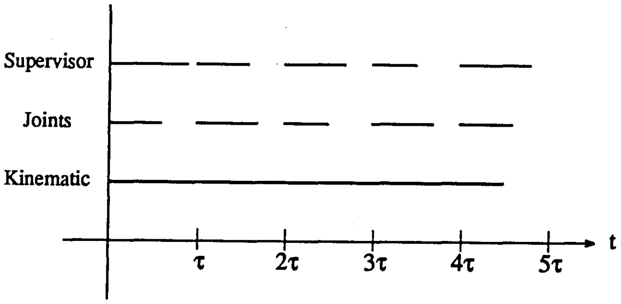

Figure 3. Process Scheduling

When homogeneous transformations are used to describe positions, the servo rate is limited by the complexity of the position equation associated with the current motion, since the more complex the position equation, the more matrix operations are required, and the longer sampling period would result. To eliminate the dependency of the sampling period on the complexity of the position equation, we are exploring solutions such as using the matrix multiplier [5] or high speed floating point processor to perform the matrix operations.

6. Discussion and Summary

We have endeavored to design a robot manipulator controller with sufficient computational bandwidth and precision so that the manipulator performance rather than the controller limits the performance of the system. We have done this in an economical manner using off-the-shelf components as much as possible. All coding is in the "C" language to facilitate understanding and future modification of the system.

The system provides for both position and force control implementing the hybrid force control system proposed by Craig and Raibert. The system is not based on a programming language but is specified in terms of network message formats. An Ethernet interface is provided so that the system may be directly interfaced with many other sensors and robot coordinator in a very simple manner, and that the motion can be controlled by sensors in real time.

Software Engineering for Rule-based Systems

Robert J.K. Jacob
Judith N. Froscher

Naval Research Laboratory
Washington, D.C. 20375

Abstract. Current expert systems are typically difficult to change once they are built. The objective of the present study is to develop a design methodology, which will make a knowledge-based system easier to change, particularly by people other than its original developer. The basic approach for solving this problem is to divide the information in a knowledge base and attempt to reduce the amount of information that each single knowledge engineer must understand before he can make a change to the knowledge base. We thus divide the domain knowledge in an expert system into *groups* and then attempt to limit carefully and specify formally the flow of information between these groups, in order to localize the effects of typical changes within the groups.

As the commercial promise for expert system technology grows, the problem of ongoing maintenance and modification of knowledge bases is becoming a significant concern. The designs of typical current knowledge-based systems are *ad hoc*, one of a kind, and difficult to maintain. The information in the knowledge base is interconnected in such a way that changing one part of the knowledge base may have unpredictable effects on other parts.

This research attempts to develop a design methodology similar to those used in software engineering,[1,2] which will make a knowledge-based production system easier to change, particularly by people other than its original developer. We have chosen to concentrate on production systems because they are the most widely-used type of knowledge representation in expert systems, particularly among those existing systems large enough and mature enough to have experienced the types of maintenance problems we hope to alleviate. In the future, we will attempt to extend the approach to suit other, newer knowledge representations, such as frames and semantic nets, as large systems begin to be written using them.

This paper describes the approach we are taking to build maintainability into production systems. It introduces a programming methodology for developing production systems. It discusses our study of structure and connectivity in already existing knowledge bases. It then presents algorithms we have devised for separating the information in a knowledge base and results obtained with them. Finally, it discusses tools for supporting the methodology.

Methodology

The basic approach we have taken for building maintainability into an expert system is to divide the information in the knowledge base and attempt to reduce the amount of information that each single knowledge engineer must understand before he can make a change to the knowledge base. We thus divide the domain knowledge in an expert system into *groups* and then attempt to limit carefully and specify formally the flow of information between these groups, in order to localize the effects of typical changes within the groups.

Production systems comprise extensive domain knowledge, expressed as if-then rules, and a relatively simple inference mechanism or rule interpreter. The interpreter tests the values of the facts on the left-hand side of a rule; if the test succeeds, new values for facts are set according to the right-hand side of the rule. In the present approach, we divide these rules into separate groups. The guiding principle for grouping two rules together is: *If a change were made to one rule, to what extent would the other rule be affected?* In this study, a *fact* refers to that part of the data representation that, if changed by one rule, would affect another rule in some way; in a simple production system where the data are represented as sequences of attribute-value pairs, a fact corresponds to an attribute. The knowledge engineer building the system would group together rules that use or produce values for the same sets of facts. With this arrangement, a fact in the knowledge base can be characterized either as being generated and used by rules entirely within a single rule group or else as spanning two or more groups. The latter will prove critical to future changes to the knowledge base, since they are the "glue" that holds the groups together.

Whenever rules in one group use facts generated by rules in other groups, such facts will be specially flagged, so that the knowledge engineer will know that their values may have been set outside this group. More importantly, those facts produced by one group and used by rules in other groups must be flagged too.

For each such fact, the programmer of the group that produces the fact makes an assertion, comprising a brief summary of the information represented by that fact. This assertion is the only information about that fact that should be relied upon by the programmers of other groups that use the fact. It is not a formal specification of the information represented by the fact, but rather an informal summary of what the fact should "mean" to outside users.

Given this structure, a programmer who wants to make changes to the system would assume the responsibility of understanding thoroughly and preserving the correct workings of a single group of rules (but not the entire body of rules, as with conventional systems). He or she would be free to make changes to the rules in the group provided only that he preserves the validity of the assertions associated with any facts that are produced by his group and used by other groups. Similarly, whenever he used a fact that was produced by another group, he would rely only on the assertion provided for it by the programmer of the other group and not on any specific information about the fact that might be obtainable from examining the inner workings of the other group.

Following our methodology, the developer would first divide the rules into groups. This can be done manually or automatically, as described below. One approach is to apply one of the automatic grouping algorithms to the initial prototype expert system and use the resulting grouping to guide the organization and development of the final production version. Then, a software tool will characterize each fact as inter-group or intra-group, and flag the former. The developer of a rule group that produces inter-group facts then provides an assertion describing each such fact. That description is the only information about the fact that should be used in the development of any other groups containing rules that use the value of the fact.

Thus, the set of rules will be divided into groups, the inter-group facts used and produced by each group will be identified, and descriptions will be entered for those produced by each group. Figure 1 shows the language used to provide this information, using an excerpt from a simple example knowledge base.[5] The figure illustrates the syntax for describing rule groups; a larger system would look exactly the same, except that it would list more rules, facts, and groups.

To modify a group, the maintenance programmer must understand the internal operations of that group, but not of the rest of the knowledge base. If he preserves the correct functioning of the rules within the group and does not change the validity of the assertions about its inter-group facts, the maintenance programmer can be confident that the change that has been made will not adversely affect the rest of the system. Conversely, if he wants to use additional inter-group facts from other groups, he should rely only on the assertions provided for them, not on the internal workings of the rules in the other group. (Of course, changes that pervade several groups would still have to be handled as they always have been, but the grouping is intended to minimize these.)

Figure 1. Example of a grouped set of rules.

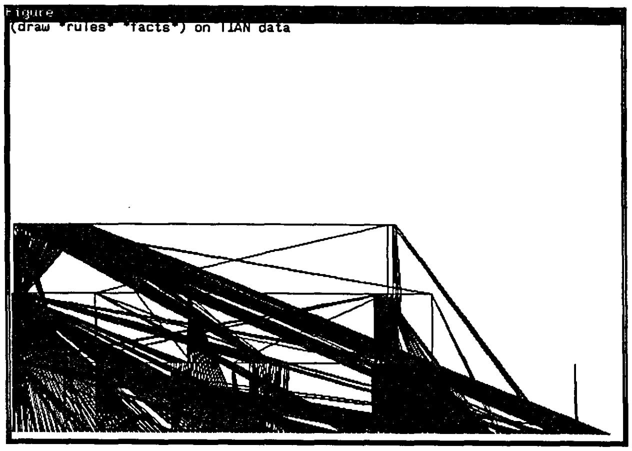
Partitioning the Knowledge Base

To decide whether partitioning a knowledge base is a feasible approach, we are analyzing existing production systems to determine how the rules in the system are related to each other. We have developed a software tool that analyzes the connections between the rules of a production system. The input to the tool is a set of rules expressed in an abstract form.

We are using the tool to determine whether the rules are indeed thoroughly intertwined or sufficiently separated that they could be divided into groups. To date, we have analyzed several knowledge bases and found that there is considerable separability and latent structure to the relationships between the rules in these systems, which could be exploited to improve maintainability.

Next, we are attempting to divide. the rules of existing systems into appropriate groups automatically, using several new approaches. By grouping the rules of existing production systems, we hope to determine whether such systems *could* have been cast in the mold required by the new method or whether it would have imposed excessive restrictions and unnatural structure on the developer. Based on the latent structure in rules found thus far, initial results suggest that the present approach can be imposed on many rule-based systems. They also suggest that an ideal, but not always attainable, grouping of rules is one in which each group of rules sets the value of only one fact that is used by rules outside this group.

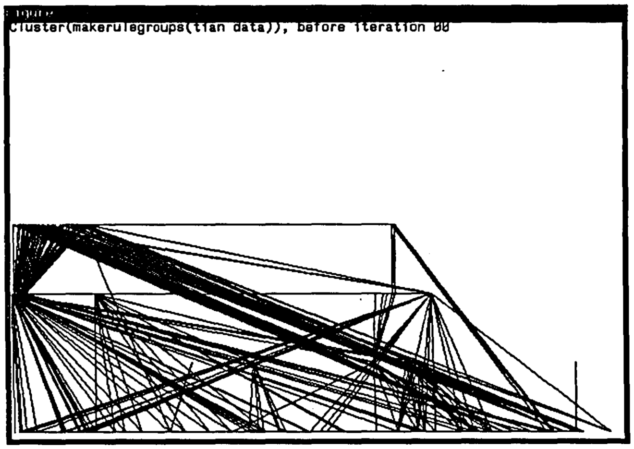
Rules are related to each other through the facts whose values they use or modify. First, we depicted these relationships in a graph, showing the inference hierarchy for the system. Figure 2 shows such a graph for an expert system developed by Reggia at the University of Maryland, using the KES language;[3] it is used to diagnose stroke and related diseases. In Figure 2, each node, or point, represents a rule and each link, or line, between two rules represents a fact whose value is set by one rule and used by the other.



(draw *rules* *facts*) on TIAN data

Figure 2. Plot of individual rules of an expert system.

The first algorithm considered attempts to partition this graph into a collection of rooted trees of rules, where the "root" of each such tree is a fact. That is, divide the rules into groups such that each group of rules produces only one fact that is used by other groups. This provides the desideratum mentioned above, since each rule group sets the value of only one external fact. Figure 3 shows the same system as Figure 2, after such an algorithm was applied. Each node now represents a group of rules, and each link represents a fact that is produced by rules in one group and used by those in another group. Facts that are produced and used entirely within a single group do not appear in the graph.

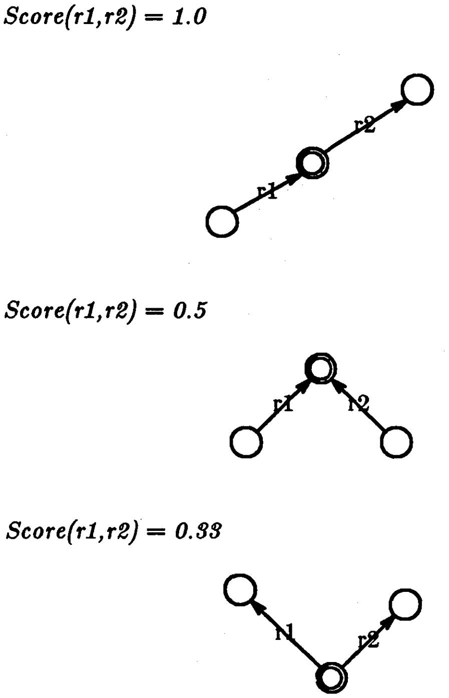


Cluster(makerulegroups(tian data)), before iteration 80

Figure 3. Rules of expert system, grouped into trees.

This algorithm tends to divide the knowledge base into many small groups. Each such group contains a collection of rules whose effect on other groups is entirely summarized by the fact at the root of the tree. Hence rules in these groups intuitively belong together under any grouping scheme. The problem is that the many small groups now must be combined into larger agglomerations. One alternative tested was to weaken the criterion for being a "rooted tree." That is, divide the rules into groups such that each group produces no more than **n** external facts, where **n** is now greater than 1. However, as **n** was increased, this approach did not appear to expose any natural structure in the knowledge bases.

Next, an approach based on cluster analysis was developed. Given a collection of objects, a clustering algorithm partitions them into groups of like objects. To use such an algorithm, though, a measure of distance or "relatedness" between rules must be defined. Since our ultimate concern is for a programmer making changes to the knowledge base, the similarity between two rules should measure: *If one rule were changed, how likely is the other rule to have to be changed also.* Rules affect each other through the facts they have in common. Thus a simple measure of the "relatedness" of two rules is the number of facts that are mentioned in the left or right hand sides of both rules. Since there are several ways in which two rules could refer to the same fact, we decided to weight this count. The two rules `if A then B` and `if B then C` share fact `B` in common; so do the two rules `if A then B` and `if C then B`. The rules of the former pair seem to have a greater programming effect on each other than the latter pair, and hence should be more "related." Figure 4 summarizes the three ways in which two rules can share a fact, and the weights given to each. The total "relatedness" measure between two rules is, then, a weighted count of the facts shared by both rules, where each fact is weighted by the score that indicates in which of the three possible ways the two rules use the fact.



Score(r1,r2) = 1.0

Score(r1,r2) = 0.5

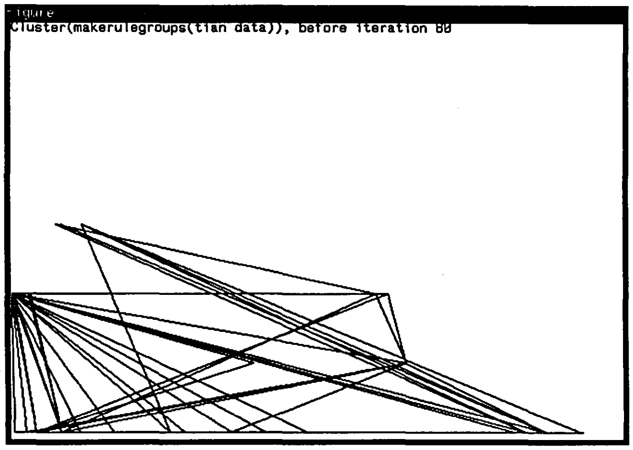
Score(r1,r2) = 0.33

Figure 4. Components of "relatedness" measure between two rules.

Given such a measure, we can proceed with a straightforward clustering algorithm. First, measure the similarities between all pairs of rules, select the closest pair, and put those two rules together into one cluster. Then, repeat the procedure, grouping rules with each other or possibly with already-formed clusters. In the latter case, we must measure the "relatedness" between a rule and a cluster of rules. This is simply defined as the mean of the similarities between the individual rule and each of the rules in the cluster, corresponding to an average-linkage clustering procedure. The algorithm proceeds iteratively.

The clustering algorithm can also be started with the small groups found by the rooted-tree algorithm above, instead of starting with individual rules. Since the tree groups appeared promising, but just too numerous, this is a reasonable alternative, and it appears to produce slightly better results. Figure 5 shows the rule groups of the system of Figures 2 and 3 after clustering in this fashion.

Thus far, this method appears to do the best job of partitioning a set of rules in an intuitively reasonable way. One drawback to the algorithm is that on each iteration it makes the best possible agglomeration of two groups, but it never backtracks, in case there might be a better grouping for the system considered as a whole. Also, like most clustering algorithms, if it runs for enough iterations it will eventually group all the rules into one large group; a stopping rule is thus needed.



Cluster(makerulegroups(tian data)), before iteration 80

Figure 5. Rules, grouped into trees then clustered.

Software Tools and Measurements

We have developed software tools to support this programming methodology. The developer can define the grouping of rules and input the knowledge base in the form shown in Figure 1, or he can run one of the grouping algorithms discussed to produce the grouping. These groupings have no impact on system performance since they are invisible to the rule interpreter. Given such a grouping, the software then automatically identifies the intra-group and inter-group facts. It flags all inter-group facts produced by a group, so the programmer can provide assertions for them; it flags all inter-group facts used by a group and retrieves their descriptions, so the programmer can rely on them when using such facts. Other software tools can trace all effects of changing a given rule and can find any unused rules or groups.

The division of a set of rules into groups should attempt to minimize the amount of coupling between the groups and maximize the amount of cohesiveness within each group.[4] Defining measures for these notions will provide data to help compare alternative groupings of a given set of rules. Once a set of rules is divided into groups, each fact in the system can be characterized as being used and produced by rules entirely within a single group or else as being used or produced by rules in more than one group. One simple measure of coupling is the proportion of facts in the second category, while cohesion is represented by the proportion of facts in the first.

Another approach to these measures is also being investigated. For coupling, it uses the average "relatedness" between all pairs of rules, where members of the pairs lie in different groups. For overall cohesion, it uses the average relatedness of every pair of rules that lie in the same group. For the example shown above, these quantities are 0.0798 average coupling and 0.9238 average cohesion, suggesting a far better than random organization.

Conclusions

By studying the connectivity of rules and facts in several typical rule-based expert systems, we found that they indeed have a latent structure, which can be used to support a new programming methodology. We have developed a methodology based on dividing the rules into groups and concentrating on those facts that carry information between rules in different groups. We have also studied several algorithms for grouping the rules automatically. Finally, we have developed a simple language and some software tools and measures to support the new method.

The resulting programming methodology requires the knowledge engineer who develops a rule-based system to declare groups of rules, flag all between-group facts, and provide descriptions of those facts to any rule groups that use such facts. The knowledge engineer who wants to modify such a system then gives special attention to the between-group facts and preserves or relies on their descriptions when making changes.

An interesting aspect of this approach is that it draws distinctions between the facts contained in working memory of a production system. Certain facts are flagged as being important to the overall software structure of the system, while others are "internal" to particular modules and thus less important. Programmers can be advised to pay special attention to rules that involve the "important" facts. This is in contrast to the homogeneous way in which the facts of a rule-based system are usually viewed, where they must all command equal attention or inattention from the programmer.

To determine how well this programming methodology will work, we are attempting to retro-fit several existing knowledge bases with this approach. This will help determine how well the structure implied by the new programming methodology can fit the structures observed in actual rule bases. We will use the grouping algorithms to divide the rules and then use measures of coupling and cohesion to compare alternative groupings. Next we will attempt to measure the extent to which the new method helps or hinders maintenance of an expert system. We will attempt to make changes both to a conventional expert system and to one divided into groups following the proposed method and compare the results. Based on our preliminary results, the method does not impose unreasonable restrictions on the developer nor does it lead to unnatural structures.

AN ORGANIZATIONAL FRAMEWORK FOR COMPARING ADAPTIVE ARTIFICIAL INTELLIGENCE SYSTEMS

Teresa A. Blaxton and Brian G. Kushner

The BDM Corporation
7915 Jones Branch Drive
McLean, Virginia 22102

One of the most interesting topics of investigation in the field of AI is machine learning where systems are being made to automatically "adapt" or learn over time. The following paper presents a common framework for organizing several diverse adaptive AI systems. Nine systems are discussed with regard to: (a) the types of knowledge representations they employ; (b) storage; (c) retrieval mechanisms; (d) conflict resolution principles; and (e) means of adapting knowledge and control structures as a function of changing experience.

There is a new trend evolving in artificial intelligence which directly impacts the work being done on expert systems. More and more, people are becoming unsatisfied with constructing static knowledge bases which are obsolete almost as soon as they are completed and must be updated on a continual basis. The alternative being explored is that of creating systems which adapt with the addition of new knowledge, not only learning new facts but actually changing their own memory organizations and control structures to accommodate the new data more efficiently.[1,2,3] Such systems are potentially more user oriented, more flexible to operate, and are less costly from a software/life-cycle support viewpoint.

Although several researchers have attempted to build adaptive systems (ASs), they have unfortunately done so without the benefit of any guiding theory. Those frameworks that have been offered have not been sufficiently general to encompass the wide variety of systems that have been developed.[4,5,6] Consequently, the literature addresses ASs from multiple perspectives and with inconsistent terminology, making it difficult to compare the accomplishments of these systems with one another. In this article, an organizational structure will be suggested for this body of research, hopefully lending some insights into directions for future development.

This organizational framework has several parts, all focusing on issues relating to the incorporation and utilization of knowledge in ASs. In terms of distinctions between various ASs, the type of knowledge acquired by these systems, as well as how this knowledge is represented, are the aspects most similar to those of traditional expert systems. Other familiar elements of this framework include the retrieval operations used by the AS to access previously stored information, and the mechanisms used to control the processing in the system. But that is where the similarity ends, since both the mechanisms by which incoming knowledge is automatically stored in the system, and the strategies for modifying or adapting the knowledge base and control structure, are by necessity unique features of these adaptive systems. These criteria will be discussed in greater detail in subsequent sections of this paper, where we will in turn (a) establish the need for building ASs; (b) outline a framework of the concerns one might face when trying to build an AS; (c) compare and contrast several already existing ASs; and (d) lay out some guiding principles for building an "ideal" AS.

Problems With Traditional Expert Systems

Many have argued that expert systems are the one area in which the AI enterprise has been truly successful.[8,9] These claims are based upon the proven utility of some computerized expert systems that are used to aid human experts in solving problems within limited application domains.[10,11] Despite these successes, there are still many nontrivial problems associated with building and maintaining expert systems, a few of which will now be enumerated.

To begin, the process of knowledge engineering, whereby the knowledge base of an expert system is acquired, is fraught with difficulties.[12] At worst, the availability of the main expert or experts may be limited or inadequate during the knowledge base construction period. Barring this eventuality, the experts that are available may disagree as to what knowledge to include, leaving the knowledge

CH2345-7/86/0000/0190$01.00 © 1986 IEEE

engineer at a loss as to how to resolve the dilemma. Perhaps more seriously, the knowledge engineer is faced with the task of obtaining procedural knowledge from the expert who can report only declarative knowledge. That is, the expert can declare that something is true, but cannot accurately describe how to do it.

Aside from problems encountered in the construction of traditional expert systems, a host of difficulties arise once the system is completed. Foremost among these is the challenge of updating the knowledge base to keep it current while maintaining truth value in the system. This becomes particularly acute as the size of the knowledge base increases. The practice of modularizing the knowledge base into separate sections and assigning each to a different knowledge engineer has eased this situation somewhat.[13] However, most would agree that there is still room for improvement, since there are still problems associated with maintaining knowledge consistency and coordination across these modules. Perhaps even a larger concern is that most expert system formulations offer no provision for automatically augmenting the knowledge base and control structure as the need arises. These difficulties, coupled with the often limited domain of applicability of most systems, suggest that investigation of an alternative approach is warranted.

Recent Advances: Adaptive Systems

As was already mentioned, recent work in the area of adaptive systems has led to theoretical advances over traditional expert system formulations.[14] If realized on a large scale, AS would be preferred to expert systems for several reasons. First ASs may be implemented without access to an "expert" per se. That is, the system may start out at a novice knowledge level, and gradually build up to a higher level of expertise through experience and through interaction with some external "knowledge sources." Such a system would be useful in so-called "cutting edge technology" domains where the current knowledge base is small, but expected to grow.

In terms of the user/system interface, ASs may be particularly beneficial in the development of individualized systems where commands accepted by the system are customized for a small set of users. In addition, one might imagine that an AS that has itself progressed from the novice to expert stages would provide more understandable responses to queries made by a novice user than would a traditional expert system.[14]

In a more global sense, ASs are preferable to traditional expert systems for the simple reason that intelligence is dynamic, and in any domain of interest the knowledge and heuristics utilized are bound to change with time. A major amount of effort has been expended in the past to find domains which are suitably narrow and static for building expert systems. In spite of this, the systems that have been developed must still be updated and augmented fairly frequently, and hence require costly, manpower intensive, support tails. One way to avoid this pitfall is to build systems that adapt. Therefore, it is our belief that the performance of the system will be improved to the degree that the system and its knowledge base adapt to the gradual evolution of the domain itself. *

Much of the pioneering work on ASs has been conducted by cognitive psychologists interested in modeling different aspects of human cognition. These researchers have experimented with the application of learning principles to AI systems in domains as diverse as number categorization, puzzle solving, language acquisition, and manipulation of geometric figures. Due to the disparity of these topics, readers of this literature may sometimes find it difficult to apprehend relevant similarities and differences among these systems. The organizational framework presented here is intended to bring a certain order to this chaos by providing points of comparison common to all of these systems, varied though they may be. For purposes of the present paper, the framework will be discussed in regard to only a subset of ASs. ** Before presenting the framework, each of ASs to be discussed will first be briefly described.

Representative Crossection of Adaptive Systems

The first AS to be described is called ACT* and was published by John Anderson.[1] Intended as a comprehensive theory of human cognition, ACT* models such complex activities as rotating mental images, solving geometry proofs, retrieval processes involved in reading, and language acquisition. It is by far the most fully developed system to be described in this article. Since ACT* was designed to model human cognition, it may embody some constraints that are unattractive in the realm of AI applications. Nevertheless it is argued that there is much to learn about building ASs from the study of such a system.

* It has been argued elsewhere that building ASs is not necessarily a worthwhile enterprise in that learning can be a long and iterative process, perhaps requiring more effort than is merited.[33] it is our position, however, that the long term benefits realized from the construction of ASs in dynamic domains will far outweigh any initial startup costs.

** As the reader may notice, the nine systems described in this article constitute only a small number of those programs presented elsewhere as ASs. Some of those other systems have been eliminated from our present discussion because they are better labeled as frameworks for knowledge representation rather than as full blown systems Still others were omitted because they are not truly adaptive in the sense of having mechanisms responsible for reorganizing memory and control structures. Finally, those deemed too narrow in scope to be of general interest were not included for discussion.[37]

The BACON.5 program written by Langley, Bradshaw, and Simon [15] was intended for a very different purpose. Given numeric data and variable specifications it notices patterns, abstracting out regularities among combinations of variables as "concepts". BACON.5 has discovered the Ideal Gas Law, Ohm's Law, and the law of gravitation, among others. A program somewhat similar to BACON.5 is UNIMEM.[16] It categorizes and makes generalizations from numeric data without using any statistical heuristics such as those employed in the BACON.5 system. For example, given data on areas and populations of states, it categories them into "large" and "small" classes and forms appropriate generalizations about those classes. For instance, it generalizes that small states have small populations without incorrectly inferring that large states necessarily have large populations (e.g., Alaska).

The next three systems are similar to one another in that they all start out with little or no knowledge about a given topic and progress up to an expert level. Kolodner's [17,2,18] Computerized Yale Retrieval and Updating System (CYRUS) learns facts about Cyrus Vance and Edmund Muskie's terms as Secretary of State. The Integrated Partial Parser, IPP, learns about international terrorism from newspaper articles. Finally, a follow-up to IPP called RESEARCHER [19] learns and answers questions about patent abstracts.

For purposes of the present paper, the most notable aspects of all of these systems are that they have mechanisms for organizing and updating their knowledge bases such that interesting generalizations and discriminations result. For example, after learning about a number of instances in which kidnap victims in Italy happened to be businessman, IPP is able to generalize that a new (unidentified) Italian who is kidnapped is likely to be a businessman. IPP does not make the error of the converse, however, which would be to infer that a given kidnapping took place in Italy simply because the victim is a businessman.

An example of an AS in a very different domain is the Blocks World program, first introduced by Winograd [20] and then updated by Winston.[21] This system learns about various possible configurations of a set of geometric figures. For example, Winograd's [20] system can remember sequences of moves for any given object in the blocks world and infer procedures necessary for those sequences to have been performed, even though that information was not explicitly stored.

The last two ASs learn rules about how to solve some problem. The highly acclaimed Meta-DENDRAL [22] is a program which sits over the expert system DENDRAL and learns cleavage rules used by mass spectrometers. The second version of the Strategic Acquisition Governed by Experimentation system, SAGE.2 [3] learns rules for solving the Tower of Hanoi puzzle task. Starting out with a small number of heuristics this program quickly acquires the knowledge necessary to solve the puzzle in the minimum number of moves.

Having read these descriptions the reader should now have an appreciation for how diverse these ASs really are. Nevertheless, it is argued that an organizational framework may be used to view these systems which will allow their simultaneous comparison on a number of dimensions. That framework will now be presented.

Framework for Comparing Adaptive Systems

The ASs listed just described may be compared with regard to the following features: (a) the types of representation schemes employed; (b) the mechanisms by which incoming knowledge is stored in the system; (c) retrieval operations used to access previously stored information; (d) mechanisms used to control information processing in the system; and (e) strategies for adapting the knowledge base and control structure to accommodate the changing environment. In this section, our set of ASs will be discussed with regard to each of these features. Following this, an evaluation of the different designs employed in building these ASs will be presented.

A. Type of Knowledge Representations Used

1. Production Rules

The first type of representation listed in Table 1 is the production rule. Production rules are if-then or condition-action pairs which invoke a particular action to be carried out when the contents of working memory match a specified condition. By this description it is clear that production rules embody procedural knowledge, but they are closely tied to declarative knowledge as well. Consider the following example of a production rule in the BACON system: [23]

> If you see a number of descriptions at Level L in which the dependent variable (D) has the same number value (V),
>
> Then create a new description at level L+1 in which the value of D is also V and which has all conditions common to the observed descriptions.

This rule results in the creation of another production, which will, in some sense, represent declarative knowledge within its own conditions. When these new conditions are matched by the contents of working memory, the new rule will be eligible for implementation. Production rules are used in ACT*, BACON.5, Meta-DENDRAL, and SAGE.2.

2. Memory Organization Packets (MOPs)

Following in a tradition somewhat similar to that of Minsky's frames, [24] Schank and Abelson's scripts, [25] and Schank's dynamic memory, [26] UNIMEM, CYRUS, IPP, and RESEARCHER all use memory organization packets, or MOPs. MOPs are a type of semantic network within which knowledge is arranged hierarchically by topic.[27] Information that constitutes a specific exception to the theme of the MOP is given a separate index, or label, which may be used to locate it more quickly during the retrieval process. When two or more elements are organized under one index, a new sub-MOP is formed, thus preserving the modularity of the memory network.

3. Propositions

Propositions have become a fairly common means of abstract knowledge representation in AI systems. They preserve semantic relationships between arguments or objects. For instance, the proposition "(kiss Sue Bill)" preserves the relation "kiss" between the arguments "Sue" and "Bill". Notice that the proposition's structure is independent of information order.[1] That is, "(kiss Sue Bill)" does not encode the difference between "Sue kissed Bill" and "Bill was kissed by Sue". Only the semantic relation is represented. Propositional representations are used both in ACT* and the Blocks World system.

4. Temporal Strings

Temporal strings are a type of representation used in the ACT* system to maintain order information. Knowledge about order is important to many tasks, one of which is the analysis of linguistic information. Temporal strings provide a more efficient means of storing order than do propositions, but cannot be used in the place of propositions since they do not incorporate information about meaning as effectively.

5. Spatial Images

This final type of representation preserves the configuration of elements in a spatial array. This construct is used in the ACT* system to model pattern recognition behavior in humans. The important point to note here about spatial images is that they preserve only information about the relative physical positions of objects in an array, and not necessarily information about what these objects actually look like.

B. Information Storage Strategies

Having established the tools for representing knowledge in our set of ASs, it is now of interest to explore the strategies used to store new information in these systems.

As shown in Table 2, one strategy for adding new information to the system is to learn every new stimulus as it is presented. This simple approach is used in the UNIMEM, CYRUS, Blocks World, and Meta-DENDRAL systems. Another alternative is to be more discriminating and store new information in the network only after it has been shown to have some importance, for instance after it has occurred several times. The ACT*, BACON.5, IPP, RESEARCHER, AND SAGE.2 systems all employ this type of approach.

Once the decision has been made to add new information to the system, the question arises as to how it will be stored in relation to already existing memory elements. Of course the new data could simply be added randomly. However, a more strategic approach is to store related items "near" one another in the network. The ACT*, UNIMEM, CYRUS, IPP, and RESEARCHER systems all employ this design, linking together items which are semantically or contextually related.

This method of storage serves two useful purposes. First, provided one uses the right type of knowledge representation, it will not be necessary to explicitly store all semantic features associated with every new element since some of those may already be represented in nearby (subsuming) structures. Second, retrieval of information is facilitated when memory is organized thematically. that is, one need only get to the right area in memory and look there rather than exhaustively searching the entire network.

Another useful tactic, implemented in UNIMEM, CYRUS, IPP and RESEARCHER, is to mark new elements with special indices which denote the way in which their themes differ from those of their "parent" nodes in the network. This approach has the same advantages as storing related items near one another in memory. It is particularly useful in retrieval as will be illustrated in the next section.

C. Retrieval Mechanisms

The three types of retrieval mechanisms employed by our set of ASs are listed in Table 3. The first of these, pattern matching, is a method whereby an item is retrieved from memory if the physical features of its representation match those of some retrieval cue. Pattern matching is commonly used in production systems where rules are selected for use based on the match between their conditions and the elements in working memory. The implementation of this mechanism usually involves exhaustive memory search. The ACT*, BACON.5, Blocks World, Meta-DENDRAL, and SAGE.2 systems all employ pattern matching.

A very different approach to retrieval is to search the network by traversing indices associated with individual categorical memory structures. Recall that the MOPs used to represent knowledge in the UNIMEM, CYRUS, IPP, and RESEARCHER systems have indices, or labels, associated with the. There are indices which denotes the thematic content of an MOP and other indices which tag elements involving exceptions to these themes. Retrieval begins with an index which is compared to other indices in the network. When a match is found, the memory elements subsumed underneath that index are searched. The result is that the scope of the retrieval process is limited to only those areas of memory which are the most relevant, a more efficient strategy than exhaustive search.

Another way of facilitating economic search is through spreading activation, as implemented in ACT*. At any given time, the memory elements that match the contents of working memory are temporarily activated, and this activation spreads to "nearby" connected elements in the network. Since the storage strategy in ACT* is to form connections among related items as they are learned, the nearby items that get activated will also be related to the contents of working memory. That is, all activated elements will be potentially relevant to the current context. Search is quite efficient since the retrieval process is directed only to the areas of the network that are activated, rather than to the network as a whole.

D. Principles of Control and Conflict Resolution

As might be expected, the search mechanisms just described often result in the retrieval of more than one acceptable memory element. The problem then arises as to how to choose among the potential candidates, selecting the most appropriate one for instantiation. A set of principles used to resolve these conflicts is presented in Table 4.

The most obvious means of deciding among potential elements is to choose the one which most closely matches the retrieval cue (or contents of working memory). this strategy is adopted in all of the ASs we are considering. In practice, however, one might find that as systems get more and more complex, this simple tactic will not always work well. That is, there may be several elements which match to the same degree, in which case further means for choosing among elements must be provided.

The ACT* and SAGE.2 systems employ several strategies for resolving these conflicts which rely on analysis of features of the operators themselves. For instance, each operator in these ASs has some strength associated with it which is either increased or decreased after each instantiation, depending on the outcome. Competing operators are then selected depending upon their relative strengths or histories of being useful. The field of potential candidates can be narrowed further using a principle called data refractoriness whereby no one operator can serve in two patterns simultaneously. Finally, the ACT* program relies on a principle of specificity whereby the most specific of two operators which match equally well will be chosen. For instance, if the pattern "barn" were being matched and the two elements "ba" and "bar" were competing, "bar" would be chosen since it is the most specific.

In addition to relying on traits of the individual operators to resolve conflicts, system behavior may be controlled in both ACT* and SAGE.2 by contextual constraints. Context is used to govern choice of operators in SAGE.2 through the "recency of use" rule. That is, the most recently used operator is chosen over others on the assumption that it must be the most relevant to the problem at hand. This choice will have nothing to do directly with the strength of the operator or whether the pattern is already represented elsewhere.

Perhaps a more interesting mechanism is used in the ACT* program. Problem solving in ACT* is goal-driven. That is, a large task having one ultimate goal can be broken down into several subtasks, each having a goal of its own. The current goal of interest is represented in working memory and, as such, disallows the instantiation of any operators not directly related to its completion. This mechanism greatly reduces the field of potential candidates from the start, thus eliminating many conflicts that might otherwise arise.

E. Mechanisms for Adaptation

Thus far the types of mechanisms described are not in any way peculiar to systems under consideration here. For instance, any traditional production system has to have some means of retrieving information from memory (usually pattern matching), and some way to resolve conflicts among competing memory elements (usually degree of match and specificity). The trouble with these typical expert systems, however, is that when they "learn" they do so simply by adding new facts or rules. These additions are, for the most part, made without regard to the integration and reorganization of this new information with existing knowledge.[28]. What sets adaptive systems apart from traditional expert systems is their ability to modify their own knowledge an control structures with experience in some meaningful manner. The ways in which adaptation occurs are listed in Table 5.

The most common way of incorporating experience into the system is to strengthen operators that have either been presented a number of times or have somehow proven useful in the past. In fact, every AS in our set of nine except Blocks World employs this method. However, the converse of this strategy, which is to weaken an operator whose instantiation has produced undesirable results, is not as popular. Only the ACT* and SAGE.2 systems employ this tactic. A method more drastic than weakening the strength of an operator is to remove it from the network altogether when if ceases to be appropriate for current applications. This is sometimes done with production rules in ACT*, but only very conservatively.

In addition to changing the relative strengths and weaknesses of operators in the system, it is possible to actually create new ones using knowledge embedded in previously existing representations. In particular, generalization involves the formation of new elements which embody common features of several representations already in the network. The new operator applies in more cases since it is less specific than its predecessors. This mechanism is implemented in every AS except Meta-DENDRAL and SAGE.2.

In contrast to generalization, new representations may be created through the process of discrimination. Discrimination occurs when extra delimiting features are added to an operator which restrict the contexts in which it can apply. In other words, discrimination creates constructs that are special cases of already existing ones. This is the type of process that occurs in CYRUS, for instance, when an index is added beneath the top level of an MOP to signify that an element contains information in exception to the theme of the parent MOP. Although potentially quite powerful, this strategy is employed only in the ACT* and CYRUS systems.

The discussion up to this point has focussed on the comparison of our nine ASs with regard to the types of knowledge they acquire, along with the types of representations, storage mechanisms, retrieval strategies, control principles, and means of adaptation used by each. Now that the ASs have been couched in terms of this organizational framework, it is of interest to determine whether any guiding principles may be used in conjunction with this framework to help researchers both (a) build better ASs and (b) evaluate our nine Ass in relation to one another.

Building the "Ideal" Adaptive System

The remainder of this paper will outline some general guidelines for building what we call the "ideal" AS. These guidelines will be cast in terms of the organizational framework already presented. It is' hoped that these principles will not only aid in the design of future ASs, but might serve as a set of metrics by which to evaluate already existing systems.

First it is our feeling that there is no way to select the "best" representation a priori. In fact some might argue that, as far as the outward behavior of the system is concerned, any deficiencies associated with the choice of representation structure may be compensated for in terms of the procedures implemented to operate on those structures.[29] We will concede that some representations may lend themselves to certain types of problems more easily than others, although this will be a matter of convenience.

Having dispensed with the question of representation, we will now proceed with recommendations concerning the other issues of storage, retrieval, control, and adaptation. After reading through the earlier comparisons of the ASs on each of the dimensions just listed, the reader may feel that a "more is better" rule is applicable. That is, it might appear that variety is the key, with the better systems being those which incorporate several different types of capabilities in each of these areas. Although this is true to a certain extent, it is not necessarily the best prescription for success.

Rather than a "more is better" methodology, we advocate that researchers adopt an approach whereby a combination of both top-down and bottom-up strategies are implemented in the system design. Bottom-up strategies are those for which properties of individual operators are important, whereas top-down strategies involve overall system behavior. Perhaps this concept is best illustrated with an example.

In terms of storage mechanisms, a top-down strategy is to store related items near one another in the network. This type of strategy impacts directly on the global organization and performance of the system. Similarly, the approach of storing items in a hierarchial organization such that concepts at a given level subsume those below and are subsumed by those above will later affect global retrieval operations.

In contrast, a bottom-up storage strategy is to learn every new stimulus as it is presented, regardless of its semantic content--that is, regardless of its eventual position in the overall memory network. This strategy has not been employed as much as it could have been, probably due to the semantic primacy bias in the human memory literature.[30] The traditional wisdom has been that people primarily remember semantic content in lieu of lower level information involving physical features of stimuli. Recent experiments on human memory have shown, however, that we do indeed remember this low level information, often better than the semantic content.[31] To the degree that the human is accepted as a useful model for designing intelligent systems, the importance of bottom-up storage strategies should not be ignored when building ASs.

Assessing the relative merit of combinations of storage mechanisms of the ASs from Table 3, it may be seen that only the UNIMEM and CYRUS systems employ both top-down and bottom-up strategies. Specifically, both are designed to learn every new stimulus as it is presented and to store related items near one another in memory. In addition, both of these systems use the MOP representation from which a hierarchical organization is created.

Applying the top-down/bottom-up distinction to retrieval mechanisms, it may be argued that memory search aided by either index traversal or spreading activation is top down since these mechanisms are implemented with regard to the memory network as a whole. On the other hand, pattern matching is a bottom-up retrieval tactic since it depends only on characteristics of individual operators. Again, research on human memory has shown that both bottom-up and top-down processes play important roles in the determination of retrieval performance [32] lending credence to the assertion that this combination might be useful in the design of ASs. In Table 4 we see that the only system employing both top-down and bottom-up retrieval strategies is ACT*. Elements may be retrieved from memory in ACT* using either spreading activation or pattern matching.

As with storage and retrieval, there are principles of conflict resolution which embody both top-down and bottom-up features. For example, a top-down strategy for delimiting the field of competing operators is to impose a goal hierarchy on the system. The choice of priorities rather than the traits of any individual operators. A similar argument may be made for the strategy of choosing the most recently used operators over others that match as closely.

All other conflict resolution principles discussed earlier involve bottom-up analysis. These include degree of match, specificity, data refractoriness, and operator strength. Notice that all of these require that features of individual operators dictate which will be selected for implementation as opposed to overall contextual constraints.

Looking to Table 5 again, it may be seen that the only two systems which employ top-down and bottom-up strategies for controlling choice of operators are ACT* and SAGE.2. Both use several bottom-up strategies. Of greater interest is that the top-down approach to control in ACT* is implemented in a goal hierarchy, whereas a recency criterion serves as a context mechanism in SAGE.2.

The final dimension to be considered from the organizational framework is the manner in which systems are allowed to adapt. Of the mechanisms presented earlier, adaptation through generalization and discrimination are top-down in nature because they occur only when similarities or differences among several structures are noticed simultaneously in one context. On the other hand, the strengthening, weakening, and unlearning of individual elements all affect only one structure at a time. Since they do not directly impact on the status of other contextually-related elements, these strategies are classified as being bottom-up. All of the ASs invoke both top-down and bottom-up adaptation strategies except Meta-DENDRAL and SAGE.2 which employ only bottom-up procedures.

Conclusions

The above discussion focused on developing an organizational framework for comparing adaptive systems. These systems are of interest relative to traditional expert systems in that they (a) do not have to be updated by hand as knowledge in the domain of interest changes; (b) can start out at the novice level without explicit access to a human expert; (c) are useful in "cutting edge" domains in which few, if any, experts exist; and (d) might provide better interfaces for novice users since their own memory structures have evolved from the novice level. Nine systems were discussed with regard to an organizational framework for comparing ASs. This framework was used to compare the systems on such dimensions as the type of knowledge acquired by each and representations used; storage and retrieval strategies, control mechanisms, and methods used for adaptation. As we would expect, based on our experience with the latest generation of expert systems, we have recommended that ASs be designed using a combination of top-down and bottom-up mechanisms in each of these areas.

The development of this framework for ASs systems may also have several additional benefits. As the most near term example, this framework can aid in our understanding of AI system performance. This may allow researchers to address some of the perennial AI questions, such as how one measures the robustness of a given AI system, what are valid benchmarks for AI systems, and how an AI system can be designed for ease of testing. On this latter point, research in AS methodologies could expedite the rapid prototyping of AI systems, in a manner analogous to the techniques used in the electronics industry. Finally, continued development of ASs, particularly through rapid prototyping, can lead to a faster incorporation of AI systems into the marketplace.

Acknowledgments

The authors would like to thank Drs. L. H. Reeker, R. A. Geesey, C. B. Friedlander and C. T. Butler for their timely insights and constructive criticism throughout the development of this effort. This work was supported in part by DARPA under contract number MDA903-85-C-0056 and by DARPA/AFOSR under contract number F49620-86-C-0036.

AN OBJECT/TASK MODELING APPROACH

BASED ON DOMAIN KNOWLEDGE AND CONTROL KNOWLEDGE REPRESENTATION

Qiming Chen

National Land Information System
Research Institute of Surveying and Mapping, Beijing, China

ABSTRACT

The need for developing knowledge-based information systems has given rise to studies on integrating AI systems and DB systems. An object/task modeling approach based on knowledge representation is proposed which is characterized by specifying object behaviors and domain rules in terms of object-oriented logic programming, and specifying tasks and meta-rules in terms of network-oriented formalism. This approach may be viewed as a step to the integration of object-oriented programming, logic programming, semantic modeling and event modeling, and to the combination of forward chaining and backward chaining techniques. It can enhance the flexibility and extendability of knowledge based systems to accommodate applications in multiple domains.

INTRODUCTION

The need for developing the next generation information systems has given rise to studies on integrating database systems and Artificial Intelligence (AI) systems [Ullman 85]. The fact that both Logic Programming (LP) and Relational Database (RDB) are subsets of first order predicate calculus suggests a resemblence between them. On one hand, LP provides powerful formalism for representing database rules and deductive retrievals, on the other hand, RDB provide adequate means of storing and managing knowledge [Gall 84] [Parker 84] [Fuchi 85] [Zani 84] [Chen 86a].

However, most of the knowledge based systems and decision support systems currently in operation, support only a single model or a class of models. They are special application oriented and self-contained, their configurations are both static and intolerant from a model perspective. In other words, such systems lack the flexibility of being adaptable to the possible alterations in the problems they were originally designed to deal with, and cannot be utilized in multiple problem domains, even if those domains are closely related.

This situation is caused, to a certain extent, by lacking the formalism for modeling objects and representing control knowledge within a system framework.

In fact, to manage a knowledge base for supporting tasks, we must take into account the follows :

(1) Domain knowledge representation and control knowledge representation.

(2) The sharing of objects and their properties by multiple tasks.

Thus the Object/Task modeling contains three levels : the object level, the association level, and the task level.

The proposed approach is characterized by

(1) A rule-based object modeling mechanism based on the integration of object-oriented programming paradigm and logic programming.

(2) Modeling the control structure of a problem-solving or decision-making task as a net, and then exploring a rule-based, linguistic and precise net specification formalism and a multiple level, task-oriented constraints handling mechanism.

(3) Treating task as system objects through which a task liberary may be constructed.

Under this object/task modeling approach, database applications are specified as localized domain knowledge representation and explicit control knowledge representation. Differnt roles an object plays in different tasks can be identified distinctly.

This approach is being designed and partially implemented on top of System G, an extended experimental RDB system [Melk 83ab] [Chen 85b] on a VAX computer.

THREE LEVEL OBJECT/TASK MODELING

To illustrate the proposed concepts we first introduce a decision-making example concerning a simplified manufacturing order processing system for an instrument assembling company. The information needed is stored in certain relations (predicates), includes "order" (states orders), "asmb-des" (lists the parts needed for each model of machines, as well as the assembly time); "parts-inv" and "products-inv" (describe the inventories of parts and ready-made machines), and "parts" and "machines" (descride models and costs), whose instances are viewed as facts of the following form :

```
order (order_id, model, qty, finish_qty).
parts (code, cost).
machines (model, cost).
parts_inv (code, name, amt).
products_inv (model, name, amt).
asmb_des (model, asmb_hrs,
   config(senser, cpu, monitor, frame)).
```

Level 1 Object Modeling

The rule-based object/task modeling approach described in this paper is characterized by the integration of object-oriented programming, LP and RDB.

In the object-oriented semantic modeling paradigm, reality is represented in terms of objects as well as their relationships [Cox 84]. Each object has an associated set of procedures called methods denoting its dynamic behaviors. The manipulation of objects is made by applying the methods on them, referred to as "sending the objects a message".

Integrating object-oriented programming paradigm and logic programming, generally we identify an object structurally as :

(1) a primitive one represented by an LP predicate without any nested predicate as its argument.

(2) a compound one composed in a nested or recursive fashion from two or more objects, represented by an LP predicate with at least one predicate as its argument.

Then each method is stated as an LP clause. Passing a message is specified by using the infix operator ":", (the number of arguments may be zero). We classify two kinds of methods:

(1) i-method (the individual-oriented method), which is defined on a single object instance (universally quantified), as

```
i-method : object (arg1, arg2,...)
```

(2) c-method (the class-oriented method), which is defined on a class of object instances (the simplest example is a relation with multiple tuples). Its application is represented as

```
c-method : object ()
```

(3) mc-methods (the multi-class-oriented methods).

An object type is the structural specification of a class of objects, which describes its name, structure, methods and constraints, where the structure defines the attributes and constituents possessed by that object; methods consist of the rules applicable to the objects in term of Horn clauses; integrity constraints are assertions that instances of objects are compelled to abey, which can be classified according to various criteria, such as type constraints, dependency constraints and so on. In our approach a constraint is specified similar to the body of a Horn clause.

Thus for example the object type "order" is specified as :

```
object_type  order (ORDER_ID, MODEL, QTY, FINISH_QTY)
 {
  structure      { ORDER_ID    : c4,
                   MODEL       : c8,
                   QTY         : i4,
                   FINISH_QTY  : i4.
                   key : ORDER_ID
                 }
  constraints    { MODEL [ "hc20, hc40, hc60",
                   QTY > 0, QTY < 10000,
                   QTY > FINISH_QTY.
                 }
  i-methods      { what_kind_order ([instrument,MODEL]):-
                         order (_, MODEL, _, _).
                   unfinish_qty (X) :-
                         order (_, _, QTY, FINISH_QTY),
                         X is QTY - FINISH_QTY.
                 }
  c-methods      { diff (IDa, IDb, X) :-
                         order (IDa, _, QTYa, _),
                         order (IDb, _, QTYb, _),
                         X is QTYa - QTYb.
                 }
 }
```

An instance of an object is a predicate with all the arguments been instantiated with specific values. Thus the goal

```
?- unfinish_qty (X) :
   order (0056, hc40, 30, 10).
succeeds with X = 20.
```

The interpretation of a message consists in the unification of the objects, the unification of the method and the proof of the method. If an object is declared by "isa" as an sub-object of others and therefore inheriting their behavioral properties, then the unification of the method with the methods associated with the ancestors of the object in the "isa" network, is necessary. When an object has more then one ancestors, we first determine the order of the ancestors, then use a so called "upward-first" search strategy, starting from checking the first available ancestor, observe to see whether it is a root (no further ancestor remained), if not, move upward until either the unification succeeds or back to try the next possible ancestor at the highest possible ancestry level.

Passing message implies that certain action may be taken ruled by the specified method clause, then the resulting predicate (on the left side of the clause) can be reasonably viewed as a virtual object (VO). The instance of a VO is derived from the instances of other(source) objects, and instantiated by passing message thus represents the results of the message passing. Thus VO's may be viewed as a link between data access and data processing.

The declaration of a VO contains structure (which can be the same as for the usual actual object), source objects, mapping rules and so on. The source objects can be actual or VO or a mixture of both, thus a VO may be defined hierarchically. We list below a VO specification "partsreq", in the order processing example, where one of its source object "orderproc" itself is a VO.

```
Virtual_object_type
 parts_req (ORDER_ID, req(CODE, QTY))
 {
  structure  { ORDER_ID : c4,
               req (CODE, QTY)
                  { CODE : c4,
                    QTY  : i4.
                    key  : CODE
                  }
               key : ORDER_ID
             }
  source     { asmb_des, order_proc
             }
  mapping rules
    { parts_req (ORDER_ID, req(CODE, QTY)) :-
      order_proc (ORDER_ID, _, _, _, 0, _),  !, fail.

      parts_req (ORDER_ID, req(CODE, QTY)) :-
      order_proc (ORDER_ID, MODEL, _, ASMB_QTY, WAIT_QTY, _),
      asmb_des (MODEL, _, config(CODE_S,CODE_C,CODE_M,CODE_F)), !,
      parts_inv (CODE, _, AMT),
      (CODE = CODE_S; CODE = CODE_C; CODE = CODE_M; CODE = CODE_F),
      QTY is ASMB_QTY + WAIT_QTY - AMT,
      write (parts_req (ORDER_ID, req(CODE, QTY))), fail.
    }
 }
```

Unification is the way to make VO's physically accessible. In the case that a VO has virtual source objects, the latter must be instantiated in advance according to their own definitions, and such a process may spread upward in the virtual object network until all the actual and VO's involved are fully instantiated. Syntactically, the instantiation of a VO, such as "partsreq", is represented by the clause

```
mapping (parts_req).
```

The instance of a VO has a life time which extends over a single task. Duplicate unification for VO's in a task can be reduced unless its source objects are altered.

Although a VO mapping is just one or a cluster of rules, a VO is a more feasible entity than a rule. a VO has a structure definition, can be directly queried at a high level, with a printing format; It can, flexibly, either be used as a source object for other VO's, or be involved in tasks.

level 2 Heuristic Association

Although in general everything could be viewed as an object [Wilson 83], It is best to consider only the semantically meaniningful objects. In fact, the need to represent associative behaviors of a group of different type objects, without creating any "fuzzy" object, does arise in many situations. For this purpose we introduce a concept called "association", which describes the non-hierarchical, heuristic relationships among classes, typically represented by mc-methods.

In fact, an association neither introduces any new object, nor reffers to any storage structure, it only mentions the dynamic behaviors caused by a group of different types objects, and is more suitable to be interpreted as a schema, which provides a link from the problem space to the solution space.

Level 3 Task Modeling

The task modeling concerns not only the domain knowledge (about objects), but also the control structure (about scheme) whose description may be viewed as certain meta-rules, determining the usage of domain knowledge and the linkage of actions which make up an operational scheme with desired run-time control [Mel 83a].

Since the task scheme is basically a forward chaining network with a number of paths, our proposed task specification approach is founded on a rule-based linguistic net description formalism which was presented in author's another paper [Chen 85b], involving three basic kinds of components : action, linker and net.

In the object-oriented paradigm, actions are denoted by the messages (methods on objects) to be passed. An action specification gives the correspondence between the statically described message and the action as its execution. A message passing at different stage of a task must be identified separately, except in the case of a loop. There is a one-to-many mapping from the space of methods to the space of actions.

Linkers describe the conditions for each possible path in the net denoting the task scheme, that is, the connection rules. Each linker has four arguments (attributes), as linker (LINKERNAME, LINKMODE, TERMINATEMODE, CONDITION). The LINKMODE may be 'r' (regular) or 'c' (conditional branch). The TERMINATEMODE includes 'h' (hard termination with system state recovery, if errors are detected), and 's' (soft termination without state recovery).

A net definition specifies the internal linkage among the actions and the control flow (not data flow, as a rule, all inter-action communication must be carried out by accessing data/knowledge base, which may be viewed as "mailboxes").

The major feature of the proposed net specification approach consists in lifting net specification fron the structure level to the function level. This is characterized by introducing the concepts of net-structures and net forming operations called path forms for constructing new nets from existing ones, which map net-structures to net-structures in general.

A path form is an expression denoting a combination of net-structures which depend on the actions, linkers and sub-nets that form the parameters of the expression.

Examples of parth forms are

A > B (Composition),

A > (P)B (conditional composition through a linker P),

[A; B] (serialization),

(P){A; B; C} (conditional branch),

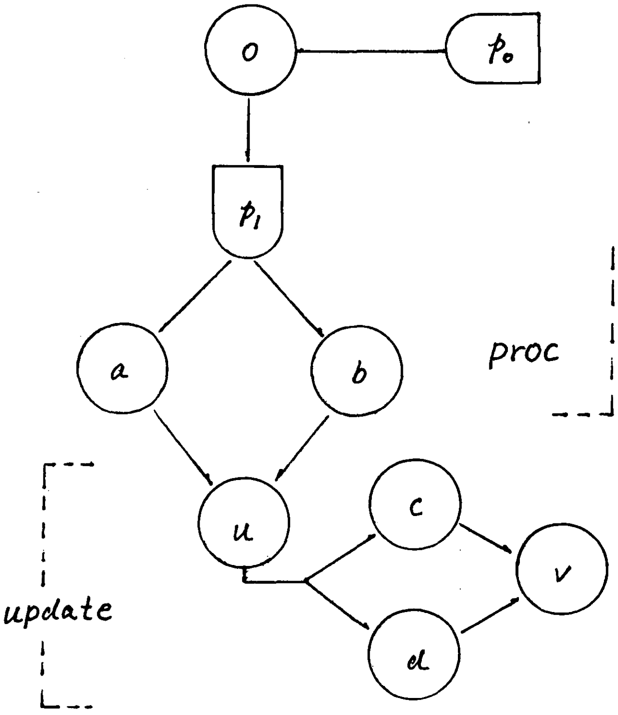
A >> {B; C; D} (compose-to-all, means [A>B; A>C; A>D]).

These path forms can be utilized hierarchically or recursively for representing a complex net as the combination of certain simpler (or lower level) nets. And in fact more additional path forms may be defined and implemented.

Loops are handled by a naming mechanism, the first-meet rule, describing how to handle a symbol for an action, a linker or a sub-net, which appears more than once in a net-expression, by going back to the leftmost position in the expression where the symbol appears.

To illustrate the proposed approach, we will give a complete rule-based task specification for the order processing example mentioned before, as following.

Figure 1.



```
task order_processing
  {
   object_specification
     { actual_objects  { order,products_inv,parts_inv,asmb_des,parts,machines
                       }
       virtual_objects { order_proc, parts_req, wk_ticket
                       }
       mc-methods  { update_inv (MESSAGE) :-
                      order_proc (ORDER_ID, MODEL, PICK_QTY, ASMB_QTY,
                                  WAIT_QTY, SALES_VALUE)),
                      asmb_des (MODEL, _, config(CODE_S,CODE_C,CODE_M,CODE_F)),
                      retract (products_inv (MODEL, NAME, AMT)),
                      NEW_AMT is AMT - PICK_QTY,
                      assert (products_inv (MODEL, NAME, NEW_AMT),
                      retract (parts_inv (CODE_S, NAME_S, AMT_S)),
                      retract (parts_inv (CODE_C, NAME_C, AMT_C)),
                      retract (parts_inv (CODE_M, NAME_M, AMT_M)),
                      retract (parts_inv (CODE_F, NAME_F, AMT_F)),
                      NEW_AMT_S is AMT_S - ASMB_QTY,
                      NEW_AMT_C is AMT_C - ASMB_QTY,
                      NEW_AMT_M is AMT_M - ASMB_QTY,
                      NEW_AMT_F is AMT_F - ASMB_QTY,
                      assert (parts_inv (CODE_S, NAME_S, NEW_AMT_S)),
                      assert (parts_inv (CODE_C, NAME_C, NEW_AMT_C)),
                      assert (parts_inv (CODE_M, NAME_M, NEW_AMT_M)),
                      assert (parts_inv (CODE_F, NAME_F, NEW_AMT_F)),
                      MESSAGE = invetories_updated.

                     update_order (MESSAGE) :-
                      order_proc (ORDER_ID, MODEL, PICK_QTY, ASMB_QTY,
                                  WAIT_QTY, SALES_VALUE)).
                      retract (order (ORDER_ID, MODEL, QTY, FINISH_QTY)),
                      NEW_FINISH_QTY is FINISH_QTY + PICK_QTY + ASMB_QTY,
                      assert (order (ORDER_ID, MODEL, QTY, NEW_FINISH_QTY)),
                      MESSAGE = order_updated.
                   }
       constraints { order with_cons {MODEL [ "hc40, hc60"}
                     products_inv  with_cons  {products_inv (MODEL, NAME, AMT),
                                               machines (MODEL, COST),
                                               COST * AMT < 500,000}
                   }
    scheme_specification
     { action    { o  is  mapping (order_proc).
                   a  is  mapping (wk_ticket).
                   b  is  mapping (parts_req).
                   u  is  update_inv (MESSAGE) : parts_inv(), products_inv(),
                                                 asmb_des (), order_proc ().
                   c  is  listing (parts_inv).
                   d  is  listing (products_inv).
                   v  is  update_order (MESSAGE) : order (), order_proc ().
                 }
       net       { order_processing   is  (p0) @proc > @update .
                   proc               is  o > (p1)[a; b] .
                   update             is  u > [c; d] > v .
                 }
       linker    { p0  is  (r, h, (order with_cons {QTY > 10})) .
                   p1  is  (r, h, (order_proc with_cons {ASMB_QTY > 0},
                                   parts_inv with_cons {QTY > 0})) .
                 }
     }
  }
```

We assume that all the anticipating objects are previously declared. Within this task, the virtual objects only need to be instantiated once (by "mapping"). In fact, the three virtual objects, holding the resulting data of the order processing task, can also be simply queried outside this task, just for estimation, without updating the system. This is an evidence showing the flexibility offered by our multiple level object/task modeling approach.

The net representation for the task is illustrated in Figure 1. Its performance can be described as follows: Action o, a, and b carry out the order processing in terms of computing virtual objects "orderproc", "workticket" and "partsreq", and convey the resulting data to users; actions u and v update the inventories and the order; action c, d display the new state of inventories after processing the current order. Certain control rules are specified at linkers p0 and p1.

TASKS AS SYSTEM OBJECTS

Tasks can be viewed as system objects as well, the meaning for this is two folds :

(1) In this approach, the "task" is treated as a special type of system objects with a set of operations defined on it, such as query, update, execute,...etc. Thus a knowledge based "Task Libraries" could possibly be built easily.

(2) A task may correspond to a cluster of special VO's which hold the resulting data of the task running.

The concept of Generalized Virtual Object (GVO) is developed for integrating action capabilities and operational dynamics, conveying therefore the execution results of complex decision/action schemes to end-users in terms of high-level data accessing.

Different from the approach for handling VO's, the GVO computing is characterized by active (vs passive) and dynamic (vs static) which may invoke any transactions, bring broad state changes and, on the other hand, be contributed by the feed-back effects of above state alterations. A process handling approach is also developed which can directly translate a net-oriented decision/action scheme making up a GVO mapping into an implementation.

CONCLUSIONS

Logic Programming and Functional Programming have set a bridge between AI and other fields [Chen 85a]. For developing more intelligent information systems, in this work we have combined object-oriented paradigm, logic programming, semantic modeling and event modeling, providing therefore complementary benifits in inference, deductive query support, integrity control, and explicit control knowledge representation, towards a generalized management of data, action and operational schemes.

ABSTRACT

A Plant Intelligent Supervisory Control Expert System (PISCES) is being developed in the Knowledge Engineering Laboratory at the University of Tennessee Space Institute (UTSI). PISCES is a knowledge-based system whose control strategy can be applied to most types of process control plants. PISCES will be employed at the power plant research facility located at UTSI. PISCES uses a modified form of backward chaining which allows the system to dynamically generate new top level hypotheses. PISCES control strategy also performs multiple lines of reasoning during hypothesis verification. Since PISCES must operate in a real time environment, knowledge base indexing utilizing discrimination nets have been implemented to increase system efficiency. PISCES also contains an explanation facility and rule editor that increases confidence in the system diagnostics and facilitates knowledge acquistion.

INTRODUCTION

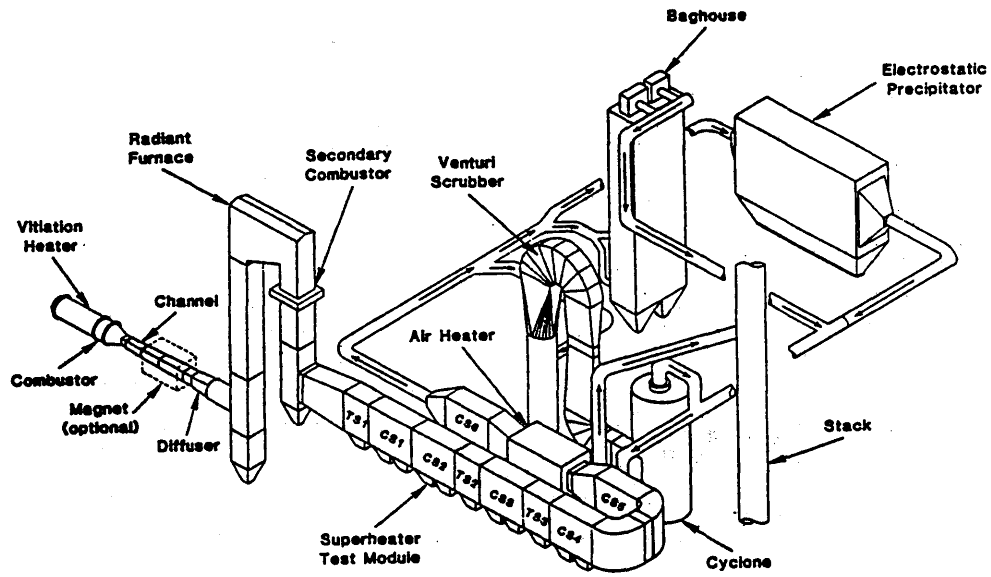
At UTSI we are developing an expert system called PISCES. PISCES is designed to provide an on-line aid in monitoring plant performance and in diagnosing plant system malfunctions in the United States Department of Energy's (DOE) Coal Fired Flow Facility (CFFF) magnetohydrodynamics (MHD) test facility located at UTSI. The Low Mass Flow (LMF) Test Train, located in the CFFF at UTSI, is an experimental magnetohydrodynamics (MHD) flow train designed for a thermal input of 28 MW. Fig. 1 is a schematic showing the current configuration of the flow train. Futher description of the facility is given in reference 3.

PISCES is a modified form of EX[1-2]. EX and PISCES are both rule based systems that use a modified form of backward chaining which allows the system to generate new top level hypotheses. EX was developed to perform fault diagnostics for setting oxidant flows during the vitiation heater ignition. The knowledge base of EX contained approximately 100 rules about the oxygen and nitrogen system flows, pressure, temperature and the oxidants delivery system control valves. PISCES will perform fault diagnostics and facility parameter monitoring not only during vitiation heater ignition, but also during ignition of the primary and secondary combustors. Once steady state operations is achieved, PISCES will monitor facility performance. Since PISCES will operate online, it is necessary that it provide real time response. To reduce system reponse time, the sequential data structure was replaced with an indexed structure which employs a discrimination net to implement the indexing. An additional improvement in response was accomplished by eliminating the need for a search in PISCES explanation facility. PISCES also provides a rule editor that allows knowledge acquistion while the system is operating.

PROBLEM DOMAIN

The architecture of PISCES includes plant monitoring and fault diagnostics in the domain of facility operation from checkout to secondary combustor ignition. The successful ignition of the CFFF

CH2345-7/86/0000/0207$01.00 © 1986 IEEE



LMF4 FLOW TRAIN

FIG. 1

secondary combustor requires that the correct sequence of procedures and events be followed. Before operation of the facility can begin, certain pre-operational and operational procedures must be performed on the facility and test train components. After these have been accomplished, the vitiation heater (oxidant pre-heater) must be ignited. This is followed by the ignition of the primary combustor on fuel oil and then coal. During each step in the sequence certain conditions and selected parameter values must be satisfied before the next sequence in the chain of events can begin.

Operation of the facility begins with the heating of the radiant furnace to operating temperature using industrial gas burners. This prevents thermal shocking of the furnace refractory. Once the furnace is sufficiently heated, ignition of the vitiation heater is accomplished by first setting nitrogen flow followed by oxygen flow. When the oxidants flows have been established the fuel oil flow to the vitiation heater burner plate is initiated. Ignition is accomplished using a spark igniter. After successful ignition of the vitiation heater, fuel oil is introduced to the primary combustor. This oil ignites in the presence of the 1500 °F oxidants. Next, coal flow to the primary combustor is started. The ignition of the secondary combustor requires the proper test conditions to be set which results in a stoichiometric value of 0.85 . It is in this domain in which PISCES will be used. During each phase of facility operation, if PISCES determines that a parameter is outside of its normal operating range or an event does not occur in the proper sequence, PISCES will display a message and attempt to determine the cause and possible solution to the problem. PISCES also allows the plant operators to request assistance in solving problems.

KNOWLEDGE BASE

A PISCES knowledge base has been developed on the basis of the knowledge acquired from three MHD engineers. One of the experts was the project leader for the design and fabrication of the CFFF. The other two experts are in charge of test operation for the CFFF. Written procedures and component operation manuals have also been used as a source of knowledge about the domain of PISCES. There are currently 200 rules in the knowledge base. They contain information about the proper sequence of events, operational procedures, the nominal ranges of parameter values and the characteristic behavior of the test train components up to and including the radiant furnace. A typical rule in the knowledge base contains IF and THEN clauses. An optional ELSE clause can also be contained in a rule. The IF clause contains the antecedents of the rule. The THEN clause contains the consequents of the rule. The ELSE clause contains the alternates to the THEN clause. If the antecedents are true, the THEN consequents are asserted to be true. However, if the antecedents fail, the ELSE clause triggers a multiples lines of reasoning to be pursued. Examples of rules with and without the optional ELSE clause are shown in Figures 2 and 3. Each of the clauses may contain one of the following:

1. A pseudo English representation of some known condition.
2. An assertion that needs to be verified before a conclusion can be drawn.
3. A LISP function to be evaluated.

With each THEN or ELSE clause a certainty factor is associated. The certainty factor represents the expert degree of confidence in the conclusion drawn if antecedents are known with absolute certainty (certainty factor equals 1.0). Positive numbers indicate belief and negative numbers indicate disbelief. When the antecedent's themselves are not known with absolute certainty, a new value of certainty factor is computed by employing an approach similar to MYCIN[4]. The examples presented in Fig. 4 and 5 from a typical session compares PISCES finding when antecedents are known with certainty and when they are not.

```
(rule 1
   (if   (LISP prog ()
   (cond  (N2-sensors-polled  (return  t))  )
   (setq  N2-sensors-polled  t)
   (write  T  '/Open  N2  isolation  valve/)
   (write  T  '/Set  N2  control  valve/)
   (write  T  '/Polling  sensors/)
   (return  t))
   (N2  flow  setting  succeeds)
   (LISP  prog  ()
   (cond  (O2-sensors-polled  (return  t))  )
   (setq  O2-sensors-polled  t)
   (write  T  '/Open  O2  isolation  valve/)
   (write  T  '/Set  O2  control  valve/)
   (write  T  '/Polling  sensors/)
   (return  t))
   (O2  flow  setting  succeeds))
   (then     (1.0  ignition  succeeds))
   )

During backward chaining, EX[1-2] performed sequential searching which resulted in slow system response. In order to minimize search time, PISCES replaced the sequential knowledge structure with an indexed knowledge structure. The rules are currently indexed on the syntatic structure of the individual members of the THEN clause. PISCES uses a discrimination net to attach properties to arbitary expressions. Encoding the information represented in the THEN clause using this scheme allows us to attach to each unique member of any THEN clause the list of rule numbers in which it is contained. Each element in the THEN clause is used as a link in the discrimination tree. When searching for a rule that contains the hypothesis "*(O2 pressure sensor failed)* " in its THEN clause, each link is followed until we either reach a terminal node that contains a list of all the rules with this hypothesis in its THEN part, or we discover that there is no node with a transition on the current element. These two possibilities are illustrated in Fig. 6. The advantage of this method over the sequential search is that the search time is significantly reduced. In a sequential structure the entire knowledge base must be searched to retrieve the rules that relate to an hypothesis. However, in PISCES knowledge structure a traversal of the discrimination net will retrieve all the rules that apply to the hypothesis. If no path through the net can be found the algorithm will terminate again eliminating the time wasted in unsuccessful searches in sequential structures. The knowledge acquistion algorithm works the same way, except that instead of returning failure, a path is created to a new terminal node for this rule. The algorithm also checks for rule duplication when new rules are added. If the rule is a duplicate it is not added to the knowledge base. The rule itself is stored on the property list of its rule number.

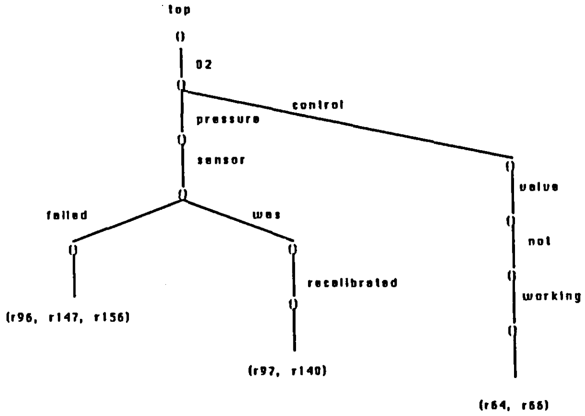

Fig. 6 Simple Discrimination Net

CONTROL STRATEGY

PISCES has a top level loop that manages the systems resources. This top level loop provides the lower level functions of synchronization and communication. The low level functions provide parameter checking, handling of keyboard interrupts, goal verification and knowledge base maintenance. If the monitor function detects an abnormal condition, the top level calls the correct function that generates a goal to determine the cause of the fault. A user request for a goal verification can also be entered from the keyboard.

PISCES uses modified backward chaining that allows multiple lines of reasoning to verify an hypothesis. In traditional backward chaining a list of one or more hypotheses is verified by using the following strategy:

1. See if the current hypothesis is already a known fact.
2. If it is known, it is verified. Therefore return SUCCESS.
3. Otherwise, find rules in your knowledge base that contain the hypothesis in their consequent clause.
4. Then use the antecedent clause of these rules to generate a new list of hypotheses.
5. If no rule can be found, ask user.
6. Now repeat the above steps starting at one.
7. If all rules have been exhausted and the current hypothesis has not been verified, return FAILURE.

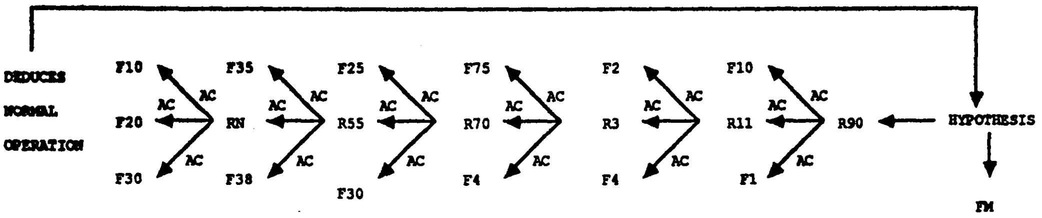
PISCES differs from the traditional backward chaining, in that if it fails to verify an hypothesis, it can, at the request of the current rule, attempt to determine the reason for the failure of the hypothesis. This is accomplished by adding the following steps:

8. Upon failure to verify the hypothesis, if an ELSE clause is part of the rule, use it to generate an alternate list of hypotheses
9. If all the rules have been exhausted and the alternate list of hypotheses have not been verified, return FAILURE.

Shown in Fig. 7 is the flow of control in a traditional backward chaining system. As can be seen from the diagram shown in Fig. 7, a system using traditional backward chaining can report success only on successful verification of the original hypothesis. For example, the hypothesis requiring verification is contained in the consequent clause of rule R90. The antecedent clause of rule R90 contains a sub-hypothesis that can be verified by rule R11. As illustrated in Fig. 7, rules R3, R70, R55 and finally rule Rn must be successfully executed before the original hypothesis is verified. If at any sub-level in the verification process a sub-hypothesis fails, the single line of reasoning approach must report failure and give up. However the diagram shown in Fig. 8 illustrates the ability of PISCES to dynamically generate new top level hypotheses. If rule R1 fails to verify, PISCES will use the knowledge contained in the rule R2's else clause to generate new top level hypotheses (multiple lines of reasoning) to determine the cause of the failure of the original hypothesis. Also shown in Fig. 8 is PISCES' ability to determine the relationship between a fault and it's effects from any of the following cases:

Single Fault -> Single Effect
Single Fault -> Multiple Effects
Multiple Faults -> Single Effect
Multiple Faults -> Multiple Effects

In PISCES multiple lines of reasoning are usually pursued due to an unsuccessful verification of an hypothesis involving the normal operating condition of a component or the normal operating range of a parameter value. The rule shown in Fig. 9 would be used to ascertain whether the nitrogen flow differential pressure value was in the correct range. Rule 9 contains one conditional clause that requests a LISP expression to be evaluated. This expression checks the range of the nitrogen differential pressure. If the expression evaluates to true, the fact "N2 differential pressures is normal" would be asserted. But, if the expression evaluates to false, then the fact "N2 differential pressures is not normal" would be asserted. This is indicated by the negative 1.0 certainty factor of the first clause in the ELSE part.



HYPOTHESIS : IGNITION SEQUENCE SUCCEEDS SUCCESSFULLY

Fi REPRESENTS EITHER A FACT IN KNOWLEDGE BASE OR SENSOR VALUE

Ri REPRESENTS THE i-th RULE

Fig. 7 Control Strategy with Single-line of Reasoning

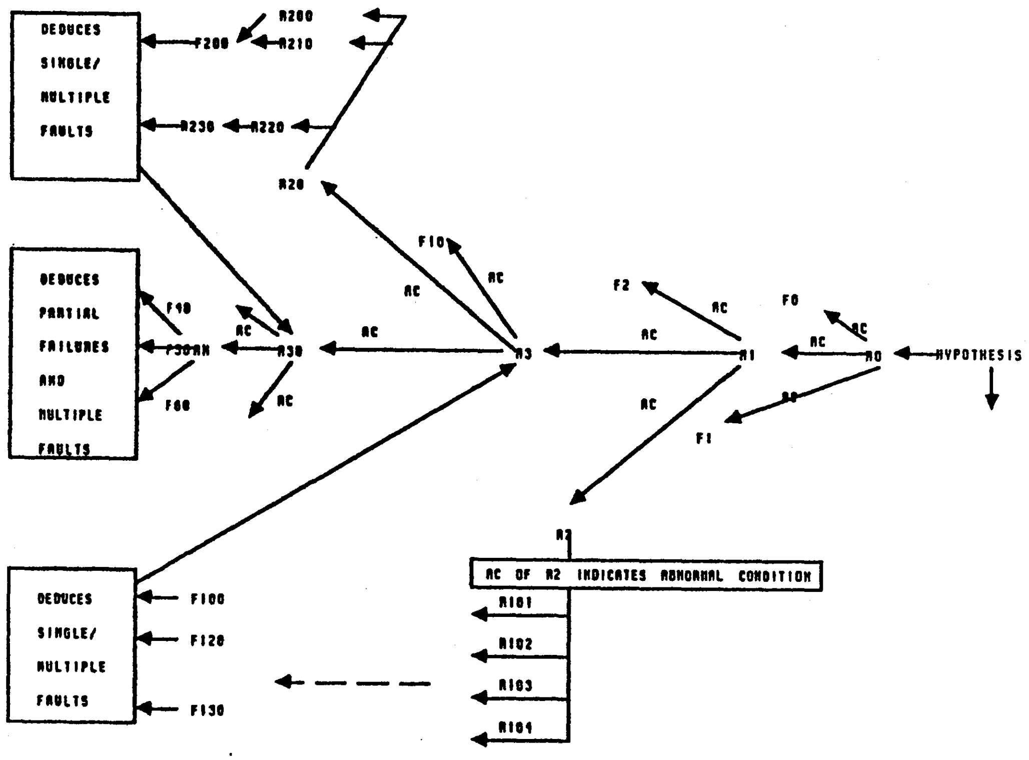


Fig. 8 Control Strategy With Multiple Lines of Reasoning

```
(rule 9  (if
   (LISP  and  (<  N2_differential_pressure
                30)
   (plusp  N2_differential_pressure)))
   (then    (0.95  N2  differential  pressure
             is  normal))
   (else    (-1.0  N2  differential  pressure  is
          normal)
   (LISP  check
   (N2  differential  pressure  is  not
      normal)
   (N2  isolation  valve  is  closed)
   (N2  tank  is  empty)
   (N2  differential  pressure  sensor  failed)
   (N2  pipe  is  leaking)))
   )
```

Fig. 9 Example of Multiple Lines of Reasoning

The terminal session presented in Fig. 10 illustrates the process PISCES uses to determine the root cause of the abnormal nitrogen differential pressure. When PISCES is requested to verify that nitrogen differential pressure is normal, it finds that the parameter value is out of range. It then asserts that the parameter value is not normal. Then the ELSE clause is executed and the LISP function activates multiple lines of reasoning to determine the cause of the fault.

```
enter hypotheses
? (N2 differential pressure is
normal)
Rule r00009 deduces
[1]    n2 differential pressure is
normal with certainty of -1.0
```

Fig. 10a:

Here, the operator query PISCES as to whether nitrogen differential pressure is normal. PISCES using rule 9 determines that· the nitrogen differential pressure is not normal.

```
Is this true:
n2 tank pressure gauge indicates very
low pressure? n
Rule r00013 deduces
[3]    n2 tank is not empty
with certainty of 1.0

Is this true:
n2 differential pressure sensor
output is greater than 5 volt? n
Is this true:
n2 differential pressure sensor
output is 0 volt? y
Rule r00020 deduces
[5]    n2 differential pressure sensor
failed with certainty of 0.85

n2 differential pressure is not
normal because n2 differential
pressure sensor failed
```

Fig. 10b:

The failure to verify the normal operating condition causes PISCES to follow the alternate line of reasoning contained in rule 9 ELSE clause. In the above dialog PISCES questions the operator about information it needs to aid in determining the root cause of the fault. Once PISCES determines the cause of the fault, it reports to the operator its findings.

EXPLANATION FACILITY

During the course of a session it is not uncommon for the operator to inquire as to the rationale behind the current line of questioning or to ask why a particular conclusion was reached. To provide the capability for dialog between the operator and PISCES, the explanation facility of EX[1-2] was incorporated into PISCES and was essentially unchanged with one exception. EX attaches each assertion it makes to a unique number. Later if the operator requests an explanation or justification of a particular assertion by entering a statement number, EX must search the knowledge base to find the rule containing the statement. PISCES avoids this search by not only attaching the assertion to the statement number, but the number of the rule used to justify it. In the example of the terminal (shown in Fig. 10) PISCES asks the operator whether the N2 tank pressure gauge indicated a very low pressure. At this point in the dialog the operator could ask PISCES why it needs to know this information. This exchange is shown in Fig. 11. For a more detailed description of the explanation facility see reference [1-2].

```
enter hypotheses

    ? (N2 differential pressure is
    normal)
    [1]    n2 differential pressure is
    normal with certainty of -1.0

    Is this true:
    n2 tank pressure gauge indicates very
    low pressure? why

    Because knowing whether n2 tank
    pressure gauge indicates very low
    pressure will help determine whether
    n2 tank is empty
```

Fig. 11a:
Here the operator wants to know the relationship between the nitrogen tank gauge reading and the assertion that nitrogen differential pressure is not normal.

```
Rule r00013 deduces
[3]    n2 tank is not empty
with certainty of 1.0

Is this true:
n2 differential pressure sensor
output is greater than 5 volt?

how 3

[i.e., how do I know that 1.0 n2 tank
is not empty?]

It is known that...
lisp not- '(n2 tank is empty)

and rule r00013 says that
if
lisp not- '(n2 tank is empty)
then
1.0 n2 tank is not empty

therefore...
1.0 n2 tank is not empty
```

Fig. 11b:
At this point PISCES has deduced that the nitrogen tank is not empty and is persuing the line of reasoning that the sensor may be faulty. However, the operator would like to know the rationale for the assertion that the tank is not empty. PISCES responds that knowledge base rule 13 says that if it cannot be proven that the nitrogen tank is empty then it not empty.

RULE EDITOR

A simple rule editor is provided with PISCES. It provides a parentheses free interface for adding rules to the knowledge base. The editor also performs syntax checking during rule input. The keywords IF, THEN, ELSE and END are used to direct the action of the editor. A sample session is presented in Fig. 12.

```
enter rule in the form of :
if
.... <if clauses> ....
then
.... <then clauses> ....
else
....<else clauses> ....
end
```

Fig. 12a Structure of PISCES rule

```
if
vh temp profile normal
flame detector normal
combustor pressure normal
then
combustor performing well
else
combustor not performing well
end

do you wish to input another rule
(y/n)

? n
```

Fig 12b:
To input a rule the operator first enters the keyword "if" followed by the rule antecedents. Next enter the keyword "then" which is followed by the consequents. The "else" and the else clause are optional. Upon completion of the rule the operator must enter end.

CONCLUSION

In this paper we have presented a description of PISCES. PISCES is a rule-based system that uses an English-like syntax to converse with the operator and represents knowledge about the domain of its application. PISCES has the ability to explain its action or to request more information in attempting to reach a solution. PISCES has been implemented in a computer simulation environment to prevent interruption of the MHD plant testing schedule. Prior to installing PISCES on the MHD plant computer the current syntatical indexing scheme will be replaced with a semantic indexing scheme. Currently, the syntactic indexing requires the operators to specify hypotheses exactly as they are stored in the Knowledge base, in order to request assistance from the system. In the next version of PISCES we will implement a natural language interface that transforms user queries into the internal representation used by the system.

ABSTRACT

A knowledge-based method is proposed for the layout design of industrial plants and applied as a layout design system for an electric power substation. In this method, dependency directed backtracking is adopted as the means to realize efficient modifications of intermediate layout plans while maintaining consistency among the data of the modified plan. The layout design system developed for the substation automatically generates layout plans which satisfy constraints and evaluates them as to construction cost, noise level, and other performance factors.

1. INTRODUCTION

A knowledge-based method is proposed for the layout design of industrial plants and applied as a layout design system for an electric power substation. The substation is an industrial plant which converts high voltage electric power to low voltage power. In designing a substation, one of the key phases is the layout of those components at the plant site. A substation is composed of hundreds of electrical, mechanical and architectural components. Layout designers are faced with the problems of treating the various attributes of these components, the spatial relation between them, and the spatial relation between them and the plant site when determining a layout plan. This complicated design process has been partially computerized to assist designers in this area.

Conventional computer-aided design (CAD) systems for the layout of a substation support the drawing of a layout plan on graphic terminals and/or numerical calculations to evaluate the construction cost, noise level from transformers, etc. [1] Few efforts, however, have been carried out to support the generation of layout plans which is essential to layout design. Ideally this facet of design should also be supported by a CAD system to enhance productivity in the layout design for industrial plants. It is, however, necessary for a CAD system to use designers' expertise directly in order to support the layout plan generation.

Knowledge-based design systems have been proposed in the field of engineering design to realize the direct utilization of experts' knowledge. [2]-[4] Emphases are placed on the use of heuristic knowledge in declarative form and the simple inference engine in those application systems, though a numerical procedure separate from the inference mechanism is also employed in the works of Refs. [3] and [4].

Expert designers, for example, use their heuristic procedures to solve the layout problem efficiently in a conventional design method for a substation. It is important for a layout design system to have intelligent functions which simulate designers' procedures to realize efficient problem-solving process. Hardly any research efforts, however, have been directed to their embodiment.

The objectives of this study are to develop a knowledge-based method to realize the most efficient design process by the use of designers' procedures and apply it to a layout design system for a substation.

2. METHOD OF INDUSTRIAL PLANT LAYOUT

2.1 Experts' Knowledge for Industrial Plant Layout Design

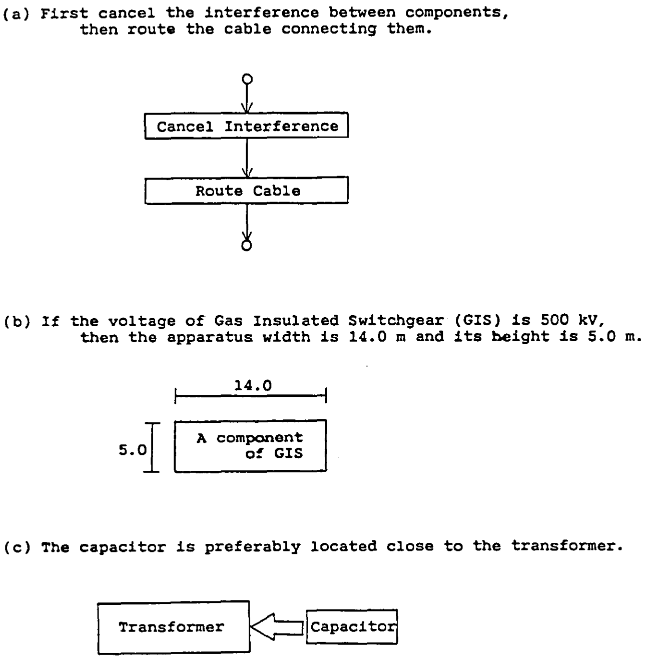
In the industrial plant layout design, designers determine the layout of the various components at the plant site. The layout design of a substation is chosen as an example to examine the characteristics of knowledge and its utilization in the design process.

Analysis of the layout process of expert designers gives the following characteristics.

(1) The use of declarative and procedural knowledge

Three typical examples of knowledge which are used in the design process are illustrated in Fig.1. Fig.1(a) shows knowledge about the sequence of two steps to realize an efficient layout process. This is an example of procedural knowledge. Fig.1(b) shows

CH2345-7/86/0000/0216$01.00 © 1986 IEEE



(a) First cancel the interference between components, then route the cable connecting them.

(b) If the voltage of Gas Insulated Switchgear (GIS) is 500 kV, then the apparatus width is 14.0 m and its height is 5.0 m.

(c) The capacitor is preferably located close to the transformer.

Figure 1. Examples of Domain Specific Knowledge

declarative knowledge about the size of GIS (Gas Insulated Switchgear). Fig.1(c) shows declarative knowledge about the relation between the location of a transformer and that of a capacitor.

(2) The efficient modification of an intermediate plan

In the design process, decisions made at an early phase are not necessarily correct later. It is necessary, then, to modify the previous decisions while maintaining the consistency among the data of the modified layout. It is, for example, difficult to predict if a component being placed now will interfere with the components placed in the future. Designers are able to modify the location of components and correct the layout plan efficiently.

(3) The preparation of design alternatives

Design criteria of various types are available for the layout design of a substation. Differences in the initial conditions result in different plans, as do different criteria. Designers often prepare several layout plans based on different sets of design criteria and compare them to select the optimal plan for overall performance.

These characteristic functions are related to designers' expertise by which expert designers can solve the layout problem efficiently. It is, therefore, necessary to embody these functions in the layout design system in order to improve productivity of the layout design of industrial plants. The individual methods to realize these functions in the knowledge-based layout design system are outlined in the subsequent sections.

2.2 Knowledge Representation

2.2.1 Procedural knowledge

Procedural knowledge is represented by a functional module, which is a set of rules together with the control information to use them. Figure 2 shows example representations of procedural knowledge. The functional module shown in Fig.2 is the representation of the knowledge shown in Fig.1(a), and is a procedure for routing the cable between components. The control information attached to this procedure is "(and rules)". This means "Rules in this module will be evaluated sequentially". When this module is invoked, first the procedure to adjust the interference between components is used, then that to plan the cable routes is used. The statements "(infer 'adjust-interference)" and "(infer 'make-cable-main)" causes activation of these functional modules.

The general design process is also controlled by the functional modules. The inference engine first invokes the modules which make an outline of the layout plan, and then invokes those which provide the details.

```
; Following statements define the procedure
;       for routing the cable.
(module make-cable

        ; Rules in this functional module
        ;       will be used sequentially.
        (and rules)

        ; if the interference between components
        ;       are not canceled yet,
        ; then cancel it.
        (if (not (eq 'adjusted layout.interference))
            (infer 'adjust-interfere))

        ; if the interference between components are canceled,
        ;    and the cables are not routed yet,
        ; then route cable.
        (if (and (eq 'adjusted layout.interference)
                 (not (eq 'made layout.cable)))
            (infer 'make-cable-main))
        )
```

Figure 2. Example of Functional Module

2.2.2 Declarative knowledge

The declarative knowledge is used to determine the layout of components at a specific layout step. This kind of knowledge is represented by two types of methods; functional modules and demons. Demons are procedures that execute whenever a particular condition about the data in the working area becomes satisfied.

The functional module represents a procedure to be executed in a specific situation of the layout process. For example, the knowledge shown in Fig.1(c) is not usable until locations of the main components, such as transformers and GIS are defined.

The demon is used to represent knowledge which is invariable in the design process, such as values of common specifications of components. A typical example is the dimensions of the transformer. The knowledge shown in Fig.1(b) is represented by a demon as shown in Fig.3. The inference engine always watches when the demon in the knowledge base is activated. If the activation condition of the demon is satisfied, the demon is invoked and a change is made in the data of the layout plan. For example, if a designer specifies the voltage of a GIS as 500 kV, the activation condition of the demon shown in Fig.3 is satisfied, and the width of the GIS is set as 14.0 m.

```
; Following statements define attribute of
;       a component of gas insulated switchgear (GIS)
(class  GIS
        ...
        (demon  ...

                ; if voltage of $ ( one of GIS ) is 500 k Volt,
                ; then width of it is 14.0 m
                ;                     and height of it is 5.0 m.
                (if (eq 500K $.volt)
                    (and (:= $.width 14.0)
                         (:= $.height 5.0)))
                ...
                )
        ...
        )
```

Figure 3. Example of a Demon

2.3 Modification of Layout

In the layout design process, it is necessary to modify a previous decision and maintain the consistency among the data in the modified layout plan. It is often difficult to predict the impact of a local modification on another part of the layout plan, for which a secondary modification is required to maintain consistency for the primary modification. Some efficient mechanism to backtrack and regenerate the layout plan should be added to an inference engine to realize efficient modification of an intermediate layout plan, while maintaining consistency among the data of the modified plan.

The dependency directed backtracking can be a mechanism to modify the layout plan and to adjust side effects of the modification. Few attempts have been done to use it as a means to keep data in an intermediate plan consistent when the layout plan is modified, though the technique of dependency directed backtracking has been experimentally studied for other purposes. [5]-[8] The modification mechanism which requires minimum data deletion is developed on the basis of the dependency between data to describe a layout plan.

Figure 4 shows a simplified example which illustrates the efficient modification function. In Fig.4(a), transmission towers are placed on the upper and lower sides of the center line of the transformer facility on the basis of knowledge on the spatial relation between transmission towers and the facility. Their locations depend directly on the location of the transformer facility. After the transformer facility is placed, a noise evaluation program written in Fortran is invoked and the result reveals that the noise level at a residential area exceeds the limitation. In this situation, the inference engine invokes a functional module which finds an alternative facility location to satisfy the constraint on the noise level. This procedure is stored in the knowledge base, and identified as procedural knowledge to adjust the spatial relation between the location of the residential area and that of the transformer facility. Fig.4(b) describes the situation after the facility location is modified. Now, the transmission tower locations are inconsistent, no longer being on the center line. This is the side effect caused by the primary modification of the layout plan.

Figure 4. Example of Layout Modification

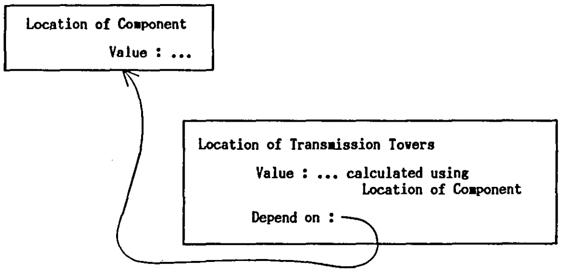
The secondary modification is done by the dependency directed backtracker and demons to adjust the undesirable side effect and to make data of the layout plan consistent. The backtracker deletes the locations of transmission towers that depend on the invalid location of the transformer facility from the working area, on the basis of the information about the dependency between the locations of components. Fig.4(c) shows this situation.

Finally, the demon is invoked to determine the locations of transmission towers. Their modified locations are shown in Fig.4(d).

The characteristics of this method to modify the layout plan are listed below.

(1) The procedure to find an alternative location of the transformer facility requires a limited search space, because it efficiently uses information about what the problem is and knowledge about how to solve it.

(2) In the working area, values of data are stored with information about the dependency between data. Figure 5 shows the dependency information of a transformer facility and its transmission towers. After the procedure modifies the layout plan, the dependency directed backtracker makes the data in the working area consistent.



Location of Component
Value : ...
Location of Transmission Towers
Value : ... calculated using Location of Component
Depend on :

Figure 5. Dependency Information

(3) If the dependency directed backtracker deletes invalid data from the working area, demons are used to reproduce the data making them compatible with the new modified data.

This mechanism, embedded into the inference engine, constitutes a functional module to find alternative locations of the transformer facility simply, because the functional module to modify the layout plan does not need to be concerned with both the existence and consistency of the data in the working area.

2.4 Alternatives to Layout Plan

It is often essential to obtain design alternatives of a layout plan in the course of design optimization. The data for different layout plans should be handled to obtain systematically several design alternatives.

Figure 6 shows the structure of a knowledge base and working area to support this function. The knowledge base includes two kinds of knowledge, and the working area includes two kinds of temporary data. The knowledge base stores knowledge to control the search process of the alternatives, and to generate layout plans from different initial conditions. The knowledge for layout plans is utilized to complete the individual layout plan, and the knowledge for control is utilized to select the next alternative layout plan to be processed.

To maintain several layout plans simultaneously, the data for layout plans are structured in the working area. The working area stores both the data to represent the layout plans and the data to describe their content. In Fig.6, three different layout plans are connected to different configurations of the main components.

3. SUBSTATION LAYOUT SYSTEM : XL-S

3.1 Configuration of XL-S

The demonstration system XL-S (eXpert system for Layout design for Substation) for layout design of a substation is based on the knowledge-based method described in the previous chapter.

The XL-S configuration is depicted in Fig.7. The system is composed of four elements; knowledge base, working area, inference engine and graphic interface. The knowledge base stores declarative and procedural knowledge in the form of functional modules and demons. The working area temporarily stores intermediate or/and final results of several layout

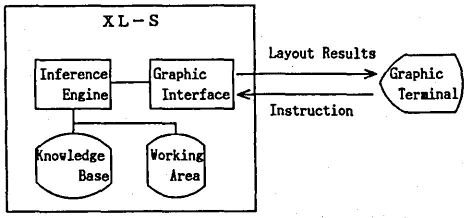

Figure 7. Configuration of Layout Design System XL-S

plans and control data. The inference engine drives the design process by forward chaining, generates hypothetical layout plans, and modifies intermediate layout plans. Through graphic interface, the substation layout is displayed on the graphic terminal and designer's instructions are sent to the inference engine.

The general flow of the layout process with XL-S is depicted in Fig.8. In the first step, the designer inputs the substation specifications such as the input voltage and capacity. In the second step, the system proposes an incremental change in the layout plan. Typical examples of these changes are the addition of a component to the layout space and the evaluation of a design parameter. The system assembles component areas and determines their placement using a standard layout process. The designer can intercept and modify the layout plan which is being incrementally made by XL-S at any layout step. If the proposed change in the layout plan satisfies the predefined constraints and is judged to be acceptable, the system continues to propose additional changes in the layout plan through the confirmation loop.

XL-S memorizes the default component size and the default relation between components in the knowledge base to minimize the amount of input data from the user. The designer thus handles fewer input data in this system than in a conventional graphic CAD system used for drafting. The system detects violations of constraints and initiates functional modules to remedy them. The designer can also directly specify modifications of the layout plan. Any modification invokes the dependency directed backtracker and demons to assure consistency among the data in the modified layout plan. With this automated function, the designer is relieved of the burdens of maintaining a consistent layout plan in the working area, and reproducing necessary data.

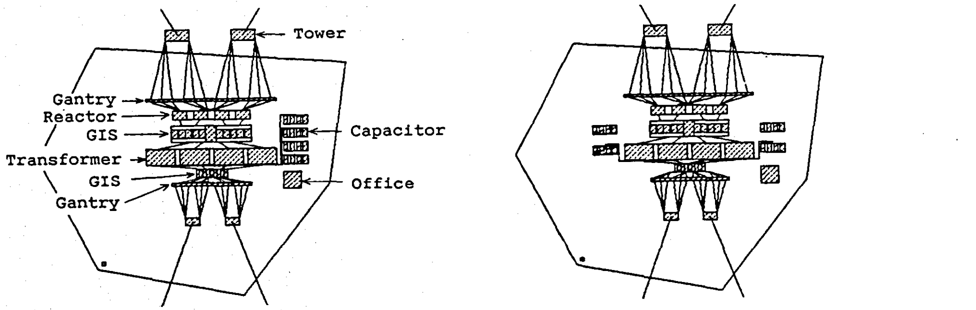
3.2 Results

The layout design system XL-S was applied to the layout design of a typical substation. The input and output voltages of the substation are 1000 kV and 500 kV respectively, and its total capacity is 8000 MVA. The main components are gantries, reactors, GIS's, transformers, capacitors, transmission towers, and an office building. A typical result from this system is shown in Fig.9(a).



(a) Results of a Layout Plan (b) Results of a Modification Specified by a Designer

Figure 9. Examples of Layout Plans

XL-S generated this layout plan mainly on the basis of knowledge on the spatial relation between components. The system also evaluated the layout plan as to the construction cost, noise level and other performance factors.

Fig.9(b) shows a modified layout plan based on that shown in Fig.9(a). In this case, the location of the four component areas which include a capacitor are modified directly by the designer. The total number of data that are modified is 12. This primary modification requires a secondary modification of related components. Modification of even limited data can cause a large-scale change in the layout plan. It is often inappropriate to recover consistency among data through manual operation and a simple backtracking method. With the dependency directed backtracker and demons, XL-S modifies over 200 data in this example. Figure 10 shows the main dependency in the working area of XL-S that is concerned with the modification.

Figure 10. Dependency in Layout Plan

The layout design system XL-S is now undergoing functional tests conducted by expert designers. The preliminary results suggest that XL-S can reduce the period which is required to complete layout design of a substation. The reasons are listed below:

(1) The user does not need to handle the large amount of input data owing to default data and predefined procedures stored in the knowledge base.

(2) The user does not need to be concerned with both the existence and consistency of the data in the working area owing to dependency directed backtracking and demons.

4. CONCLUSION

A knowledge-based method has been developed for the layout design of industrial plants and applied to the layout design system for a substation. The proposed method is characterized not only by the direct utilization of designers' expertise, but also by intelligent functions embedded into the inference mechanism. These characteristics are summarized as follows:

(1) Designers' knowledge is utilized to generate layout plans that satisfy constraints and to evaluate the construction cost, noise level and other performance factors.

(2) The modification procedure is adopted to modify the data of an intermediate layout plan. The dependency directed backtracker deletes invalid data to make the data consistent in the layout plan, and demons reproduce new data for the modified layout plan.

(3) The knowledge base stores knowledge to control the search process for alternative plans, and to generate layout plans from different initial conditions. This allows it to support several alternative layout plans simultaneously.

The layout design system XL-S is now undergoing functional tests conducted by expert designers. The preliminary results suggest that XL-S can reduce the period which is required to complete layout design of a substation.

ACKNOWLEDGEMENTS

It is a pleasure for the authors to acknowledge the persons who have guided and encouraged them. In particular, they are grateful to Mr. R. Kadoi of the Tokyo Electric Power Co.,Inc. and Drs. S. Yamada, A. Doi, K. Inoue, H. Motoda, Mr. H. Sakai and Ms. R. Hara of Hitachi,Ltd.

Abstract

In this paper, we will propose a logic programming approach to design a frame-based language. The relationship among frame, logic and Prolog is our basic design issue. Frame is considered as a collection of slot-relations, and frame reference/inference procedure can be specified in logic form. Prolog is used to represent all of these concepts. Frame is encoded with Prolog facts and rules. This type of frame representation has the advantages of multiple access methods, ease of frame modification, slot inference rule creation and faster recognition. A frame recognition algorithm, similarity reference, is given as an example using our frame notation. With this approach, on the one hand, the semantics of logic makes it quite clear what frame and its deduction mean, and on the other hand, the simply extended Prolog will be more adequate and efficacious to represent knowledge.

1. Introduction

A good knowledge representation tool is not only adequate to the expression, but also efficacious to the reasoning [16]. Frames, which have good expressive power, were first proposed in [10]. Since then, several frame-based languages, such as FRL [6,13], KL-ONE [1], etc.[15], have been developed and used to implement systems in a variety of domains. How frames are involved in knowledge system's reasoning process was discussed in [5]. In most applications, e.g. natural language processing [1], diagnostic problems [12], and so on, frame recognition is one of major steps in the frame reference/inference process. How to select a frame to "best" match the observations, which are some attributes of an object, from large frame database, becomes an important problem. Thus, notation efficacy of frame representation affects the recognition step deeply. In this paper, we will propose a mechanism to encode frame notation with Prolog rules and facts, and make deduction from frame database with logic programming techniques.

Because "predicate logic as a programming language" is the basic idea behind Prolog [8], Prolog inherits many interesting features from logic [14]. We will emphasize the relationship between logic and frame [7], and take it into consideration of our logic programming approach. Section 2 will discuss briefly the relationship among frame, logic and Prolog. Section 3 will propose a frame representation with Prolog clauses, and its reference/inference mechanisms with logic form. A frame recognition algorithm will be given as an example using our frame notation. This experimental language, called LOGFOL (Pro<u>log</u>-based <u>F</u>rame-<u>o</u>riented <u>L</u>anguage) in [3], is implemented in CProlog [11], and operates on a DEC VAX-11/750 VMS system.

2. Frame, logic and Prolog

A frame is a data structure to represent stereotyped situations [10]. What constitutes a frame is implementation dependent, but it must be able to represent the properties of an object and the specifications of each property. For example, a classroom which is a complex object may be described by board, chalk, brush, and desk-and-chair. We can define a classroom with these properties as a lambda expression:

$$\lambda x\ (\text{board}(x,y_1) \wedge \text{chalk}(x,y_2) \wedge \text{brush}(x,y_3) \wedge \text{desk-and-chair}(x,y_4))$$

where x is some specific classroom;
y_1, y_2, y_3 and y_4 are its contents.

Properties board, chalk, brush and desk-and-chair are called slots of a classroom. Terms y_1, y_2, y_3 and y_4 are called fillers of some classroom. Relationship denoted by slot exists between a frame and its filler. Thus, on the one hand, given a frame that represents a concept, we can generate an instance of the concept by filling its slots to make these relations true. A logic formula expresses this concept as:

* The author is also a graduate student in the Institute of Electrical Engineering, National Taiwan University.

CH2345-7/86/0000/0223$01.00 © 1986 IEEE

$$\forall x\ (\mathrm{frame}(x) \rightarrow \exists\ y_1, y_2, \ldots, y_n\ (\mathrm{slot}_1(x, y_1) \wedge \mathrm{slot}_2(x,y_2) \wedge \ldots \wedge \mathrm{slot}_n(x, y_n)))$$

On the other hand, if we can find fillers for all the slots of a frame, then an appropriate instance of the concept exists. This concept can also be formalized as:

$$\forall x\ (\exists\ y_1, y_2, \ldots, y_n\ (\mathrm{slot}_1(x, y_1) \wedge \mathrm{slot}_2(x, y_2) \wedge \ldots \wedge \mathrm{slot}_n(x, y_n)) \rightarrow \mathrm{frame}(x))$$

Therefore, we can express the frame concept as logic formulae, and consider a frame as a collection of slot-relations.

Prolog is a powerful language which is used to solve problems that can be expressed in the form of objects and their relationship. It has some interesting features [9,14] helpful to design a frame-based language:

(1) Algorithm = Logic + Control [9]
The idea of Prolog is to specify the logic part only, not to care for the control part. If we regard a frame concept as a bundle of slot-relations and design it with logic programming techniques, then metaphysical and implementation interpretation of frames [7] are the same. So, frame reference/inference can be thought intuitively.

(2) multiple-purpose procedures
Not necessary to distinguish the roles of arguments in advance, some frame manipulation predicates may have more than one function. Especially, a predicate might be thought as a generator which generates result(s), or as a verifier which, given all arguments as inputs, checks whether a slot-relation is valid.

(3) high level form of iteration
Procedures may generate, through backtracking, a sequence of alternative results. Frame-based system is organized as a hierarchical network. The solution(s) in a frame reference/inference process depend on the completeness of the given information. Some search operations involved in frame reference/inference are tentative. It is likely to make trials until a solution is found. Backtracking mechanism embedded in Prolog takes care of the trial and error process very well.

(4) general record structure
Term structure makes frame representation more flexible. We can represent knowledge in a most appropriate way.

3. Language Structure

The programming structure of our extended Prolog system is shown in Fig. 1.

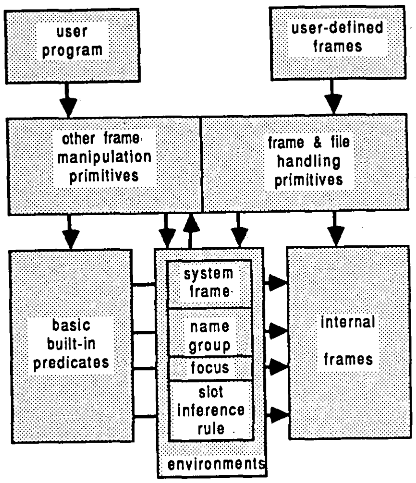

Figure 1 The programming structure of our extended Prolog system

This language includes three layers. The bottom layer is the frame definition, including two forms: the external one, with which users may represent knowledge of given problem domains intuitively, and the internal one, on which basic built-in predicates operate. The next-to-bottom layer consists of a collection of Prolog predicates used to manipulate the frame database. Frame reference/inference mechanisms constitute the top layer. All the frame manipulations are done under the current environments (system configuration, name group, focus and slot inference rule). We will discuss these issues in Section 3.1 and 3.2.

3.1 Frame Representation

From macroscopic viewpoint, a frame database is a collection of frames linked together. From microscopic viewpoint, a frame is like a tree (see Fig. 2 in FRL terms [6,13]).

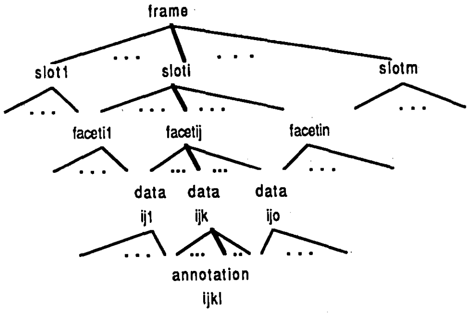

Figure 2 Frame in external form is like a tree.

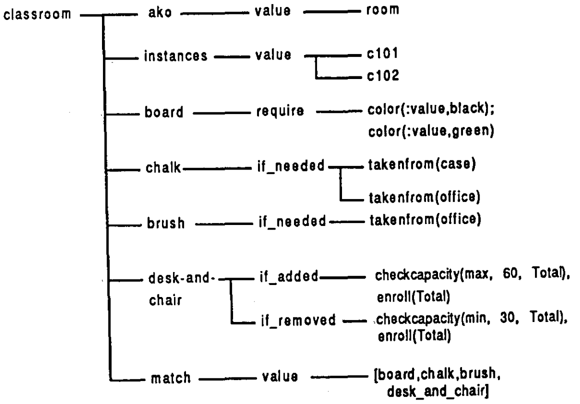
Frame forms the semantics of a concept. Slot defines a property of a frame. Slot may be either system-defined or user-defined. There are system-defined slots specified in the system frame.

such as classification (generic/individual), ako and instances(for network construction) and match (for frame recognition). User-defined slot describes a specific feature for some concept. Facet specifies value, default, restrictions or interpretative hooks [1] in the corresponding slot. Useful built-in facets are: value, which specifies the slot's value; default, which denotes the default value; require, which defines the restrictions that filler must meet; if_needed, which provides a deduction rule (a sequence of goals) for the filler; and if_added and if_removed, which are used for network maintenance. Data may be either values or a goal statement depending on its facet's usage. Annotation specifies the source (perspective, ...) from which the information is collected. Such a definition constitutes a complete frame. A frame example (a generic classroom) which has been taken its syntactic sugar out is shown as follows:



Before the external frame is put into frame database, it must be preprocessed to a number of frame fragments, called internal frame. A frame fragment is retrieved along the path frame - slot - facet - data - annotation from the tree in Fig. 2 (see dark line). It is represented as a Prolog fact or rule, depending on its facet:

(1) value facet

```
slotname(framename, datum:annotation).
        or
slotname(framename, datum).
                            /* no comment */
```

This fact can be read as:

From annotation, the filler in the slot of a frame is datum (the relationship between frame and datum is slot).

(2) default facet

```
slotname(framename, default,
        datum:annotation).
        or
slotname(framename, default, datum).
                            /* no comment */
```

This fact can be read as:

From annotation, the default value in the slot of a frame is datum.

(3) other facets

```
slotname(framename, facetname, annotation)
    :- attached goals.
        or
slotname(framename, facetname,
        no_comment) :- attached goals.
```

This rule can be read as:

From annotation, the filler meets the facet's specification in the slot of a frame if attached goals succeed.

This viewpoint may be compared with Chang [2] who uses n-ary predicate to represent frame. Deliyanni and Kowalski [4] have discussed the advantages and disadvantages between binary representation and n-ary representation of logic form in the knowledge-based system.

An example (a generic classroom frame) is given below to illustrate this two-place or three-place slot-relation:

```
frame(classroom, [ako, instances, board, chalk,
                  brush, desk_and_chair, match]).
ako(classroom, room).
instances(classroom, c101).
instances(classroom, c102).
board(classroom, require, no_comment) :-
        curr_env(_frame, _slot, _facet, _value),
                /* current focus environment */
        (color(_value, black); color(_value, green)).
chalk(classroom, if_needed, no_comment) :-
        takenfrom(case); takenfrom(office).
brush(classroom, if_needed, no_comment) :-
        takenfrom(office).
desk_and_chair(classroom, if_added,
                no_comment) :-
        checkcapacity(max, 60, Total),
        enroll(Total).
desk_and_chair(classroom, if_removed,
                no_comment) :-
        checkcapacity(min, 30, Total),
        enroll(Total).
match(classroom, [board,chalk,brush,
                  desk_and_chair]).
```

Predicate frame denotes a generic classroom frame that has seven slots - ako, instances, board, chalk, brush, desk_and_chair and match.

This type of frame representation in Prolog fact or rule has the advantages of

(1) multiple access methods:

We may use "?- frame(framename, SlotList)." to find all the slots with a given frame name,

or use "?- slot(framename, Datum)." to find all the values with a given slot name of some frame,

or use "?- slot(Framename, datum)." to find all the frames with a given slot and its value.

In this retrieval process, no special hash mechanisms are required, because they are embedded in the Prolog system. This is in concordance with the idea of logic programming [9].

(2) ease of frame modification:
A good representation scheme must have capability of managing incomplete knowledge. In our paradigm, a newly invented property can merge into an existing frame easily; and on the other hand, an unsuitable property can also be retracted easily. These advantages are offered over the n-ary representation by the binary representation [4].

(3) slot inference rule creation:
Representing a slot as a relation enables slot-to-slot transference to be clear. For example,

"Y is a key of X if X has Y and Y is a key"
can be represented as:
keyof(X,Y) :- having(X,Y), iskey(Y).

Slot "keyof" is mapped into slot "having" by slot inference rule. Seeing-as relation proposed in [7] can also be specified by this type of inference rule.

(4) faster recognition:
During frame recognition, we will select a "best" frame which matches the observed features. In our paradigm, features of a frame are put in the form of slot-relations whose orders are not important. We can start out recognition with some evident features.

3.2 Environments

For each frame, there might be several names, one primary name and some secondary names, that can be used to identify it. Thus, each frame must have an associated list of allowable names which directly access it. We call each name a member of the name group of a frame. The name group is a set representing a collection of allowable names used to access some frame structure. To group two frame name X and Y together, we can use fgroup(X,Y), where X specifies an existing frame and Y is a frame name not bound to any existing frame yet. All the frame manipulations are through name group environment.

When one looks something in the world, he always concentrates on some part of it. However, he can retrieve all the relevant knowledge from this starting-point. There may be similar in the frame manipulation. During the frame manipulation, we focus only on some property (slot) of a specific frame. How to access other frame fragments within the same or different frame is an important issue. Because a frame is represented as a set of Prolog facts and rules, frame fragments are connected by the same frame name, and different frames are connected by instances, ako, or other relations. Focus transference is specified by environment change. Fact curr_env(frame, slot, facet, data) defines current focus environment. Structure :frame, :slot, :facet and :value in the clause refer to the current focus (see the generic classroom in the last section and its internal frame transformation). When a built-in predicate changes environment, the focusing frame fragment also changes at the same time.

The system configuration is defined by 'system' frame. A system frame is given as an example in the following:

```
sys_slots(system, classification).
sys_slots(system, ako).
sys_slots(system, instances).
sys_slots(system, match).
classification(system, default, generic).
primary(system, ako).
primary(system, instances).
```

Slot 'sys_slots' specifies system-defined slots. The default value of classification slot is generic. The value in the ako and instances slot must be a primary frame name. With system frame, we can maintain an appropriate system configuration for our own applications.

3.3 Example: similarity reference

The general process to manipulate a frame database of an application involves two steps:

(1) selecting a specific frame, and then
(2) applying operations on this frame.

We call step (1) frame reference. We may simply refer to a concept explicitly by its name. However, we may not know the name of the referred frame. Moreover, we cannot assure whether the frame already exists in the database. What we have known about an object is some of its features gathered from external world. So, frame reference becomes a recognition process. This type of reference, called similarity reference, is guided by the features of an object in question. We express the object's features as a collection of slot-relations, which constitute a temporary frame. If this frame does not exist in the database, an instantiation of some generic frame may be needed.

A set of requirements needs to be satisfied to ensure that a temporary frame X and a candidate frame Y are similar. In frame recognition, we express this concept in logic form as follows:

$$\forall X \ \forall Y \ (\text{relation}_1(Y,f_1(X)) \wedge \text{relation}_2(Y,f_2(X)) \wedge \ldots \wedge \text{relation}_m(Y,f_m(X)) \rightarrow \text{similarity}(X,Y))$$

In the above sentence, those conditions for X are specified by the frame Y. Relation$_i$ may be interpreted as a relationship between frame Y and the corresponding slot's value of temporary frame X. Function f_i tries to deduce the value from current knowledge base. Thus, when we specify f_i for each slot, we can define criteria to identify the frame. This sentence may be translated into Prolog-like clauses:

(c1) similarity(X,Y):- relation$_1$(Y,X), relation$_2$(Y,X), ..., relation$_m$(Y,X).

(c2) relation$_i$(Y,X):- slot$_i$(X,Z), slot$_i$(Y,Z).

(c3) relation$_i$(Y,X):- slot$_i$(X,Z), meet_requirement_of(Z, Y, slot$_i$).

We use (c2) and (c3) to simulate a deduction function f$_i$. The pragmatic requirement to consider two slots to be matched is either they have the same value (c2), or with the value conflict, but the pragmatic feature of the temporary frame meets the requirements of the corresponding slot of a candidate frame Y (c3).

The system built-in slot 'match' of a frame defines a frame recognition procedure. Given a temporary frame X, to identify a candidate frame Y as its referent, we trigger the recognition procedure of Y. Whether the identification succeeds depends on the satisfaction of this procedure call.

Match slot has two modes available: system mode and user mode. In system mode, interpreter takes the value of match slot, which is a list of slot names of a candidate frame, as input to a system-defined procedure (see next paragraph). The default for match slot is a list of all the slot name of the frame, except system built-in slots defined in the system frame. If the value of match slot is not a list of slot names, interpreter regards the value as an user-defined recognition procedure, and calls it directly. The latter usage is in user mode, which a user has all his own right to control the recognition process. The presentation of this mode increases the flexibility in the recognition process.

The system-defined procedure in system mode is clause (c1)-(c3). The i-th relation corresponds to the pragmatic requirement to match slot$_i$. The data in 'require' facet is any Prolog predicates, which constrain the allowable values of the slot, and control the slot matching. The 'require' facet specifies the requirement used by meet_requirement_of(Z, Y, slot$_i$) in the clause (c3).

A sample predicate

funify(TemporaryFrame,CandidateFrame,
UnmatchedSlotNameList)

which takes care of the recognition process mentioned above is shown below:

```
funify(FN1, FN2, UMSL) :-
    nonvarl([FN1, FN2]),                  /*FN1 and FN2 are instantiated  */
    get_fn(FN1, F1),                      /* get primary frame name from  */
    get_fn(FN2, F2),                      /* name group                   */
    ((fgeti(F2, match, value, P),         /* user-defined recognition     */
     not list(P),                         /* procedure                    */
      call(P),
      UMSL=[]);
     (not fgeti(F2, match, value, _), /*default for match slot: the      */
      fslots(F2, SNL),                    /* list of all the slot names of */

```

Some of the built-in predicates used in the above example are summarized as follows. We use a notation to specify the role of an argument:

<i> input argument,
<o> output argument,
<*> input/output argument.

fget(FrameName<i>,SlotName<i>,
Facet-Datum-Annotation<i>, ItemList<*>)

The predicate fget gets a list of items along the path specified by FrameName, SlotName and Facet-Datum-Annotation, if ItemList is uninstantiated.

fgeti(FrameName<i>,SlotName<i>,
Facet-Datum-Annotation<i>, Item<*>)

The predicate fgeti is similar to fget, except that fgeti returns one item at a time. When backtracking, it will return another item, if exists.

fheritage(FrameName<i>,SlotName<i>,Facet<i>, ItemList<*>)

The predicate fheritage gets a list of data indicated by FrameName, SlotName and Facet, and data inherited along the slot ako, if ItemList is uninstantiated.

fslots(FrameName<i>, SlotNameList<*>)

SlotNameList<o>: The predicate returns a list of slotnames that belong to the frame specified by FrameName.

SlotNameList<i>: The predicate verifies the frame-slots relationship.

4. Conclusion

In this paper, we have described the design issues of our frame-based language, which represents and manipulates frames with logic programming techniques. On the one hand, we consider a frame to be a bundle of slot-relations, with which one may directly access a slot and its value. This design speeds up frame access operations and it has a merit of putting frames and matching assumptions into logic forms. The semantics of logic makes it quite clear what a frame structure means. On the other hand, we encode a frame mechanism in Prolog such that the simply extended Prolog will be more adequate and efficacious to represent knowledge.

INTERFACING PROLOG TO PASCAL

KENNETH MAGEL

NORTH DAKOTA STATE UNIVERSITY

ABSTRACT

This paper presents the implementation of a mechanism for linking an existing Prolog interpreter with Pascal programs so that each may call the other and so that each may share data with the other. Various approaches for linking the two languages are considered and compared. Some performance results for mixed applications are described.

INTRODUCTION

Prolog presents a convenient paradigm for implementing applications in areas which involve a set of facts and ask for inferences from those facts and rules relating facts. Prolog includes a naive automatic backtracking mechanism as well as a pattern matching-triggered application of rules. Even in these areas, however, Prolog does not provide all of the features which would make implementation as convenient as possible. In some situations where the Prolog implementation is easily constructed, the implementation will be inefficient. For example, sorting may be written rather easily in Prolog as the generation of successive permutations of a list and the testing of each to determine which is sorted. Unfortunately, such an approach is much less efficient than a more procedural one such as might be written in Pascal.

Many already written and debugged routines exist in widely used languages such as Pascal. Being able to use these routines from a Prolog program would be extremely valuable for many applications. A major advantage of newer procedural languages such as ADA and Modula-2 is their extensive support for the construction and use of libraries of routines (called packages or modules).

When Prolog is implemented on conventional vonNeumann computers, the implementation is usually inefficient and requires rather complex data structures to handle the fluid data typing, support for manipulation of not yet defined quantities, backtracking, and tentative assignments [1]. Some applications and parts of applications which could conveniently be done in Prolog can be done more efficiently in other languages because of these implementation considerations.

For these reasons, we set out to link an existing Prolog implementation [2] with programs written in a procedural language. We wanted the interference to be as open and flexible as possible. In particular, we wanted routines in each language to be able to invoke routines in the other language. Routines in each language should be able to manipulate global data and structured parameters and to return any value which a routine in the native language could return. We choose an extended Pascal which supported separate compilation for two reasons: (1) we had substantial code and expertise in Pascal; and (2) the Prolog implementation is written in a common subset of Pascal. The approach should be applicable to linking Prolog with other languages as well. We presently are starting a project to link another version of Prolog implementation in C with Pascal and Fortran programs. The Fortran-Prolog system will be particularly useful to some engineers on our campus who are developing expert systems to support engineering applications.

RELATED WORK

Three approaches have been tried to mixing languages in a single application: (1) extending an existing or proposed language to incorporate features from other languages and paradigms [3]; (2) using an intermediate file or files to communicate information between programs in each language; and (3) some sort of escape mechanism which a program in one language may employ to call upon routines in other languages. The following paragraphs discuss each of these approaches.

Incorporating multiple paradigms into one language has several advantages. The problem of passing information from one paradigm to another is handled entirely by the one language implementation. Paradigms may be mixed freely, even for rather small units of shifting paradigms. The major disadvantage from our perspective is the difficulty in using existing programs in a procedural language. Further, our experience indicates that programmers may have difficulty in understanding and using effectively a variety of paradigms which are presented in the same setting. In addition to the work described in [3], C. Mellish et al describes a POPLOG implementation which

CH2345-7/86/0000/0229$01.00 © 1986 IEEE

provides an integrated environment for writing POP-11 and Prolog programs which communicate [4]. The compilers generate a common intermediate language.

The intermediate file approach gets around the problem of communicating structured data since each language has an output facility and an input facility. As long as one language provides the capability of outputing data in a form which the other language can input, this approach works. The major problem with the intermediate file is its inefficiency. Input and output usually are the slowest operations in any language because the underlying hardware is relatively slow. When intermediate files are used, the application units implemented in each language must be quite large to make up for the time overhead of the file communication. A mechanism such as the pipes of UNIX can reduce this overhead significantly. Nevertheless, the need to translate the data from its internal form for one language to an eternal form and then to the internal form of the other language still imposes substantial overhead.

The escape mechanism approach can be implemented efficiently. Unfortunately, it is a one-way approach in the sense that communication via the escape mechanism goes from one language to the other, but not in the other direction. A further problem is the complexity of the data structure for a term in our version of Prolog. Figure 1 shows the data structure for a term in our version of Prolog. Arrows indicate references by pointers to subsidiary structures. Double vertical lines are used to indicate the additional fields which are present when the upper field has the indicated value. The routines in the other language must be written to be careful not to affect the integrity of the Prolog data structures. A final problem involves how to handle backtracking when the language escaped to does not include such a concept. There have been some previous efforts to utilize the escape mechanism approach. These efforts have been limited in either of two ways: (1) they were set up to handle specific applications with specific communications needs; or (2) they support calling programs in the other language, but only limited data transfer back and forth. Perhaps the earliest such effort was by Santane-Toth and associates in Hungary [5]. They set up a system to invoke Fortran subroutines from Prolog, but only simple non-structured data could be passed across the interface. The goal was a system which would support numerical processing in Fortran with all other aspects of the application done in Prolog. Nilsson described a small structure-sharing Prolog interpreter implemented in LISP which supported an escape to LISP evaluable predicate [6]. Several authors have considered the integration of Prolog with functional programming [7,8].

OUR IMPLEMENTATION

We choose to use the escape mechanism approach, but extended it to support two way communication. We handled backtracking by deciding that all actions done by Pascal programs on Pascal data would not be undoable. All changes made by the Pascal programs to Prolog data would follow the same rules as if those changes had been made by Prolog code at the point of the invocation of the escape mechanism. If backtracking passes back through a point of invocation of the escape4 predicate, the escape interface is called with a special first parameter to indicate that. All changes made to Pascal data by Prolog code are not undoable. This solution is not wholly satisfactory, but alternatives seem to require re-implementation of a backtracking mechanism for Pascal. We are designing a mechanism to support backtracking of Prolog changes to Pascal data. The mechanism requires a stack of previous values for each Pascal variable and may offset some of the speed advantage of using Pascal. The possibility of using precompiled Pascal routines would be eliminated. We expect to use the non-undoable version of Pascal nearly all the time.

One evaluable predicate, escape4 was added to Prolog. This predicate takes four parameters which may be any type of data in the Prolog system including anonymous variables, uninstantiated variables, unchanged goals, atoms, integers, operator expressions, complex terms, or lists. This data may be changed in arbitrary ways by the Pascal routines. In addition, some routines were added to the Prolog interpreter which may be invoked by the Pascal programs. These routines support retrieval by the Pascal programs of any global data from the Prolog side and the execution of parts of the Prolog program as subroutines of the Pascal programs. They also provide the ability for the Pascal programs to use the program modification facilities of Prolog to change the Prolog program.

The Prolog implementation of escape4 calls a Pascal external routine named EscapeRoutine. This routine may be written by the user, but we provide two versions which may be used as is or as models. The first is given as the appendix to this paper and provides some simple routines to manipulate the Prolog data passed as parameters, but leaves most of the burden of handling the complicated Prolog data structures to the user.

The second version of EscapeRoutine is much larger and provides a simple set of abstract datatypes to hide the actual data structure implementations. These allow the user to retrieve fields of any parameter data structure, and to set fields of any accessible data. New data of any type may be created as well. The abstractions are identical with those we expect to provide to Pascal and Fortran from the C implementation of Prolog. They involve arrays and single data values plus a flag to indicate undefined and another flag to indicate if the assignment should be permanent or only until backtracking goes through the statement which invoked the escape routine. As much as possible, we try to present the Pascal or Fortran programmer with facilities which are consistent with Pascal or Fortran. We try to give the Prolog programmer facilities which are consistent with Prolog.

intended for use in large applications where different programmers might be writing the procedural code from those writing the Prolog code. We use a graphical view of the shared data structure to indicate to each group and what data is available and how that data may be used by each side. A Prolog program is used to develop and maintain these data diagrams. We are implementing a program in Prolog to check Prolog and Pascal programs for adherence to the constraints described in the data diagram.

Forty-three statements of Pascal were added to the existing interpreter in all. The simpler EscapeRoutine is 120 lines of Pascal while the more complex one is about 2100 lines. We have done two applications in Prolog and in the mixed Prolog-Pascal system to determine if the mixed system was of use or not. In each case, the application was written in Prolog, and debugged. Then a trace was used to identify where in the Prolog program significant time was spent. Those sections were considered for reimplementation in Pascal. Hence the results are skewed in favor of the mixed system. The first application is a primitive calendar system which provides reminders of appointments on a daily or weekly basis and warns of overlapping commitments. The second application is a keyword-based reference retrieval system. With the first system, approximately twelve percent of the total 260 Prolog statements were rewritten in Pascal. On a typical run, the mixed system ran seventy-two percent faster than the Prolog version. With the second system, approximately seven percent of the total 174 Prolog statements were rewritten in Pascal. On a typical run, the mixed system ran twenty-one percent faster than the Prolog version. Results of twenty test runs with different data ranged from fourteen to forty-one percent faster for the mixed version compared to the Prolog version.

The approach presented here may be extended in several directions. Languages which incorporate other paradigms (e.g., object-oriented as in SMALLTALK) could be accessed from Prolog or a procedural language in the same manner. Spreadsheets, databases, painting programs, and other applications could be accessed in some cases. An interlanguage tracing and debugging tool should be developed to assist production of multiple language systems.

Knowledge-Based Optimization in Prolog Compiler

Naoyuki Tamura
Science Institute, IBM Japan, Ltd.

Abstract

This paper describes an optimization technique used in a Prolog compiler. The compiler generates efficient code for several machines including IBM System/370 and a RISC machine, IBM RT PC.

We stress on *knowledge-based approach* for optimization. Prolog programs are compiled into intermediate code and the code is translated into a graph for optimization. The optimization consists of following two steps; (1) tracing the graph to infer the behavior of the intermediate code by using a *semantic definition of the intermediate language*; and (2) simplifying the graph by *graph reduction rules.*

This optimization improves the performance of a list concatenation program by a factor of 1.8. And when some user's declarations are added, the improvement of the optimization becomes about 2.0.

1 Introduction

This paper describes an optimization technique used in a Prolog compiler. The compiler generates efficient code for several machines including IBM System/370 and a RISC machine, IBM RT PC [6].

Figure 1 shows the outline of the compiler [7].

In phase-1, Prolog programs are compiled into intermediate code. The intermediate language is based on David Warren's "Abstract Prolog Instruction Set" [5], but some instructions are decomposed into lower level instructions.

In phase-2, the intermediate code is translated into a graph. The optimizations are then performed on this graphical representation of the program. Then the optimized graph is translated back to intermediate code.

In phase-3, the intermediate code is translated into a high level language program — PL.8 [1] — as an object code.

Phase-4 is a PL.8 compilation phase.

2 Prolog compiler

There are some problems with the compilation of Prolog programs compared with other conventional languages, such as FORTRAN and Pascal.

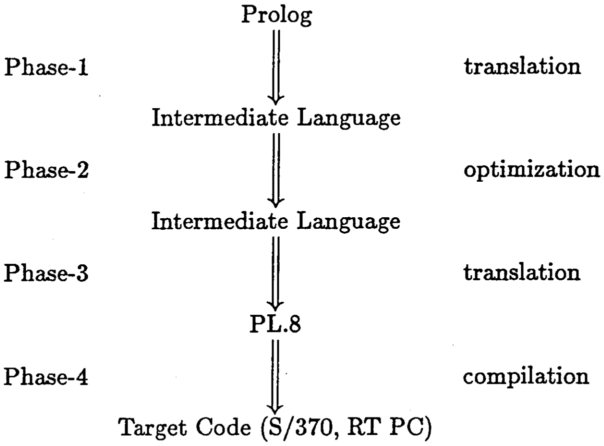

Figure 1: Outline of the Prolog compiler

- **typelessness**
  Prolog is basically a typeless language. Variables can contain any type of data and different operations are required for different data types.

- **bidirectionality**
  Any argument can work as both input and output. The same argument can be used to construct the structure or to read the elements of the structure.

In David Warren's "Abstract Prolog Instruction Set" [5], the first point is solved by using tags to distinguish data types. The second is done by using read/write modes to indicate whether the unification in process is destructive or constructive.

Tick and Warren's "Pipelined Prolog Engine" has a piece of hardware to test tags and read/write modes at execution time with little overhead [3]. But for conventional machines, testing at execution time requires several instructions and is an overhead. Therefore, for those machines, optimizing test operations is useful to improve the performance.

However, the level of Warren's instruction set is too high to perform the optimization because testing operations are implicitly embedded in most instructions. For example, the instruction, `get_list A1`, implies following operations:

1. test the tag of the register `A1`

2. if A1 is a bound variable,
   dereference A1 and go to 1

3. if A1 is an unbound variable,
   create a list cell and set to write mode

4. if A1 is a list,
   get the address of the list and set to read mode

5. otherwise,
   fail

As far as get_list is used as a primitive instruction, it is impossible to optimize it even if A1 is always a list.

Therefore, in our compiler, about 30% of instructions are decomposed into lower level instructions. Especially, in get and unify instructions, testing data types and read/write modes are explicitly coded so that the compiler can optimize the code.

3 Optimizations

The optimizer uses a graph representation of the intermediate language. The graph consists of nodes and directed edges, and represents the control flow of the intermediate code. In general, there is one node for each intermediate instruction, and there is a directed edge from a node N_1 to a node N_2 if N_2 could immediately follow N_1 during execution.

The following two steps are applied repeatedly for the graph:

- *graph tracing*
- *graph simplification*

In the "graph tracing" step, the optimizer traces the graph in a depth-first manner and infers the possible data types and read/write modes. In the "graph simplification" step, the optimizer simplifies the graph by using information generated in the tracing step.

These two steps are repeatedly executed as long as there is a node that can be deleted.

3.1 Data types and case instruction

Before the discussion of the optimizations, data types and case instruction of the intermediate language are described.

The type of a variable is expressed by the term type(V)=T where V is a variable and T is a type, such as int, atom, nil, list, struct, and ref.

The case instruction is used to test a data type or a read/write mode. The case instruction for type testing of a variable V has a form:

```
case type(V) of {
  T1  ->  S1;
  T2  ->  S2;
    ...
  Tn  ->  Sn
}
```

where
T_i is a data type,
S_i is a statement of the intermediate language.

All T_i must be exclusive like a guarded command [2]. As for the case instruction for mode testing, a form is

```
case mode of { ... }
```

and T_i is either read or write.

3.2 Graph tracing

In this step, the graph is traced to get the information of possible data types and modes. That is, the optimizer starts from an entry node with no information, and then, step by step, traces the graph updating the information.

In fact, the information is a condition of data types and read/write modes for each edge of the graph. For example, suppose an edge has the condition type(a(1))=list. This implies the register a(1) is always a list at that edge at the execution time.

While tracing, the optimizer uses a *semantic definition table* to know the effect of each intermediate instruction. The table defines the post-condition of each instruction. For example, the post-condition of the instruction put_nil(V) is type(V)=nil that means the type of variable V will be nil after the execution of the instruction. Post-conditions of some built-in predicates are also described in the semantic definition table.

Marking of traced nodes are also performed in this step to distinguish unreachable nodes.

3.3 Graph simplification

Graph reduction rules are applied to the graph by using the information obtained in the previous inference steps. Rules for the following optimizations are described as an example.

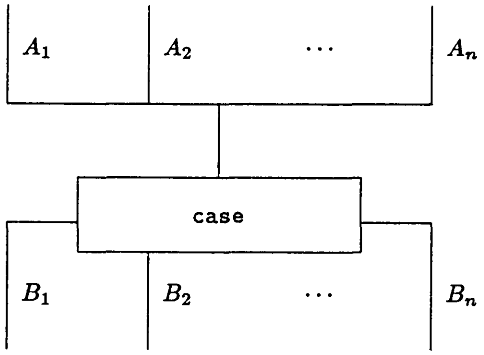
1. eliminating redundant case instructions
2. eliminating never-selected case entries
3. eliminating unreachable instructions

For the explanation of 1 and 2, suppose there is a subgraph shown in Figure 2 where A_i is a condition obtained by the inference step, and B_j is a condition to select that case entry. Optimization rules 1 and 2 are:

Rule 1 : If
$(A_1 \,|\, A_2 \,|\, \ldots \,|\, A_n) \,\&\, B_j$ is false for some j,
the entry B_j can be omitted.

Rule 2 : If

Figure 2: case node in a graph



A_i & B_j is true for some i and j
and
A_i & B_k is false for all $k \neq j$,
the edge from A_i can be redirected to B_j to skip the case instruction.

Rule 3 is very simple:

Rule 3 : If
a node is unmarked in the tracing step,
it can be deleted.

3.4 Example

The following is an example of optimization.

```
label_1 :
  case type(a(1)) of {
    ....................
    list -> goto(label_2);    <-- (a)
    ....................
  };
  ....................
label_2 :
  case type(a(1)) of {
    nil  -> goto(label_3);    <-- (b)
    list -> goto(label_4)     <-- (c)
  };
  ....................
label_3 :
  ....................
label_4 :
  ....................
```

Suppose goto statement at (a) is the only one for label_2. Then the condition at the label_2 would be type(a(1))=list. The *Rule 1* can be applied to the case instruction to delete the entry (b) because type(a(1))=nil is always false. And also, the *Rule 2* can be used because then entry (c) is the only choice. Therefore, the second case instruction can be skipped by redirecting the destination of (a) to label_4. Moreover, in the next graph simplification step, the case instruction at label_2 will be deleted by *Rule 3* because there is no goto for that label.

After these optimizations, the code will be as follows:

```
label_1 :
  case type(a(1)) of {
    ....................
    list -> goto(label_4);
    ....................
  };
  ....................
label_3 :
  ....................
label_4 :
  ....................
```

3.5 User's hints

In DEC-10 Prolog [4], input/output mode declaration is used to improve the performance. Such kind of information simplifies the control flow of the code and helps the optimizer by reducing the number of cases to be considered.

We introduced type declarations. These declarations are used to assert the data types of the arguments of a predicate.

When these declarations are added by a user, the code is considerably optimized compared to the code with no declarations.

3.6 Measurement of Optimization

Table 1 shows the improvement of the optimization for a list concatenation program. The source code is as follows:

```
concat({},L,L).
concat({X|L1},L2,{X|L3}) <- concat(L1,L2,L3).
```

In Table 1, are only considered the effects of the optimization techniques described in this paper. The results displayed in the "Opt" case have been obtained which using all the optimization techniques we have developed for our compiler (as described in [7]). In the "No opt" case, we have only omitted the optimizations obtained by the techniques described in this paper.

In case of no declarations, the performance is improved by a factor of 1.79, and when mode and type declarations are added, by a factor of 1.99.

Table 1: Improvement of the optimization for the procedure concat

concat	No declarations		Mode & type declarations	
	No opt	Opt	No opt	Opt
Number of nodes	103	95	99	51
Performance on IBM 3081K (KLIPS)	341	611	362	720

Table 2: Improvement of the optimization for other programs (number of nodes)

Number of nodes	No declarations		Mode & type declarations	
	No opt	Opt	No opt	Opt
nreverse	162	143	156	86
quick sort	260	235	254	169
N queen	327	287	317	177

Improvements for other typical benchmark programs are shown in Table 2. The number of nodes before optimization and after optimization is displayed in this table.

4 Conclusion

In this paper, optimization techniques used in a Prolog compiler are described. The optimizer is designed using a knowledge-based approach. Optimizations are performed by (1) inferring the behavior of the intermediate code and (2) simplifying the graph by using the inferred information.

This optimization improves the performance of a list concatenation program by a factor of 1.8. And when mode and type declarations are added, the improvement of the optimization is about 2.0.

Acknowledgement

I wish to thank Yasuo Asakawa and Hideaki Komatsu for their cooperation of designing and implementing the compiler. I would like to give thanks to Toshiaki Kurokawa, Tetsunosuke Fujisaki, and Peter Woon for their helpful advice.

Communication with Expert Systems

Abstract

The use of natural language to interact with an underlying expert system entails problems in both generation and interpretation that differ significantly from problems that have been addressed in interfaces to other types of systems. In this paper, we show how a natural language interface to an expert system can make use of the discourse environment to generate explanations that are tailored to an individual user's concerns and must derive facts in addition to a query when interpreting an input question. The techniques presented are applicable as well to more general problem solving, advising, and consulting systems.

1 Introduction

In the past, expert systems that communicated interactively with their users to gather data and convey results used relatively simple interfaces for interaction such as menus (e.g., MYCIN (Shortliffe 76)) or restricted forms of natural language (e.g., Prospector (Duda 78)). The development of a full-blown natural language interface for expert systems raises a number of difficult research questions. This paper explores how questions that must be addressed for natural language within the expert system environment differ from questions that have been addressed in the database environment, shows how the expert system provides an ideal environment to address problems in user modeling and natural language generation, and identifies requirements for natural language interpretation in the expert system environment.

The use of a natural language interface in place of a menu interface means that any single request for advice is embedded within an ongoing dialog which can provide information about a user's higher level problems and concerns. A natural language system can use this information to generate explanations that are tailored to an individual user's concerns. Furthermore, a user can provide information in a single natural language question or statement that would have to be requested via a sequence of questions in a menu system. This means that a natural language interface can avoid lengthy interactive sequences to gather information and more quickly provide the desired advice. To achieve this end, however, a natural language interface must be able to derive facts as well as a goal to prove from a single input question and must be able to use those facts in inferencing to avoid asking for irrelevant information.

These problems are currently being addressed in two ongoing projects at Columbia. The generation of explanations tailored to the system user is being addressed within the context of a student advising system which can provide advice about whether a student can or should take a particular course (McKeown, Wish, and Matthews 85). Natural language interpretation for expert systems is being addressed within the context of a tax advising system[2] which can provide assistance in filling out an income tax return (Datskovsky 85; Datskovsky and Ensor 86). Our examples come from a subsystem of the tax advisor, the dependency module, which can determine whether or not a user can claim another specified person on their federal tax return.

2 Comparisons with Natural Language Database Systems

In designing a natural language interface for an expert system one natural approach is to turn to the database environment for techniques where the development of natural language interfaces has been quite successful. In comparing the two environments, however, it immediately becomes apparent that there are significant differences between what is required for natural language in each case. The differences appear in the type of discourse (i.e., sequences of interaction) that will occur and in the results of parsing (i.e., the correlate of a natural language question in the underlying system).

2.1 Discourse

One main difference between the database and expert system environment is in the type of extended discourse possible with the system. The influence of the discourse situation on the meaning of an utterance and on the generation of a response has been noted by many researchers (e.g., Allen and Perrault 80; Appelt 81; Carberry 83; Cohen 78 Litman and Allen 84; McCoy 85). If a system can identify context and higher-level problems from the discourse that the user is attempting to solve through interaction with the system, it can supply a meaningful response.

In a natural language database system, a user is allowed to ask questions and the system will respond. An extended discourse, therefore, would consist of a sequence of questions. Whether or not questions in a sequence are related to each other depends upon whether the user is randomly asking questions or is gathering information to solve a problem. If the latter, then the sequence of questions may be related to the underlying problem.

For example, suppose the database contains information about course offerings in a university, as is the case in our student advising domain. If the user wants to determine which course to take next semester, s/he might ask the following sequence of questions to gather the information needed to make the decision.

1. What courses are offered next semester?
2. What are the pre-requisites?
3. Which of those courses are sophomore level

[1] The work described in this paper is partially supported by ONR grant N00014-82-K-0256 and by NSF grant IST-84-51438.

[2] The tax advisor, TAXPERT, is being developed primarily by AT&T Bell Laboratories (Ensor et. al. 86). Columbia's focus is on one module, the dependency module, and its natural language interface.

CH2345-7/86/0000/0241$01.00 © 1986 IEEE

courses?

4. What is the programming load in each course?

There are two main observations to be made. First, because the user is restricted to asking questions, the underlying problem being solved is never clearly stated. If the system wants to use that problem in deciding how to respond to a question, it must do quite a bit of guesswork in inferring the problem as well as criteria the user has for how the problem is to be satisfied. Second, since the user has responsibility for determining what information is needed to solve the problem and for producing the final solution, whether the questions in a discourse segment are connected depends upon the user. The user may alternate questions about several problems, making the task of inferring the underlying problem more difficult.

In contrast, in the expert system environment, the underlying expert system has responsibility for coming up with a solution to a given problem and thus, the natural language interface is aware of information needed to solve that problem. It can use that information to take responsibility for directing discourse towards the problem solution (see Matthews 85). Moreover, since the system must ask the user to enter information needed to do problem solving, the user has the opportunity to state the problem s/he is concerned with and any criteria s/he has for how the problem must be satisfied.

As an example, consider again the problem of deciding what course to take in a coming semester. If the underlying expert system can determine whether a student should take a course in the coming semester, we might expect extended discourse similar to that shown in Figure 1.

1) User: I'm a sophomore and just finished data structures. What courses should I take this spring?
2) System: Have you taken discrete math?
3) User: Yes.
4) System: Are there any courses you'd particularly like to take?
5) User: I'd like to take less programming courses.
6) System: I suggest you take fundamental algorithms and finite math which are both offered next semester. You should have finished both courses by the end of your sophomore year and only fundamental algorithms requires programming.

Figure 1: Expert System Discourse

This discourse segment is clearly concerned with a single purpose which is stated by the user at the beginning of the session[3]. This is the goal that the expert system must pursue and the ensuing discourse is directed at gathering information and defining criteria that are pertinent to this goal. Since the system must ask the user for information to solve the problem, the user is given the opportunity to provide additional relevant information. Even if this information is not strictly necessary for the problem-solving activity, it provides information about the user's plans and concerns and allows the system to select information in its justification which is aimed at those concerns. Thus, in the above example, the system can use the volunteered information that the user is a sophomore and wants to take less programming courses to tailor its justification to just those concerns, leaving out other potentially relevant information.

2.2 Parsing

Since the main purpose of a database system is to store and retrieve information, most database management systems provide formal query languages for searching and retrieving information from the database. In a natural language interface, a user asks a question in place of issuing a formal query. Parsing a question, then, requires producing as output the corresponding query. In producing the query, a parser must take into account the kind of search that is required and determine constraints on the search. Whether a parser uses a syntactic or semantic grammar, a top-down or bottom-up algorithm, its task remains the same: to produce the corresponding formal query.

The main purpose of an expert system is to apply large amounts of domain specific knowledge on a narrow real-world problem to arrive at a solution. Depending on how many problems it can solve, an expert system has one or more *goals* it can prove (e.g., one goal in MYCIN (Shortliffe 76) is to determine whether or not the patient has meningitus). We might expect a question, then, to indicate the goal the user wants proved.

For example, in our tax advising domain, one goal is **(claim ?x)** (i.e. to determine whether the user can claim whoever ?x refers to as a dependent). Possible questions for the domain would be of the sort "Can I claim my sister as a dependent?". If an expert system has a number of such goals, then parsing questions for this environment can be compared to parsing questions for the database environment, with instantiated goals replacing formal queries as output.

There are complications, however. In order to do problem solving, an expert system must gather information about the problem at hand. In the tax advising domain, for example, there are a number of tests that must be satisfied in order to allow a user to claim another as a dependent. The potential dependent must be a relative, a US citizen, if over 19 a student, etc. Existing expert systems either query the user for such information (e.g., MYCIN) or gather it from the environment (e.g., an online database as in ACE (Stolfo and Vesonder 82)). While a natural language interface may also have to ask questions of the user to gather the needed information, some facts may be provided in the initial question in addition to the system goal, thus reducing the number of queries the system must pose. In the question "Can I claim my sister as a dependent?", the user indicates that the potential dependent is a relative, in fact, a sister.

An interface for an expert system, therefore, must be able to produce a system goal to prove (analogous to a database query) and in addition, facts to add to working memory which the inference engine can use in the deduction process. This has no analogy in current natural language database systems but would be similar to allowing a user to both query and update the database with a single question (see Joshi 78 for a discussion of an approach to this problem).

2.3 Consequences

These differences have several consequences for natural language in the expert system environment. First, given that discourse segments revolving around an underlying problem the user wants

[3] Over a longer sequence of discourse, more than a single user purpose is likely to surface. We are concerned here with *discourse segments* which deal with a single or related set of purposes.

solved are very likely to occur, an expert system provides an ideal environment for addressing the problem of generating responses (in this case, explanations) that are tailored to the user's concerns. Second, interpretation requires the development of new techniques as opposed to simply adapting those from an existing environment. In particular, a system must have the facilities for deriving facts as well as the queried system goal from an input question. The following sections discuss ongoing work at Columbia that addresses these two issues. Since the approaches taken augment traditional expert system techniques, they are applicable to general problem solving systems as well.

3 User Modelling for Expert Systems

Given that natural language sessions with an expert system environment lend themselves to problem oriented dialog, one thrust of our work on natural language for expert systems involves the development of facilities to generate explanations that are tailored to the problems of the user. In order to generate tailored explanations, we have developed techniques to represent point of view in the underlying knowledge base to support different explanations, to derive a user goal underlying a discourse segment, and to relate the derived goal to different points of view to determine explanation content.

This work is being done within the context of an ongoing project to develop a dialogue facility for computer-aided problem solving. A student advising system is being developed which can provide information about courses and advice about whether a student can or should take a particular course. The system is currently structured as a question-answering system which invokes an underlying expert system on receiving "can" questions (e.g., "Can I take natural language this semester?") and "should" questions (e.g., "Should I take data structures?"). This production system uses its rule base to determine the advice provided (i.e., *yes* or *no*) and the trace of rule invocations is used to provide a supporting explanation of the advice.

3.1 Deriving the User Problem

If the system is to generate an explanation that addresses the higher level problem the user wants solved as well as constraints s/he has for solving the problem, the system must be able to identify what the higher level problem is. Since this is related to the user's goal in pursuing the dialogue, the large body of work on goal inference techniques (Allen and Perrault 80; Carberry 83; Litman and Allen 84) is applicable for deriving the user's goal. We have drawn heavily from Allen and Perrault's (80) work, making use of their plausible inference rules, representation of domain plans, and representation of speech acts as plans. While their work has been extremely useful, it falls short for our purposes in several ways. For example, their inferencing procedure derives a plausible goal for a user based on a single utterance, while we are interested in deriving a goal based on the current sequence of utterances[4].

Consider the discourse shown in Figure 2 below. Assuming that a database of domain plans common to the student advising domain is maintained, Allen and Perrault's techniques could be used to derive the domain goal shown following each question. But the explanation shown in Figure 2 (c) addresses not the derived goal of (c), nor any of the derived goals of the previous utterances, but instead addresses the higher level goal indicated by the derived goals of (a) and (b). The problem for responding to such goals in an explanation, then, is to be able to derive a higher level goal relating the goals of individual utterances.

a. S: I've read about the field of AI and I'm interested in learning more about it eventually. Is natural language offered next semester?
Plausible goal = take natural language
A: Yes.

b. S: Who is teaching artificial intelligence?
Plausible goal = take AI
A: Lebowitz this semester.

c. S: I haven't taken data structures yet. Should I take it this semester?
Plausible goal = take data structures
A: Yes, if you take data structures this semester, you can take AI next semester which is necessary for all later AI courses.

Figure 2: Goal Oriented Explanation

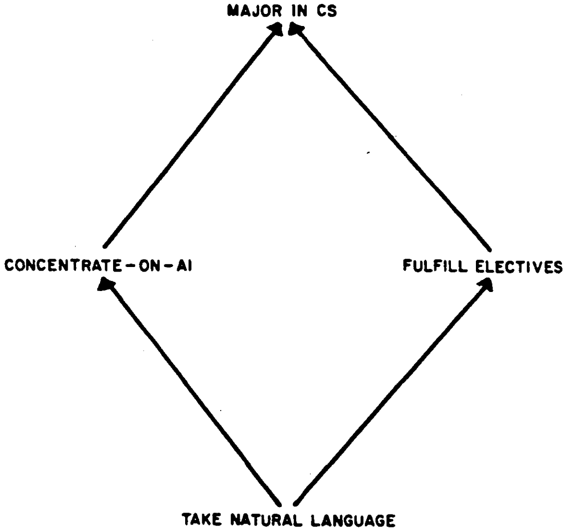
We use Allen and Perrault's rules to derive the domain goal of each individual utterance, which we term the *current goal.* We also identify a goal representing the discourse sequence which we term the *relevant goal* since it will be used to generate later explanations. Intuitively, the relevant goal is a higher level goal, if there is one, relating the goals of several utterances.

The process of determining the relevant goal involves the following steps. The current goal is first derived from the initial utterance. All higher level domain goals are then derived from the current goal using Allen and Perrault's *body-action* inference rule (i.e., if the user wants a step in the body of a plan to hold, it is plausible that s/he wants the action to hold). Any one of these is a candidate for the relevant plan. A derivation of the higher level plans for the utterance "Is natural language offered next semester?" is shown in Figure 3. Note that the action **take natural language** is a step in two separate plans, **concentrate-on-ai** and **fulfill electives**, and thus two parent paths are formed.

When the second utterance "Who is teaching artificial intelligence?" is entered, the current goal **take ai** is derived and all higher level goals derived (see Figure 4) from that using the body-action rule. The lowest level node where the two paths intersect becomes the relevant plan (**concentrate-on-ai** in this case). If the second utterance had been "When is operating systems offered?," the higher level goal **fulfill electives** would have been inferred since this is the only relation between the goals **take operating systems** and **take natural language**.

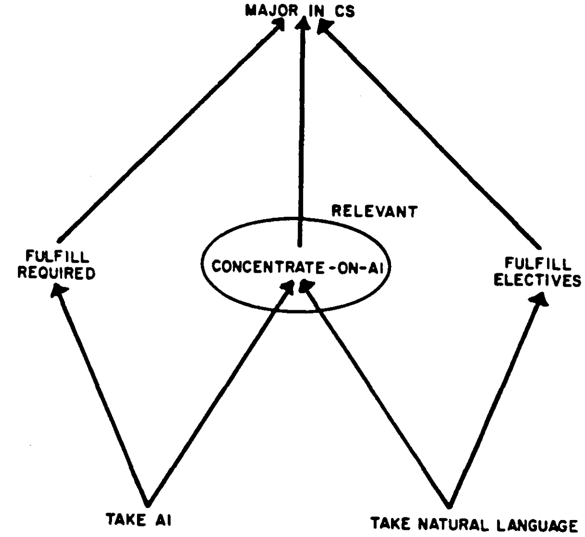
This method is essentially a search for the lowest common ancestor of the current goals of two consecutive utterances. When the third, or any subsequent utterances are encountered, the relevant goal is determined by performing the search for common ancestor using the previous relevant goal and the current goal of the new utterance.

[4] In this work, we restrict ourselves to a discourse segment that deals with a single or related set of goals. Over a longer sequence of discourse, topics may shift and the user may reveal very different goals across such boundaries. Detecting topic shifts and radical changes in goals is a difficult problem that we are not addressing.



"Is natural language offered next semester?"

Figure 3: Current and Higher Level Goals for Utterance 1



1: "Is natural language offered next semester?"
current goal = take natural language
2: "Who is teaching artificial intelligence?"
current goal = take ai
relevant goal = concentrate-on-ai

Figure 4: Relevant Goal for Utterances 1 and 2

Carberry (83) does present a method for tracking user goals over a sequence of discourse, building in the process a hierarchical model of user plans for the discourse. She uses this hierarchy and a set of focus heuristics to determine for the next incoming utterance which of several plausible plans the user could be focusing on. She does not specify which plan in the hierarchy best represents the overall discourse purpose and therefore should be addressed in succeeding explanations. Our model thus augments hers by providing this information.

3.2 How to Respond

In order to generate a response that addresses the derived relevant goal, the system must be able to identify information that is related to the goal. To do this, we are using intersecting multiple hierarchies to represent different points of view in the underlying knowledge base. The hierarchies are cross-linked by entities or processes (often courses in the student advisor domain) which can be viewed from different perspectives (and thus occur in more than one hierarchy). Hence to construct the content for explanation (c) in Figure 2 above, the system would extract information about data structures as it relates to the *AI topics* hierarchy. If the user had the goal of completing required courses as soon as possible, it would extract information from the *requirements* hierarchy. A diagram of a portion of these two hierarchies containing information for the two points of view is shown in Figure 5 below.

The partitioning of the knowledge base by intersecting hierarchies allows the generation system to distinguish between different types of information that support the same fact. From this partitioning, the system can select the portion that contains the information relevant to the current request and user goal.

After information from the appropriate hierarchy has been placed in working memory, the production system uses this information to derive the response (for explanation (c) of Figure 2, whether the user should take data structures). The trace of the reasoning is then available to provide the basis for the explanation, as is the case in traditional expert systems. Note, crucially, that information extracted from one hierarchy will allow a different set of rules to fire than will information extracted from another, thus producing different explanation content.

In constructing the explanation shown in (c) of Figure 2, the system first extracts the information shown in Figure 6 from the *AI topics* hierarchy. At this point, it also has information about what the student has already taken as well as the plan (here, *plan concentrate-on c:ai*) in working memory. After deducing that the

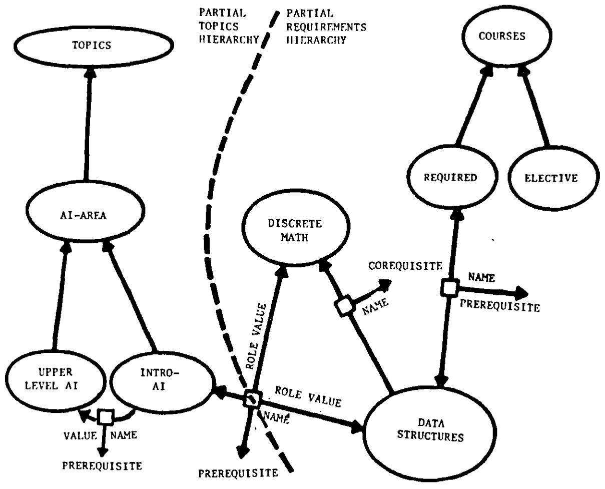


Figure 5: Representing Points of View

student *can* take these courses[5], the production system will attempt to prove that the queried action helps the user achieve his/her goals. The information shown in Figure 6, enables rule 8 to fire with **?course1** instantiated as **c:data-structures** and **?course2** instantiated as **c:intro-ai.** This rule concludes **(precursor c:data-structures c:intro-ai).** At this point rule 7 can fire, with **?future-course** instantiated as **c:intro-AI** and **?area** instantiated as **c:ai-Area,** and **?course** instantiated as **c:data-structures.** Thus, the advice is *yes* since the system can conclude **(advances-plan c:data-structures).** The instantiated rules can be used as the basis for the English explanation shown in (c) of Figure 2. Currently the inferencing component is complete, but the surface generator only partly implemented. While we can produce the content for explanation (c), we can not yet produce full English.

Note that if the user's plan had been to complete requirements, other rules indicating how the plan is advanced (such as "the course is a required course") would have fired since different information exists in working memory.

[5] Regardless of whether the user's queried action helps him/her achieve the relevant goal, if it is not permissible or will prevent the student from completing the major, the advice is always negative. Rules encoding such absolute constraints include "a course cannot be taken before its prerequisite", or "a course should not be taken if it prevents the student from completing requirements by the time s/he is a senior". Here, we assume, for convenience, that the student has already taken the prerequisites to data structures and is early enough in his/her program that s/he will be able to finish on time, and thus the absolute rules are satisfied.

Information Extracted:

```
(prerequisite c:data-structures c:intro-ai)

(superc c:intro-ai ai-area)
```

Rule 8:

```
(IF (pre-requisite ?course1 ?course2))
(THEN (precursor ?course1 ?course2)))
```

Rule 7:

```
(IF (plan concentrate-on ?area)
    (superc ?future-course ?area)
    (precursor ?future-course ?course))
(THEN (advances-plan ?course)))
```

Figure 6: Constructing Explanation Content

4 Interpretation in Expert Systems

In order to address the problem of both deriving a query (i.e., a goal to prove) as well as facts about the problem at hand from a single question, an underlying control structure for expert system inferencing that can support a natural language interface has been developed. Future work will address presuppositional analysis of noun phrases to add facts to working memory. This work is being done as part of the tax advising domain.

Since a user's question can indicate additional facts about the problem to be solved, the underlying expert system should be able to use these facts to more quickly arrive at a problem solution. If the system follows its normal problem solving chain, however, it may not make use of the given information until late in the deduction sequence in which case deduction paths that are irrelevant to the stated problem may be followed and information requested that is not needed due to the initial given information.

In order to make use of facts provided in the initial question and avoid unnecessary inferencing and system queries, an underlying control strategy is needed that can minimize queries that the system asks, maximize relevance of system queries to previous dialog, and provide information from any point in the underlying inference chain. Datskovsky developed DIRECTOR (Datskovsky and Ensor 86), embodying a control strategy for an expert system, that supports these requirements for a natural language system. She has developed three main techniques to handle these objectives: a combination of forward and backward chaining, heuristics to select which rule to fire next that minimize system queries and maximize relevance, and mechanisms to retrieve different types of information from an inference chain. DIRECTOR is currently being used as the inference engine in the dependency module of the tax advisor.

DIRECTOR's strategy for inferencing includes the following steps:

1. given all facts from the user's input, forward chain until all possible rules using existing information have fired.

2. then backward chain from the given goal using *existing* information in working memory.
3. when no further deductions can be made using existing information query the user on firing the next rule.
4. Given new input, start again at step 1.

DIRECTOR's heuristics apply at step 3. When no further rules apply using existing information, new information must be obtained from the user to continue problem solving and arrive at a solution. At this point, DIRECTOR has made maximal use of the initial given information. The rule that is fired next determines what to ask the user. As in standard expert system interfaces, the user will be queried about any facts in the left hand side of the rule not currently known by the system (i.e., not existing in working memory). Since Director wants to maximize relevance to the user's question, it chooses the rule whose left hand side contains the most known facts from the user's last input. While there is no guarantee that the solution will be found most quickly, this heuristic does guarantee maximum relevance to previous discourse and minimizes the number of queries the system will ask.

5 Conclusions

The work described here in both the tax advising domain and the student advising domain will allow for the ultimate development of full-blown natural language interfaces to expert systems. Such interfaces allow a user to receive advice more quickly, shortcutting questions the system would otherwise have had to ask, and provide the user with an explanation that addresses higher-level problems s/he is trying to solve.

Language Analysis in Not-so-Limited Domains

Paul S. Jacobs
Knowledge-Based Systems Branch
General Electric Corporate Research and Development
Schenectady, NY 12301 USA

Abstract

A fundamental problem in natural language analysis is the quantity of specialized knowledge necessary to understand language in a particular domain. Interfaces for specialized domains have proven successful, yet the amount of engineering required to develop these interfaces is often prohibitive. A design that takes advantage of general as well as specialized knowledge impacts both the portability of the natural language interface and the ease with which the interface can be extended within the domain.

Two aspects of language analysis systems are of particular importance with respect to this extensibility and adaptability. The first is the design of the lexicon, and the manner in which specialized lexical knowledge is handled. The second is in the method by which knowledge is combined during semantic interpretation. This combination, called *concretion*, uses specialized lexical knowledge to guide the semantic interpretation process.

1 Introduction

The term "natural language" still overstates the current ability of computers to communicate in human languages; yet the use of reasonable subsets of natural language in interfaces is a reality. With a great deal of development work, fairly robust and useful products that perform language analysis have been brought to market [5]. These early successes prove both the practicability of language analysis and the intensive effort required to achieve it. Surely the most important contribution of new natural language interface technology will be to minimize the individual effort needed for each interface application.

One area of application for natural language interfaces is as help facilities or interactive interpreters for operating systems [17][14][3]. There are dozens of such projects underway, and one finds published input and output from these systems most impressive. A major reason why these systems are absent from the marketplace is that they, like many AI systems, are fragile and fail to expand and adapt well. Thus a monstrous effort is required to achieve robustness.

This problem of fragility in natural language systems is addressed in a language analyzer called TRUMP (TRansportable Understanding Mechanism Package), a system designed to make use of general linguistic knowledge to serve as a natural language front end to a variety of applications. The operating system interface is one such application. Within this domain, the analyzer must be able to handle a range of input such as the following:

- (1a) Send the message to Jones.
- (1b) Send my job to the line printer.
- (2a) How can I delete a file?
- (2b) How can I delete a character?
- (3a) I want to get write permission on /tmp.
- (3b) Can you give me write permission on /tmp?
- (4a) What arguments does the command take?
- (4b) Which command gives the names of my files?

The effort required to build a robust analyzer is greatly increased by the fact that the relationship between verbs such as *send*, *delete*, *get*, *take* and *give* and their meanings is generally defined only in terms of each specialized usage. Because *delete a file* in an operating system has a meaning completely different from *delete a character*, for example, these expressions are often treated completely independently. And because *get write permission* and *give write permission* are specialized expressions, no knowledge about the verbs *give* and *get* is applied. The linguistic knowledge of the system is thus difficult to adapt because it contains knowledge of certain expressions but not knowledge *about language*.

The problem of applying this more general linguistic knowledge highlights two issues in the design of analyzers. The first is the structure of the lexicon; that is, how information about words and phrases is encoded to allow for a range of applications. The lexicon is the linguistic dictionary of the system. The second issue is the mechanism by which general interpretations are speciated or *concreted* to derive specific interpretations. For example, the verb *give* seems to refer to some general concept of *giving*; this concept is often concreted to more specific concepts such as *giving to charity*, *giving an order*, and *giving permission.* This issue is compounded by the fact that common verbs such as *giving* and *taking* are often used metaphorically to refer to events that seem to have little to do with possession, such as *kissing* ("giving a kiss") and *punching* ("taking a punch").

The method by which the TRUMP analyzer applies its linguistic knowledge facilitates the use of general knowledge even within specialized applications such as the operating system interface. For example, the system commands the use of the verb *send* well enough to understand the two senses in (1a) and (1b), and in fact makes use of some of its knowledge about the more general verb *give* in doing so. TRUMP can also deal elegantly with metaphorical examples such as (4a) and (4b); while the system uses some specialized knowledge about computer metaphors, it can apply the same metaphorical knowledge to understand both the *give* and *take* examples. This makes the analyzer more robust even within a specialized application without requiring extensive tailoring and anticipation of linguistic variants.

The next section describes how TRUMP's lexicon is designed to promote robustness and extensibility. Section 3 then describes how this lexical knowledge is concreted in the analysis process.

2 The Phrasal Lexicon Revisited

The approach to linguistic representation used in Berkeley's UNIX Consultant [17] stemmed from a variety of arguments, notably Becker's [1], which emphasized the role of quite specific phrasal knowledge in understanding language. The phrasal approach in UC was implemented in an analyzer called PHRAN [16] and a generator PHRED [7]. These programs shared a phrasal lexicon, which helped in the handling of a wide range of expressions, from "answer the door" to "Chinese restaurant" and "working directory". These expressions share the common aspect of being *nonproductive*; that is, their meaning seems not to be fully determined by their parts.

The problem with most such phrasal approaches is that they rely *too* heavily on the specialized phrasal knowledge. Expressions such as "send a message" and "send a job" were treated independently in UC, essentially as if they involved a different verb. The expression "give write permission" was independent of "get write permission". The problem seemed to be that the entries in the phrasal lexicon were consistently at a very specific level, yet it was difficult to incorporate them into more general linguistic knowledge. Much of the linguistic work on UC after PHRAN and PHRED [8][6] was devoted to making the "specialized" lexical knowledge flexible enough to cover the wealth of expressions considered. This work teases apart the phrasal knowledge of PHRAN/PHRED into a number of classes:

1. *word sequences*— Certain phrases, such as "by and large" and "let alone" are still treated simply as compound words, since there seems to be little benefit in trying to exploit their components.
2. *lexical relations*— Compound lexical items, such as "pick up" and "wipe out", are represented as lexical compounds of particular categories ("pick up" is of the *verb-particle* category). This allows these items to appear in a variety of surface forms, specifically, any surface form in which the *verb-particle* relation holds between the verb and the preposition.
3. *linguistic relations*— Linguistic relations link compounds which have syntactic as well as lexical constraints. For example, the *passive-verb-by-adjunct* relation specifies a verb in the passive voice used with an adjunct prepositional phrase with preposition "by".
4. *linguistic/conceptual relations*— Certain expressions, such as "giving permission", cannot easily be handled as exclusively linguistic constructs. The reason is that these expressions may be used with a variety of verbs in active or passive forms. This type of expression can be represented as *an abstract possession concept where the possessed is "permission"*, thus combining a class of concepts with a lexical category.
5. *conceptual relations*— Some "expressions" really do not seem to be lexical or syntactic entities at all, but distinguish different conceptual categories. For example the difference between "delete a file" and "delete a character" seems to be that the two different "deleting" concepts represent quite different subcategories of a general *deleting*, and it is possible that lexical knowledge plays no major role in distinguishing the two. In a similar fashion, "cut ones meat", and "cut ones hair" seem to express different *cut* categories, but these categories may best be distinguished by conceptual rather than lexical roles.

Entries in the lexicon combine three important types of information: (1) the lexical or syntactic knowledge required to identify an individual or compound lexical token, (2) a link between the token and an associated concept, and (3) knowledge placing that concept in the conceptual hierarchy. This is analogous to a typical dictionary, except that in the place of linguistic definitions are formal relationships among concepts known to the system.

The various types of lexical knowledge and their encoding in TRUMP will be considered below.

2.1 Basic lexical knowledge

Example: *Send* the message to Jones.

Desired effect: The verb *send* is interpreted as a verb, used similarly to *give*, with its meaning covering a variety of forms of transfers.

Lexical entry:

```
DEFINE-WORD send
    type: verb
    forms: past-tense sent
    concepts:
        sending
            (PARENT action
                    (ROLE-PLAY actor sender)
                    (ROLE-PLAY object sent-object))
            (PARENT physical-transfer-event
                    (ROLE-PLAY source sender))
        sending-transfer
            (PARENT sending)
            (PARENT transfer-event)
```

The above lexical entry provides the knowledge that the conjugated verb *send* refers to a concept *sending*, and possibly to a more specific concept *sending-transfer*. PARENT relationships place a concept as a subcategory of a more general, or parent concept. ROLE-PLAY relationships indicate correspondences between roles of more specific concepts, such as *sender*, and general roles, such as *actor*. These roles may have other information associated with them as well. Concepts such as *sending-transfer* have more than one parent, to indicate that their meaning combines that of at least two other concepts. In this case, the *transfer-event* concept represents the information that the destination of the *sending* was a *recipient*, rather than just a location. For a discussion of this form of conceptual hierarchy, see [6].

The entry for *send* provides sufficient lexical knowledge for handling expressions such as "send a file to the printer" and "send a note to Jones", as well as "send Jones a note". *Sending* is categorized as a physical transfer because the concept of *sending* "to" seems to describe a physical destination. Thus "send Jones a note" places "Jones" in the role of both *recipient* and *destination.* The details of how this is achieved depend on the intricacies of the conceptual representation, but this treatment seems to help with the problem of overly-rigid case structures pointed out by Langacker [9].

2.2 Word sequences

Example: The directory is *by and large* empty.

Desired effect: The phrase *by and large* is handled as an adverb corresponding in meaning to *mostly.*

Lexical entry:

```
DEFINE-COMPOUND by-and-large
        parts: word by, word and, word large
        type: adverb
        concept: most
```

This type of lexicon entry is relatively straightforward, because there is little flexibility in the way the expression is used and no real need to account for the role of each word. This knowledge is sufficient to account for the use of *by and large* as a synonym of *largely* or *mostly.*

2.3 Lexical relations

Example: I *sent* the message *out.*

Desired effect: The phrase *send out*, which may be expressed in a number of ways, is correctly understood as a special type of *sending.*

Lexical entry:

```
DEFINE-COMPOUND send-out
        parts: verb send, prep out
        type: verb-particle-relation
        concept:
            sending-out
                (PARENT sending)
```

The knowledge in 2.1 includes very general information about the verb *send* and the concept *sending*; more specific information is often contained in compound lexical entries, such as the one above for "send out". This knowledge specifies that *send-out* is a verb-particle compound that refers to the *sending-out* concept. This compound can appear in constructs such as "I sent the message out" and "Has the message been sent out to Jones?" The *sending-out* concept is categorized as *sending*; the difference is that this concept has no *transfer-event* subcategory so "I sent out Jones the message" does not work while "I sent out the message to Jones" does.

2.4 Linguistic relations

Example: The message *was sent out by Jones.*

Desired effect: The object of a prepositional phrase with preposition *by*, used with a passive verb, is understood as the *actor* of the action described.

Lexical entry:

```
DEFINE-COMPOUND passive-verb-with-by-adjunct
        parts: verb (voice passive), prep-phrase (prep by)
        type: verb-adjunct-relation
        concept:
            action
                (ROLE-PLAY prep-obj actor)
```

This type of lexical entry illustrates the flexibility required of the "dictionary" in a system like TRUMP. When a passive verb is used with a "by" prepositional phrase, the system can use this type of entry to understand the special role of the object of the preposition. This is dictionary-type information rather than knowledge about the syntax of English, because the prepositional phrase may appear anywhere an adverbial prepositional phrase ordinarily appears.

2.5 Linguistic/conceptual relations

Example: *Send* the message *back.*

Desired effect: The adverbial particle "back" is understood as reversing the direction of a transfer.

Lexical entry:

```
DEFINE-COMPOUND transfer-event-xxx-back
        parts: ref verb-adverbial-particle, adverb back
        type: transfer-event
        concept: return
```

The analysis of examples where lexical and conceptual knowledge combine may be complex. The meaning of the expression "send back" seems not tied to "send", but to the adverbial particle "back" when it modifies *any* transfer. Thus "send back", "sell back" "take back", and many other expressions are handled using the above linguistic/conceptual compound. The concept *return* encompasses the knowledge that the source and destination of the *transfer-event* being described are the reverse of some other *transfer-event.*

2.6 Conceptual relations

Example: *Send* Jones *the message.*

Desired effect: *Sending* here is understood as referring to communication of a message as well as a physical transfer.

Entry:

```
CONCEPT message-transfer
        (PARENT physical-transfer
                (ROLE-PLAY object message
                        (PARENT message)))
        (PARENT communication-transfer)
```

The expression "send a message" falls into the class of descriptions that are constrained by conceptual rather than lexical knowledge. Thus the information that "sending a message" describes a communication does not require any specific lexical compound. This knowledge is represented as above. This piece of knowledge specifies that a message transfer is both a physical transfer and a communication; thus "I got the message" may describe either a physical or communicative process; and "Send Jones the message" may describe the same command as "Tell Jones the message".

This section has outlined some of the basic lexical and conceptual knowledge necessary for a range of constructs. The verb phrases and particles used as examples here are complex in their behavior, and additional knowledge is required to account fully for their use. The lexical analysis presented here, however, is both sufficient for a technical domain and broad enough to apply across domains. For example, the concept of a UNIX message may be categorized as one type of message within this framework.

The discussion here has purposefully isolated the discussion of the lexicon from the process through which the lexical knowledge is used. The next section focuses on the application of lexical knowledge to the analysis of language.

3 Semantic Interpretation

Language analysis is frequently subdivided into two processes: PARSING and SEMANTIC INTERPRETATION. Parsing is the construction of a tree that accounts for each word and its syntactic role in a sentence; semantic interpretation is the derivation of a meaning representation. Some systems ignore one or the other; the assumption here is that both are necessary, and in fact, in the ideal case should interact (cf. [10]). This discussion concentrates on the derivation of meaning from lexical and linguistic relations because this is the troublesome aspect of constructing robust analyzers. While it is not difficult to construct a grammar that parses a tolerable subset of natural language inputs, it is extremely difficult to construct a system which makes tolerable sense of them.

The language analysis mechanism of TRUMP embodies three basic elements: (1) A pattern-matching or grammatical mechanism, which combines words into phrases and sentences, and instantiates linguistic relations such as those described in the previous section, (2) A mapping mechanism, which produces concepts and conceptual relations from linguistic structures, and (3) A mechanism that combines these bits and pieces of conceptual knowledge into an interpretation of the input. This mechanism, which I call CONCRETION, is the critical element of the next generation of language analyzers.

3.1 Concretion

Concretion is the process of taking abstract concepts and producing from them concepts that are more precise, or *concrete*. The motivation for this mechanism is strong in story understanding [11], because understanding a story seems to involve a continuous refinement of the major concepts into more specific categories. The following are two "story" examples:

1. Mary walked down the aisle. She picked up a can of tuna fish.
2. Bill went to the pool. He sat down in a chair.

In the first example, the concept *aisle* is being concreted to the concept of *supermarket-aisle*. Presumably, if new information had placed Mary in a church, a different kind of *aisle* would be derived. Intuitively, the term *aisle* does not seem ambiguous, rather it seems a more general concept than that which ordinarily results from a complete understanding. Similarly, the concept of a *chair* is a general one, which in the sentences above is probably concreted to *lounge-chair*. Certainly it does not refer to *electric-chair* or *desk-chair*.

The process of concretion is evident in understanding simple words and phrases in limited linguistic contexts as well. For example, the concept *cut* mentioned earlier invokes different meanings in "Mary *cut* the salami" and "Bill *cut* his hair". Similarly, the concept *deleting* may be concreted to *file-deleting* or *character-deleting*. The concept of *sending* may be concreted to *message-sending* and ultimately to *UNIX-error-message-sending*.

Most language analyzers do not really perform concretion. Unification-based systems [13][12][4] tend to refine semantic representations by adding semantic *features*, represented as variables with assignments. Some of the systems which use a KL-ONE knowledge representation [2][14] perform what is essentially concretion, but use specific interpretation rules to place concepts in more specific categories, rather than to attempt an algorithm for combining lexical and conceptual knowledge.

Concretion is important because it is the mechanism that allows general knowledge about language to apply at very specific levels of semantic interpretation. This is essential for interfaces, because it allows a core of linguistic and conceptual knowledge to be used for a variety of domains, and makes the addition of domain-specific linguistic knowledge easier. For example, knowledge about verbs such as *give* and *send* and their relation to *transfer-events* as described here applies to the UNIX domain as well as to other potential applications. It is hard to see how robustness could be achieved without this capability.

3.2 Metaphor and Indirect Meaning

Many of the examples given here emphasize the role of the interaction between general interpretations of words and more specific categories. This is not, however, the only way in which specialized constructs manifest themselves. Another common way is in metaphorical or indirect references. In fact, the "give permission" expression is an example of metaphor, because it does not seem that anything is being transferred, even in the abstract sense. Similarly, expressions such as "give a punch" and "give a kiss" are indirect descriptions of the events *punching* and *kissing*. As with the other types of specialized constructs described here, it is desirable to treat these expressions at a general level because of their apparent consistency. The idea is to have general knowledge about interpreting such expressions, even where specific lexical knowledge is used to trigger the general rule.

Looking back to examples (4) in the first section, we can see that there are many examples of verbs such as *give* and *take* in "computer talk" that refer to the input and output of operations. As with the "give a kiss" and "take a punch" expressions, it is problematic to treat these examples merely as special types of *giving* and *taking*. This is because "The command takes three arguments", even in the abstract sense, does not suggest that the command then *has* three arguments. In all these examples, what is at work is what I call a VIEW [15][8][6]. The execution of an operation is being VIEWed as a *giving* or *taking* in each expression, and the roles of input and output are VIEWed accordingly. Representing this metaphorical VIEW allows much of the same knowledge to be used in understanding numerous expressions of the same type.

In the systems interface domain, the concept of executing a system command may be a specific *execute-shell-command* concept. This concept in the conceptual hierarchy is a subcategory of the *execute-operation* concept, which may include individual functions and steps. We then have the following metaphorical knowledge:

```
(VIEW execute-operation causal-double-transfer
      (ROLE-PLAY input object-1)
      (ROLE-PLAY output object-2)
      (ROLE-PLAY user source-1)
      (ROLE-PLAY operation source-2))
```

The concept *causal-double-transfer*, which may seem somewhat arbitrary, is actually a very useful category. It represents any two *transfer-events* which are causally related. For example, *buying* and *selling*, *trading*, and *paying* may all be handled using this concept. Implicit here, but explicit in the knowledge base, is the information that *source-1* is both the *source* of the first transfer and the *recipient* of the second, while *source-2* is the *source* of the second and the *recipient* of the first.

This VIEW may be interpreted as follows: When any *execute-operation* concept is VIEWed as a *causal-double-transfer*, the *input*, *output*, *user*, and *operation* roles are VIEWed as roles of both transfers. Thus when a verb such as *give* or *take* is used to describe the *execute-operation* concept, the roles of *giving* or *taking* may be interpreted as the corresponding roles of *execute-operation*, as specified by the ROLE-PLAY relations above.

The VIEW above can be used to interpret constructs such as "the command takes three arguments", "the command gives you the file names", and even certain less common metaphors such as in " 'Echo' spits back a string." Notice that the use of *transfer-event-xxx-back*, as described in section 2, refers to a concept *return* that is entirely consistent with the concept of the *causal-double-transfer*. The expression "spits back", like "gives back", is interpreted as describing the second transfer event, where the *object* of both transfers is by default the same. The metaphorical VIEW can then be applied to result in the interpretation that the 'echo' command returns as output the same string that it takes as input.

The point of the VIEW relation here is to allow knowledge about transfers to be used to understand commands, even though the execution of these commands may not really be a transfer.

A VIEW is a powerful representational tool for encoding metaphorical relationships. A major problem with this tool, however, is that there are many metaphorical VIEWs associated with an abstract concept such as *transfer-event*, and the application of these VIEWs must be controlled. The solution to this problem is that VIEWs, like concretion, are performed only when specific lexical knowledge applies. Thus general VIEWs are triggered only by certain specialized knowledge. The algorithm through which this triggering is carried out is described in the next section.

3.3 The Interpretation Algorithm

As described earlier, the semantic interpretation process is driven by mappings from linguistic to conceptual relations, followed by the combination of these conceptual structures. The mapping process is initiated by the parser, which is not described here. For example, when the parser matches a grammatical structure which incorporates a relation between verb and indirect object, this structure is mapped into the *transfer-event* concept, with the indirect object playing the role of *recipient*. Thus " 'mv' takes two arguments" results, among other things, in the placement of the 'mv' command in the (metaphorical) role of *recipient*. The problem, then, is for the concretion mechanism to combine this knowledge with other knowledge in the system.

The details of parsing and semantic interpretation in TRUMP are omitted here; however, the following is a sketch of the iterative process that the system goes through as it scans its input and builds a conceptual interpretation:

1. *Mapping*. Apply mappings to produce new conceptual structures whenever there is a good chance that a new piece of linguistic information has changed the meaning interpretation; i. e., when each new important linguistic structure is instantiated. **Example:** In "Send Jones the message.", Mapping produces the concept *sending*, the concept *transfer-event (recipient Jones)*, and the concept *event (object message1)*.
2. *When to Concrete*. Perform concretion whenever new conceptual information might result in a more specific semantic interpretation. **Example:** Concretion of the event concept in the above sentence occurs after "send", "Jones" "message", and after the period.
3. *How to Concrete*. Produce the most specific conceptual interpretation of the input, with the appropriate roles filled, taking care to avoid conflicting interpretations. **Example:** Concretion combines *sending* with *transfer-event* to place Jones as the *recipient* of the message, and combines this with *event* to place the message in the *sent-obj* role.

The processing strategy of TRUMP is thus to apply its linguistic knowledge to parse the input, apply its lexical knowledge to produce conceptual structures, and use the conceptual hierarchy to build incrementally as specific an interpretation as is applicable. This approach allows the system to make maximal use of lexical knowledge of the various types described in section 2.

4 State of Implementation

The TRUMP parser and semantic interpreter are fully implemented and use the lexicon and concretion mechanism described here. The extensibility of the system is suggested by the fact that, once a set of linguistic constructs and their related conceptual knowledge are encoded, it becomes relatively easy to analyze many similar constructs. The catch to this method of handling specialized knowledge is that each specialized construct requires the proper encoding of certain general knowledge as well, and the improper treatment of this high-level knowledge may lead to the "house of cards" effect; that is, a modification at the high level negatively influences constructs that were previously handled correctly. Once the kinks are removed from the abstract knowledge, however, extension becomes easy. For example, the high-level knowledge about *transfer-events* has sufficed well in a variety of domains because it was carefully thought out beforehand.

The richness of lexical knowledge in TRUMP is behind two features of the system not described here. One is the ability to share a lexicon and grammar with a generator that produces natural language output. The development of TRUMP has followed from a knowledge representation framework called Ace [8] and a generator called KING [6], and the interface is thus specifically designed for both input and output capabilities. A second advantage of the system is the ease with which lexical knowledge is added "on the fly"; TRUMP includes a component that adds new information to the lexicon based on the dialogue with the user.

This system is being applied to a variety of domains, mostly dealing with natural language interactions about computers. In these domains, the benefit comes not only from the general knowledge about language, but also from knowledge about "computerese" that prevails regardless of the computer system.

5 Conclusion

The interaction of general and specialized knowledge is critical for language analysis, even in domains that are apparently constrained. The proper handling of general knowledge about language is essential both for portability and for the addition of new constructs within a given domain.

Two aspects of language analyzers are particularly useful in dealing with this interaction. The first is a lexicon that allows a variety of lexical collocations. The second is a semantic interpretation mechanism that facilitates concretion, the process of combining conceptual and metaphorical knowledge at various levels to produce a refined interpretation.

Providing Expert Systems with Integrated Natural Language and Graphical Interfaces

Philip J. Hayes
Carnegie Group Inc.
650 Commerce Court at Station Square
Pittsburgh, PA 15219, USA

Abstract

Both natural language and graphical interfaces have been advanced as the best way to provide intelligent and user-friendly interfaces to knowledge-based systems. However, neither approach is sufficient on its own. This paper outlines the design[1] of a generic set of interface facilities that integrate the two modalities and allow each to contribute its relative strengths to the interface as a whole. A more detailed account is given of how the framework interprets in an integrated manner references to entities of the underlying application. The interpretation is done with respect to both the dialogue and visual contexts and for both natural language phrases and pointing events. As the detailed account of reference processing makes clear, the interface framework described in this paper depends in an essential way on the fact that the underlying application is knowledge-based.

1. Introduction

Through the use of AI techniques, intelligent knowledge-based systems are now helping people get their job done in an enormous variety of applications, including systems from manufacturing, medical, financial, and many other domains. However, the interfaces through which people interact with these expert systems often do not display a similar level of sophistication, either in intelligence or in their ability to interact (from a purely human-factors point of view). This has meant that the users have not been able to derive the maximum advantage from the expert systems, or in the worse cases, not derived any benefit at all. This is particularly true in those knowledge-based systems in which the initiative and responsibility for problem solving is divided between user and system. For such mixed initative systems, poor interfaces mean that the user cannot understand enough about what the system knows and is doing, and is also unable effectively to communicate his goals to the system. We believe that this mismatch of capability between interface and application is a major hindrance to the wider acceptance of knowledge-based systems.

The work described here is the beginning of an effort to remedy that mismatch. The work starts from the following assumptions about desirable characteristics of interfaces to mixed-initiative knowledge-based systems:

- *The interfaces should use graphical displays to convey information whenever appropriate.* Well-designed graphical output can give the user a much clearer overall picture of the system's view of the world than a scrolled dialogue (even a natural language dialogue). For instance, if the system is concerned with scheduling machining orders through various machines on a factory floor, then a graphical depiction of the machines, their layout, the current and planned location of orders, etc. would give the user a much clearer overall picture of the current state of planning than a textual description of the same information ever could.
- *The user should be able to access and modify the system's data and knowledge through direct manipulation of the graphical display whenever possible.* For instance, a user might be able to obtain and edit a table giving further information about a specific machine (its capacity, scheduled down-times, etc.) by clicking on the icon the scheduling system uses to represent it. Direct manipulation of this kind is often more efficient and usually easier to learn than any other kind of interaction.
- *The user should also be able to access and modify data and knowledge through a natural language dialogue.* Not all questions or updates can conveniently be made by direct manipulation. For instance, it might be quite hard to devise a piece of direct manipulation that allowed the user to find out if all scheduled orders could still be processed with any three (out of the current five) milling machines. Yet, as the previous sentence shows, it is straightforward to pose that question in natural language.
- *The natural language dialogue should integrate as closely as possible with the graphical display.* In particular, the resolution of anaphoric references should take account of what is on the screen. For instance, if the user says "the grinding machine" and only one is visible on the screen, then that should be interpreted as the one the user means, even if the system knows about four other milling machines related to the topic under discussion. Also the user should be able to point at the representation of an object on the screen instead of giving a natural language description of it. It may be a lot faster to point at an icon than to type "grinding machine number 4".

[1] Nothing in this document should be interpreted as a committment to nor an announcement of specific product enhancements by Carnegie Group Inc.

2. Overall Interaction Model

With these assumptions in mind, we are investigating generic support for a class of user interfaces suitable for a wide variety of knowledge-based applications. Individual interfaces built using this support would have two conceptually distinct, but highly integrated parts:

- **graphical display of the application domain**: The interface continuously displays a two dimensional view of the knowledge-based application's world. The view will not be fixed, but will be variable in the amount of detail shown and whether all or just a part of the world is shown. If specific entities in the world have internal structure, that may be displayed in overlaying windows. The main display may itself be split into windows for simultaneously displaying different parts of the world. Aids to locate a detailed view within its larger, containing scope will also be provided. The user is always free to alter the view of the world along any of the available dimensions. However, the system may also alter the display based on the dialogue in the dialogue window.
- **dialogue window**: The interface will also maintain a single thread dialogue with the user in natural language. The user's side of the dialogue may be conducted either through typed or spoken input. In either case, the complete dialogue thread will appear in a scrollable dialogue window. The user may refer to entities that are visible on the screen by pointing at them instead of speaking or typing out descriptions. Output from the application may also involve references or modifications to the display. In both cases, display references will appear explicitly in the dialogue transcript.

The overall feel of the interface is intended to be one where the user's main picture of what the application is doing and what information it is dealing with is provided by the display of the application's world. Navigation (in terms of both location and level of detail) around this world will be an important way for the user to obtain information that is not immediately visible. The dialogue window allows the user to ask for information that is inconvenient (or impossible) to obtain through navigation around the visual world, to make requests that he finds more natural in natural language, to discuss the world at a meta-level, etc.. We believe an interface of this kind will be extremely natural and productive to use. The style of interaction is analogous to that between two people poring over a diagram or having a discussion while writing on a blackboard - a very effective and natural form of communication. Moreover, unlike a paper diagram or blackboard, the application world display is active and can modify itself under control of the user or the interface/application system. This allows a very high bandwidth of communication and hence a highly productive interaction.

This kind of interface is highly appropriate to situations where spatial relationships between domain entities and movements of the entities through the space are an important aspect of the application's world. Factory job-shop scheduling is an example of such a domain; the paths from machine to machine and the distribution of orders around the shop are important features of the domain for the scheduling task. In addition, work by Negroponte [8] and the general success of the desktop metaphor in user interface design [10, 11] have shown that distributing information spatially is a useful information access aid, even if the spatial distribution does not correspond to any actual spatial relationships. Thus, there is every chance that the kind of interface envisaged here will also be useful in domains without a specific spatial orientation, such as a personnel database. This kind of information distribution is also useful for non-spatial information in worlds with a high degree of spatial information. For instance, in a factory scheduling application, it might be convenient for the user if he could find out about the scheduled down-time for a particular machine by "zooming in" on the icon that normally represents the machine. Such zooming could overlay the icon with a window in which scheduled down-time and other detailed information about that machine was displayed in a tabular fashion.

The dialogue component of the interface is intended to allow the user to access information (or issue commands) that is inconvenient to get at by navigation through the domain world display. For instance, in a factory scheduling system, the user might want to know whether one machine could take over the orders scheduled for another (perhaps because the first one had broken down). Since this question involves a dynamically constructed relationship between two machines, there is no obvious "place" to find it in the domain world. Instead, the dialogue facilities would allow the user to say (or type) something like "Can this machine *<point at one machine>* take over the orders scheduled for that one *<point at other machine>*". The answer could be displayed in text in the dialogue transcript, or as an overlay window on the graphical display, or as both. Note how intimately the displayed world and the dialogue interact to specify this information retrieval. The display is acting analogously to the physical context immediately surrounding human participants in a dialogue, i.e. something that can be referred to by abbreviated language or gesture in the knowledge that the other participant in the dialogue can see the same thing as you.

To support the construction of interfaces of this kind, we have designed a set of generic interface facilities for knowledge-based systems. The design views the facilities as extensions to the Knowledge Craft^{TM} and Language Craft ^{TM} products of Carnegie Group. Knowledge Craft is a knowledge engineering tool based on a schema-oriented knowledge representation language, called CRL^{TM}, and incorporating OPS-5 and Prolog inference engines and a powerful graphics system. Language Craft [7] is a tool system for building natural language interfaces based on case frame parsing techniques. These techniques make Language Craft a very robust language analyser, as is appropriate to deal with the user errors that inevitably arise with interactive dialogue. The specific capabilities that the design adds to these existing systems include:

- **representation and display of domain world**: This is a generic facility for mapping the world of objects, events, and states of a knowledge-based system onto a graphical display which could be browsed by the interface user at varying levels of detail. The facility is an extension to Knowledge Craft, and its existing powerful graphics system.

- **natural language analysis:** The dialogue window needs to be supported by a robust natural language analysis system of the type provided by Language Craft. This component of the design would extend Language Craft by integrating it more fully with Knowledge Craft. This will allow the natural language analysis to communicate properly with the underlying knowledge-based system and the world display system.
- **dialogue management:** The facilities in this area allow natural language input to the system to be interpreted with respect to the context built up during interaction in the dialogue window and the visual context of the world display. In addition to the interpretation of ellipsis already provided by Language Craft, the design would support a wide variety of anaphoric reference with respect to both kinds of context through an extension to Language Craft. The dialogue context can be altered by things that the user or system say and will be represented graphically in the domain world display. The display will be managed so that the complete dialogue context is always displayed.
- **integration of natural language and speech input:** While natural language is a highly expressive and natural form of input, it can be tedious to input via a keyboard. Spoken input is much more convenient. Our design integrates the natural language interpretation capability of the interface system with a speech recognition device. In other words, Language Craft will derive the meaning of the word sequences reported by the speech recognition device. Since speech recognition is inherently error-prone, Language Craft will be used to improve the overall recognition rate of the speech device. We will do this by making all the various word hypotheses considered by the speech device (with their associated certainties) available to Language Craft and let it make the final decision using its syntactic and semantic knowledge.
- **integration of natural language and pointing input:** Given the explicit graphical representation of context, and natural language input capability, particularly in its spoken form, it will be natural for the user to mix natural language and pointing input (e.g. "move that *<point>* from here *<point>* to there *<point>*"). Our design modifies Language Craft to deal with such pointing input.

Space does not permit us to go into detail on all these facilities. Instead in the remainder of this paper, we will focus on the way the design allows the user to refer to objects from the application domain. This will involve descriptions of the underlying natural language facilities, the way they handle anaphoric reference, and the way in which graphical pointing events can be substituted for ordinary linguistic anaphors. Before proceeding, we should reemphasize that the descriptions that follow refer to the design of a system, rather than one that is fully implemented.

3. Interpreting References to Application Domain Entities

When people engage in a dialogue, they share a context of past events, objects and events mentioned in the conversation, mutual assumptions about each other's goals and motivations, etc.. This shared context allows them to communicate intelligently with each other: by resolving pronouns or other abbreviated forms of reference into objects just mentioned, by completing elliptical questions by analogy to previous utterances, by recognizing that a statement is inconsistent with the speaker's assumed goals or beliefs and (internally) correcting it so it is consistent, etc.. For a machine to appear to communicate intelligently with a person, it needs to share context in a similar kind of way. Moreover, an ability to deal with anaphora and ellipsis allows the natural language input to be much more terse. It is much quicker to say or type "it" or "the machine" than always to have to say "grinding machine number 4".

The dialogue management facilities of the interface framework we are building are currently restricted to support for anaphora and reformulation ellipsis, though we hope in the future also to add more sophisticated facilities driven by a representation of the user's goals. This paper focuses on the way we deal with anaphora, i.e. the way we use context to interpret abbreviated descriptions of domain entities. Given the integration of graphical and natural language modalities in our interface model, we need to use two kinds of context to resolve anaphoric references:

- **dialogue context:** the set of entities mentioned or implied by the recent dialogue.
- **visual context:** the set of entities visible on the screen, plus perhaps other entities closely associated with them.

Moreover, the two modalities allow two kinds of anaphoric reference:

- standard natural language anaphora (pronouns, definite noun phrases, etc.)
- reference to objects by pointing at their images on the screen. Naturally, this kind of reference is resolved only against (a localized subset of) the visual context.

The following two subsections describe how each of these kinds of anaphor are handled by our design for interface facilities.

3.1. Natural language anaphora

In this section, we turn to the anaphoric interpretation capabilities we have designed as an extension to Language Craft. There is already a substantial body of work on the resolution of anaphora with respect to dialogue context (e.g. [4, 5, 6, 9]). Our approach does not represent a significant departure from this tradition. It uses techniques developed in the previous work to produce an anaphora capability suitable for restricted domain interfaces, rather than one that is completely general. In particular, we expect to make maximum use of the restricted domain semantics and not to use any techniques that would lead to noticeable (by the interface user) processing times. The novel aspects of our approach relate to the addition of visual context (though see [1, 5]).

Many current treatments of dialogue anaphora (e.g. [5, 9]) use the concept of a set of entities that are in the immediate *focus* of the context, plus others that are outside.the immediate focus, but may become focussed. The focus may change through nesting (subtopics or digressions) or by moving to related topics. Entities in the immediate focus may be referred to by pronouns. Entities that are outside the immediate focus may be referred to by abbreviated descriptions. We have adopted this kind of approach. The focus of the dialogue context is represented as a set of domain world entities. These entities may be referenced by pronouns or other abbreviated descriptions. There is a second set of entities, those related to the focussed entities by one of a (domain-specific) class of relationships, that may also be referenced by definite noun phrases, but not by pronouns. These entities form the *potential focus* [9]. Referring to an entity in the potential focus adds it the focus.

We can see how this works in the following dialogue fragment with a hypothetical factory scheduling system:

> User*: Are any grinding machines utilized less than 80%?*
> System*: Yes, grinding machine 4 has only 65% utilization.*
> User*: Has it had unscheduled downtime since Monday?*
> System*: No.*
> User*: Preventive maintenance?*
> System*: No. It is not scheduled until Friday.*
> User*: Who is the maintainer?*
> System*: Albert Smith.*
> User*: Ask him to do the preventive maintenance today.*

Here the grinding machine mentioned by the system becomes part of the focus and is referred to via the pronoun "it" by the user (and the system) in the question about utilization. The next question relies on Language Craft's current ability to handle reformulation ellipsis [3]. The system uses the context of the previous question to interpret the user's input as though he had said "Has it had preventive maintenance since Monday?". The user then goes on to refer to an entity that has not been mentioned in the dialogue so far, but is in the potential focus, viz. the maintainer of grinding machine 4, by the incomplete description "the maintainer" (the system would presumably know about lots of maintainers). There is only one maintainer in the potential focus, so the anaphoric noun phrase can be resolved correctly and unambiguously. Mentioning the maintainer entity adds it to the focus, so that the "him" in the next input can be interpreted correctly.

Integration between Language Craft and Knowledge Craft is important for the implementation of this anaphora mechanism. We represent the dialogue focus as a set of domain entities represented as Knowledge Craft schemas. The process of resolving an anaphoric referent against such a context involves integrating the constraints provided by the pronoun (e.g. "he" is a male person, "there" is a location) or noun phrase ("maintainer" is an entity in a maintaining relationship with some other entity) with the constraints provided by sentential context (e.g. in "ask him to do the preventive maintenance today", "him" must be an entity that can be asked to do maintence - an maintenance employee), and then finding items in the context that match the integrated description. Both the integration and the matching require the support of an inheritance mechanism which Knowledge Craft provides. For instance, in the above example, "him" has the constraint of being a male person inherent in the pronoun, and the constraint of being a maintenance employee from the sentential context. These two constraints are consistent since a maintenance employee ISA person and may be either gender. So the integrated description is a male maintenance employee. In the dialogue given above, this description would match (again through an inheritance process) with the focussed entity representing Albert Smith.

Knowledge Craft inheritance is also useful in specifying the relationships which define the potential focus (e.g. the relationship between a machine and its maintainer). Knowledge Craft relations are represented by user definable and modifiable schemas. This makes it convenient to attach such information to the relations.

The kind of interface we are considering here is unusual for natural language in that it has a representation of the world separate from the dialogue itself. This allows us to provide some interesting capabilities that have only been touched on in earlier work, in particular the work by Grosz [5] on task-oriented dialogues and Bolt [1] on an integrated natural language/graphical interface. First, we allow the user to refer to any entity visible in the world display by the minimum description necessary to distinguish it. For instance, if only one milling machine is shown on the display at any given time, the user would be able to refer to it by "the milling machine" rather than by typing its full name. The entities in the world display thus play a similar role to the potential focus and are treated in the same way by the anaphora resolution mechanism. In other words, the system will look for referents for definite noun phrase descriptions both among the entities in the potential focus and among the entities currently displayed on the screen.

The second useful capability opened up by the existence of the world display is an explicit representation of the dialogue focus through highlighting on the display. This allows the user to be clear at all times on what is the system's focus of attention, and helps prevent the kind of reference problems that could arise if the user thinks he has made a shift of focus, but the system fails to pick up on it. An even more intriguing possibility is to allow the user to edit the dialogue context explicitly. In this way, he could make up for any deficiencies in the system's focus tracking. He could also, as a part of browsing through the world display, explicitly set up the dialogue focus. For instance, if he set the focus of attention to include only a particular machine, then on the next natural language input, he would be able to refer to that machine by "it". The human factors of such an interface feature have never been examined and are hard to predict in advance. We, therefore, plan to determine its usefulness empirically.

In order to maintain a visual representation of the dialogue focus, the interface system will, when necessary, adjust the domain display in such a way that the dialogue focus remains a subset of the visual context. For instance, in the above dialogue example, when the user starts to ask about details of the grinding machine (utilization, unscheduled downtime, preventive maintenance, maintainer), the display of the machine (which we will assume was a named icon) would be expanded to or overlayed by a display of its attributes. The attributes that the user focusses on would be highlighted appropriately. Again, this is breaking largely unexplored ground from a human factors point of view. And we anticipate changes to the design based on experience with an implementation. The obvious danger is that the user might become confused or annoyed by changes to the display that he did not request directly. In addition, there is the potential for overly cluttered displays if this mechanism only ever displays additional entities and never removes any. The issue of when a defocussed entity can safely be removed from the display is a tricky one, involving unresolved research issues in dialogue management. Our current design does not address it.

3.2. Anaphora by pointing

One of the most interesting capabilities opened up by the kind of interface we are discussing is intermixing natural language input with pointing input. This would allow the user of a factory scheduling system to input, for instance, "Can this machine *<point at one machine>* take over the orders scheduled for that one *<point at other machine>*", where the pointing was done to the world display. We will call this kind of pointing *natural language pointing* and treat it as a kind of anaphoric reference. Natural language pointing is extremely useful in combination with speech input, allowing a very efficient combination of gesture and speech - the most natural way for people to communicate. Its effectiveness in an interface has already been demonstrated by work at MIT [1, 8]. It is somewhat less attractive for typed input because of the overhead involved in moving the hand from keyboard to pointing device and back again. However, work on the Scholar project [2] has shown that pointing can be used effectively with typed input in the context of maps in geography lessons.

Natural language pointing can be more efficient than speech alone because it is often faster to point at something than to identify it verbally (particularly when it is not in the immediate focus of the dialogue and so cannot be referred to by a pronoun). Moreover, pointing is a more direct form of identification than speech, so that its processing is likely to be faster and less error prone, considerably reducing the need for clarification dialogues, and hence enhancing communication efficiency still further. There are even some circumstances where pointing can communicate information that is very difficult to communicate through speech. For instance, pointing at a position on a map is very much easier and probably more accurate than trying to give the same information by speaking map coordinates into the system. In such circumstances, natural language pointing would also be convenient to use with typed input, particularly if all the pointing can be done after the entire sentence has been entered.

Though there are numerous advantages to natural language pointing, there are several issues which make its inclusion in an interface less than straightforward. In particular, it is necessary to:

- determine when pointing events are natural language pointing events;
- determine where the entities pointed at fit within the overall interpretation of the natural language input;
- identify which entity was actually pointed to (an issue when the visual representations of entities are nested within each other on the screen).

The difficulty of identifying pointing events as natural language pointing events stems both from ambiguity inherent in the use of the pointing device and in ambiguity in natural language as to whether a given phrase implies that a natural language pointing event will occur. In the kind of interface we are discussing, the pointing device will have other uses besides natural language pointing. In particular, it will figure prominently in the interface that allows the user to navigate around the world display. Pointing events are then potentially ambiguous between natural language pointing and these other uses of pointing. There are several potential solutions, none of which seems ideal:

- Make natural language pointing events identifiably different from others, for instance, by dedicating one mouse button (assuming there are several) to natural language pointing. This has the advantage of being clear, but the disadvantages of being fragile and difficult to learn (use of the wrong mouse button could produce highly unexpected and unintuitive results), and of reducing the options available for the world navigation interface.
- Overload some kind of neutral pointing event from the navigation interface - one that does some kind of selection without causing any specific action to happen. This has the same disadvantages in being fragile and hard to learn, and has the additional disadvantage of not being totally unambiguous, but the constraints it places on the navigation interface are different.
- Poll for the position of the pointing device when a deictic phrase is used. This avoids the disadvantages of the other alternatives, but runs into serious trouble because it is not always possible to identify deictic references in natural language just from the words involved. For instance, "there" may indicate a deictic reference or be a reference to an item in the dialogue context ("Order 17 is in the queue for ginding machine 4". "How long has it been *there*?"). It also reduces the freedom of the user in terms of the relative ordering of pointing and the deictic reference.
- Assume that all pointing events during (or close to, see below) natural language input are natural language pointing events. This has the advantages of simplicity, robustness, and lack of ambiguity. Its main disadvantage is making world navigation impossible during natural language input (even during a pause for thought during type in).

Our design currently calls for us to use the final alternative, but we regard the choice as an empirical matter and expect to experiment with several possibilities.

Once we have determined that a pointing event is a natural language pointing event, there is still the problem of matching it up with a phrase or hole in the natural language input. The co-occurrence of words and pointing events is useful information here, but does not give the whole story. All of the following examples and many other possibilities are plausible:

Can this machine <point at one machine> take over the orders
scheduled for that one <point at other machine>

Can this <point at one machine> machine take over the orders
scheduled for that <point at other machine> one

Can this machine take over the orders
scheduled for that one <point at one machine>
<point at other machine>

The last of these is most likely in a typed input situation where the user wishes to cut down on the overhead of moving between keyboard and pointing device. The only real invariant seems to be that the natural language pointing events will occur in the same order as the phrases (or holes[2]) in the natural language input to which they correspond. Moreover, the pointing events usually come during or immediately before or after the corresponding phrase. This latter fact means that information on the start and end time of words in the natural language input is important for the analysis of natural language pointing input. This information is naturally available for speech input, and our design calls for us to extend Language Craft to make it available for typed input.

There are thus two kinds of indication, neither of them conclusive, that a phrase in the natural language input corresponds to a natural language pointing event: the temporal co-occurrence of the phrase with the pointing event, and the actual form of the phrase itself. For instance, phrases with a demonstrative determiner ("this machine") are more likely to correspond to natural language pointing than phrases with a definite determiner ("the machine"). Once a candidate correspondence has been established between a phrase and a pointing event, it must be verified that the two are compatible. This process is very similar to anaphoric reference determination, except that the candidate referent is known in advance. It involves determining the constraints on the candidate phrase both instrinsically ("this machine" must be a machine) and from the sentential context (in the above examples "that one" must be a machine since orders are scheduled for it), and then checking if the entity pointed at met those constraints.

Since there is no conclusive way to determine which phrases in the natural language input correspond to pointing events, we have designed the following heuristic procedure for finding the correspondence.

1. list in left to right order all schemas representing phrases in the input that could potentially correspond to natural language pointing events;
2. list in left to right order all natural language pointing events;
3. form all lists of pairings between schemas and pointing events, such that:
    a. the left to right ordering is preserved for both schemas and pointing events;
    b. paired schemas and pointing events are compatible in the way described above;
4. if more than one list of pairings remains, choose those with the maximum number of schemas that correspond to phrases that are linguistically likely to be deictic (including all pronouns and noun phrases with demonstrative determiners);
5. if more than one list of pairings still remains, choose those with the shortest time mismatch between the pointing events and the phrases corresponding to the schemas;
6. if there is still more than one, ask the user to decide.

In the example above, little of the complexity of this algorithm is needed. There are only two pointing events and three schemas (corresponding to "this machine", "the orders", and "that one"), and hence there are three possible list of pairings, of which only the correct one satisfies all the constraints. More complex sentences could, however, require all the steps in the algorithm to find the correct pairings.

The final major issue in dealing with natural language pointing is that there can even be uncertainy as to which entity is being pointed to. In particular, if one entity has some kind of containment or subset relation with another, then the graphical representation of the contained entity may be nested within the graphical representation of the containing entity, so that pointing at the contained entity would be ambiguous between the two. For instance, an icon representing an individual machine may be graphically contained within an area which represents the factory shop of which it is a part, so that pointing at the machine icon might mean the machine or the shop. Sometimes, the corresponding natural language phrase or its sentential context can disambiguate. For instance, if the corresponding phrase was "this machine", there would be no confusion. If such disambiguation is impossible, then the system must query the user to resolve the issue. Modifying the above algorithm to use this approach means creating, for each potentially ambiguous natural language pointing event, copies of the pairing lists which differ only in the entity referred to by the ambiguous pointing event. There would be as many copies as there were alternative interpretations.

A final complication arises if the user desires to identify a group of objects or an area of the display through natural language pointing. For instance, he might want to ask about the average utilization of a group of machines. Conventional graphics applications provide ways of making group selections by incremental selection or selection by (usually rectangular) area. A similar approach could be used for natural language pointing, but it would eliminate some of the naturalness that we hope to achieve. Instead, our design allows freehand area designation by closed curves. In addition to being natural, this allows arbitrarily shaped areas to be designated as well

[2] Our current design requires some form of deictic expression and does not allow the user just to leave a gap in the input corresponding to the pointing event as in "Can <point at one machine> take over the orders scheduled for <point at other machine>". The semantic caseframe approach used by Language Craft is already quite capable of skipping over gaps and producing a partial analysis of the input. The additional ability required to match up gaps with natural language pointing would be for Language Craft explicitly to recognize that there is a gap in the input and to determine where in the input that gap is.

as being able to select groups of individual entities. As in ordinary natural language pointing, all such line drawing during or temporally close to a natural language input will be interpreted as a natural language pointing event corresponding to some deictic phrase in the input.

4. Conclusion

Although natural language is an important component of intelligent interfaces to knowledge-based systems, it is not in general adequate as an interface in and of itself. Modern AI workstations provide sophisticated graphical capabilities, which can communicate many kinds of information much better than natural language dialogue. Moreover, direct manipulation of graphical interfaces is often a convenient, natural, and efficient way for the user to access and update a system's information.

Fortunately, it is not necessary to make a either/or choice between natural language and graphical interaction. This paper has outlined a set of generic facilities for constructing combined graphical/natural language interfaces for a broad class knowledge-based systems.

We discussed in greater detail the aspects of those facilities that deal with the interpretation of references, both natural language and pointing, to entities in the application's world. In particular, we showed how standard dialogue anaphora resolution techniques can be integrated with the presence of a visual context and with pointing events into that visual context.

Unless interfaces to knowledge-based systems display a level of intelligence similar to the underlying systems themselves and make full use of the capabilities of the available I/O hardware, then the systems as a whole will fall far short of their potential impact. We believe that the way to construct interfaces that satisfy these goals lies in the direction we have outlined in this paper, and that this direction represents the future of user interfaces to knowledge-based systems.

Abstract

This paper is a brief description of TEAM, a project whose goal was to design an experimental natural-language interface that could be transported to existing database systems by people who already possessed expertise in their use. In presenting this overview, we have concentrated on those design aspects that were most constrained by the requirements of transportability.

1 A Functional Description

A natural-language interface (NLI) to a computer database provides users with the capability of obtaining information stored in the database by querying the system in a natural language (e.g., English). The use of natural languages as a means of communication with computer systems allows users to frame a question or a statement in the way they think about the information being discussed, thereby freeing them from the need to know how the computer stores or processes the information. However, most existing NLI systems have been designed specifically to treat queries that are constrained in three ways: (1) they concern a single application domain; (2) they pertain to information in a single database; (3) they handle only a single task, namely, database query.[1] Constructing a system for a new domain or database requires a new effort almost equal to the original one in magnitude.

Transportable NLIs that can easily be adapted to new domains or databases are potentially much more useful than domain- or database-specific systems. However, because many of the techniques already developed for custom-built systems preclude automatic adaptation of the systems to new domains, the construction of transportable systems poses a number of technical and theoretical problems. In describing the transportable NLI system called TEAM (Transportable English database Access Medium), that was the focus and objective of a four-year project, this article emphasizes those choices in system design imposed by the requirement of transportability.[2] For some problems, the design decisions incorporated in TEAM are generally applicable to a wider range of natural-language processing systems; for others, we were forced to take a more limited approach.

1.1 Transportability

One of the major challenges faced in building NLIs is to provide the information needed by the system to bridge the gap between the way the user thinks about the domain of discourse and the way the computer handles the information it possesses about the domain. Existing databases employ different representational conventions, many of which favor storage efficiency over perspicuity. For example, one might encode geographic information about mountain peaks in Switzerland as part of a file of information about the mountain peaks of the world, identifying them with a "SWZ" in a COUNTRY field, or using a SWISS? feature field for which a "Y" indicates that a peak is in Switzerland and an "N" indicates it is not. Or the information might reside in a separate file on Switzerland, or one on Swiss mountain peaks. The kinds of queries a user might pose—for example "What is the highest Swiss peak?" "Are there any peaks in Switzerland higher than Mt. Whitney?" "Where is the Jungfrau?"—are equally appropriate for all the aforementioned encodings and the inputs to the NLI (an English query) remain unchanged. The output (commands to a database system), however, will be quite different. One of the main functions of the NLI is to make the necessary transformations, thus insulating the user from the particularities of the database structure.

To provide this insulation and to bridge the gap between the user's view and the system's structures requires a combination of domain-specific and general information. In particular, the system must have a model of the subject matter of the application domain. Included in this model will be information about the objects in the domain, their properties and relationships, and the words and phrases used to refer to each. Finally, the system must know the connection between entities in that model and the information in the database. A major challenge in constructing transportable systems is to provide a means for easy acquisition of domain-specific information.

TEAM is one of several recent attempts to build transportable systems (some of which are described elsewhere in this issue.) Different approaches to transportable systems reflect diverse conceptions of the kinds of skills and knowledge that might be re-

This paper has previously appeared in the quarterly newsletter of the IEEE Computer Society Technical Committee on Database Engineering, vol. 8, no. 3.

The work reported here was supported by the Defense Advanced Research Projects Agency under Contracts MDA903-83-C-0027 and DACA76-85-C-0004.

[1] This constraint is more limiting in many ways than the other two. For example, queries are typically treated largely in isolation; very few features of dialogue are handled. Since this remains a constraint in TEAM it will not be discussed further in this article.

[2] Space limitations have compelled us to omit many of the specific problems faced in this research; for a fuller treatment, please see the more extensive journal article [Gros86].

quired of those who will be doing the adaptations (in particular, whether they must have expertise in natural-language processing), and what parts of the system might change (in particular, whether the database can be restructured to fit the requirements of the NLI).

A major hypothesis underlying TEAM may be stated as follows: if an NLI is constructed in a sufficiently well-principled manner, the information needed to adapt it to a new database (and its corresponding domain) can be acquired from users who have general expertise about computer systems and the given database, but who do not have any special knowledge about natural-language processing or this NLI.

In testing this hypothesis, we also assumed (for both theoretical and practical reasons) that the database could not be restructured. Theoretically, it is the most conservative choice we could have made; it imposed general solutions upon certain issues of system design, because we could not restructure the data to alleviate problems of natural-language processing. Such restructuring can often bring about a closer match between the way information is stored and the way it is referred to in NL expressions. For instance, in the previous example, a database structure that includes the SWISS? feature field is more difficult to handle in a general manner than one that uses the COUNTRY field encoding. From a practical standpoint, the choice reflected our desire to provide techniques adequate to handle existing databases, some of which are quite large and complex, hence fairly difficult to restructure.

1.2 Using TEAM

The TEAM system is designed to interact with two kinds of users: a *database expert* (DBE) and an *end user*. The DBE engages in an acquisition dialogue with TEAM to provide the information needed to adapt the system to a new database, and, when desired, to expand its capabilities in answering questions about a database (e.g., by adding new verbs or synonyms for existing words). Once a DBE has provided TEAM with the information it needs about a database and domain, any number of end users can use the system to query the database.

The TEAM system thus has two major modes: acquisition and question-answering. The acquisition dialogue with the DBE is oriented around the database structure. It is a menu-driven interaction through which the DBE provides information about the files and fields in the database,[3] the conceptual content they encode and how they encode it, and the words and phrases used to refer to these concepts. Hence the DBE must know about the particular database structure and the subject domain its information covers, but he does not need to know how TEAM works or any special language-processing terminology.

The question-answering system consists of two major components: (1) the DIALOGIC system [Gros82] for mapping natural-language expressions onto formal logical representations of their meanings; (2) a schema translator that transforms these representations into statements of a database query language. DIALOGIC and the schema translator require both domain-specific and domain-independent information. The requisite domain-independent information is part of the core TEAM system; the domain-specific information is obtained by the acquisition component.

1.3 A Sample Database

We will use the database shown schematically in Figure 1 to help illustrate various aspects of TEAM. This database comprises four *files* (or, *relations*) of geographic data. The first file, WORLDC, has five *fields*—NAME, CONTINENT, CAPITAL, AREA and POP; respectively, they specify the continent, capital, area, and population for each country in the world. Various mountains in the world are represented in the second file, named PEAK, along with their country, height, and an indication as to whether they are volcanic. The third file, named CONT, shows the hemisphere, area, and population of the continents. The fourth file, BCITY, contains the country and population of some of the larger cities of the world. Because several files may have fields with the same names, TEAM prefixes file names to field names to form unique identifiers (e.g., WORLDC-NAME, PEAK-NAME, CONT-POP, BCITY-POP); we will do likewise in our discussion.

TEAM distinguishes among three different kinds of fields: feature, arithmetic, and symbolic. *Feature fields* contain true/false values indicating whether or not some attribute is a property of the file subject. PEAK-VOL and CONT-HEMI are feature fields. *Arithmetic fields* contain numeric values on which computations (e.g., averaging) can be performed WORLDC-AREA and PEAK-HEIGHT are examples of arithmetic fields. Let us note, however, that a field containing social security numbers would be treated more naturally as a symbolic field than as an arithmetic field, because it is unlikely that any arithmetic computations would be done on such numbers. *Symbolic fields* typically contain values that correspond to nouns or adjectives denoting the subtypes of the domain denoted by the field. WORLDC-NAME and PEAK-COUNTRY are examples.

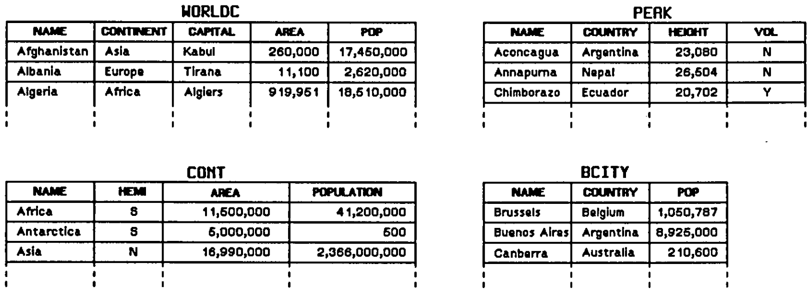
More information can be gleaned from a database than simply what the individual files contain. For instance, the continent on which a peak is located can be derived from the country in which it is located and the continent of the country. Likewise, the hemisphere in which a country is located can be determined from the continent on which the country is located and the hemisphere of that continent. TEAM allows the DBE to specify *virtual relations* that convey such additional information.

2 The TEAM System Architecture

The design of TEAM reflects several constraints imposed by the demand for transportability; our discussion will emphasize those aspects of the design. The need to decouple the representation of what a user means by a query from the procedure for obtaining that information from the database obviously affected the choice of system components. In addition, the need to separate the domain-dependent knowledge to be acquired for each new database from the domain-independent parts of the system influenced the design of the particular data structures (or "knowledge sources") selected for encoding the information used by these components.

Figure 2 illustrates the major processes of TEAM, the various sources of knowledge they use, and the flow of language-processing tasks from the analysis of an English sentence to the generation of a database query. The rectangular boxes represent

[3] TEAM currently assumes a relational database with a number of files. No difficult language-processing problems would result from conversion to other models.



WORLDC

NAME	CONTINENT	CAPITAL	AREA	POP
Afghanistan	Asia	Kabul	260,000	17,450,000
Albania	Europe	Tirana	11,100	2,620,000
Algeria	Africa	Algiers	919,951	18,510,000

PEAK

NAME	COUNTRY	HEIGHT	VOL
Aconcagua	Argentina	23,080	N
Annapurna	Nepal	26,504	N
Chimborazo	Ecuador	20,702	Y

CONT

NAME	HEMI	AREA	POPULATION
Africa	S	11,500,000	41,200,000
Antarctica	S	5,000,000	500
Asia	N	16,990,000	2,366,000,000

BCITY

NAME	COUNTRY	POP
Brussels	Belgium	1,050,787
Buenos Aires	Argentina	8,925,000
Canberra	Australia	210,600

Figure 1: Sample Database

the processes, and the ovals to their right, the various knowledge sources. The acquisition box on the right points to those knowledge sources that are augmented through interaction with the DBE. All other modules and knowledge sources are built into TEAM and remain unchanged during acquisition.

In this section we will look at the TEAM system from several angles. To begin, we will sketch the overall flow of processing during question-answering, describing the various processes involved in transforming an English query into a formal database query. Because the particular *logical form* (LF) TEAM uses to encode the meaning of a query plays a crucial role in mediating between the way queries are posed and the way information is obtained from the database, it affects the design of several components of the system. We then look in somewhat more detail at the data structures that encode domain-specific information. Finally, we discuss the overall strategy used for acquiring information about specific domains and databases.

2.1 Flow of Control

The flow of control during TEAM's translation of a natural-language query into a formal query to the database is illustrated as the path on the left side of Figure 2, from top to bottom. The transformation takes place in two major steps: first, a representation of the literal meaning of the query, or *logical form*, is constructed; second, this logical form is transformed into a database query.

The translation into logical form is performed by the DIALOGIC system, which comprises the following components, shown surrounded by the dotted box in Figure 2: the DIAMOND parser, the DIAGRAM grammar, the lexicon, semantic-interpretation functions, basic pragmatic functions, and procedures for determining the scope of quantifiers.

Since a description of DIALOGIC is provided elsewhere [Gros82], let us discuss here only those aspects of the system that were influenced by the development of TEAM. Two central data structures in DIALOGIC that are affected by TEAM's acquisition process are described: the *lexicon* and the *conceptual schema*. To understand the semantic and pragmatic components of TEAM, it is also necessary to appreciate DIALOGIC's separation of semantic interpretation operations into two main classes: *translators*, which define how the interpretations of the constituents of a phrase are combined into the phrase's interpretation; *basic semantic functions*, which are called by the translators to assemble the actual logical-form fragments that form the interpretations of phrases.

In brief, when the end user asks a query, DIALOGIC parses the sentence, producing one or more trees representing possible syntactic structures. The "best" parse tree, based on a priori syntactic criteria, is selected and annotated with semantic information [Robi82,Mart83]. Next, *pragmatic analysis* is applied to assign specific meanings that are relevant to the current domain to noun-noun combinations and to "vague" predicates like **HAVE** and **OF**.[4] Finally, the quantifier-scope determination process, after considering all possible alternatives, determines the best relative scope for the quantifiers in the query. The logical form thus constructed, using a set of predicates that are meaningful with respect to the given domain and database, constitutes an unambiguous representation of the English query.

The logical form produced by DIALOGIC is translated into a query in the SODA [Moor79] [5] database query language by the *schema translator*. In addition to the conceptual schema, the schema translator uses a database schema that furnishes information about the particular database structures. This schema, described briefly below, is also affected by the acquisition process.

Finally, the database query produced by the schema translator is given to SODA, which executes the query and displays the answer for the user. SODA was not developed as part of TEAM but was chosen for its features, which are consistent with the overall goal of transportability. SODA was designed for querying distributed databases and is capable of interfacing with several actual database management systems.

The processes TEAM executes in replying to an end user's query are similar to those that any custom-designed NLI would execute. What is different in the case of TEAM is that the

[4] We consider these predicates vague because they can be applied to many kinds of entities; they are replaced by "real" predicates during pragmatic processing.

[5] SODA is actually a query compiler that takes queries in a standard relational formalism and compiles them into optimized queries in the languages of other database management systems; both relational and codicil DBMSs have been accommodated. For our experiments, an interpreter that follows SODA commands to access a small database in primary memory was used in lieu of the actual SODA system.

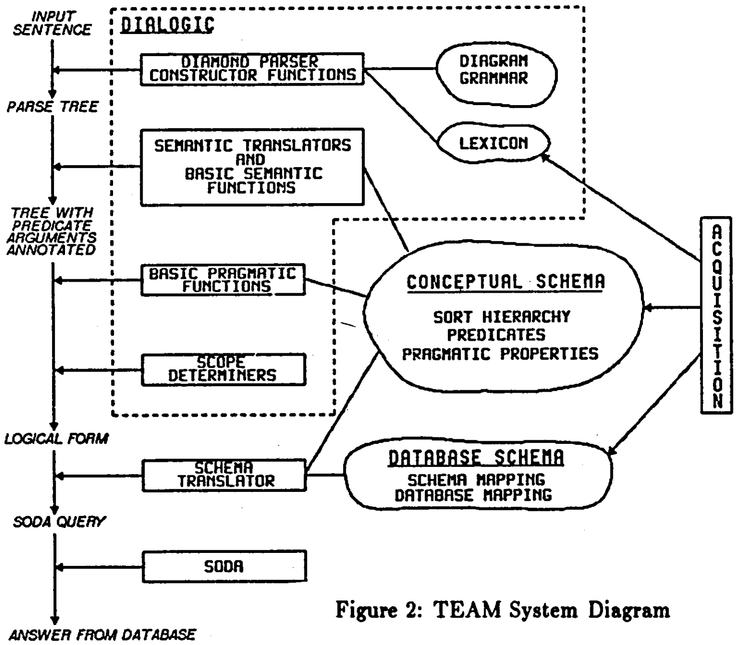


Figure 2: TEAM System Diagram

modules must be carefully designed to allow for maximal generality, which precludes many of the shortcuts that are common in custom-built NLI systems (e.g., LADDER [Hend77], PLANES [Walt75]). Two techniques that are ruled out are the using a *semantic grammar* and combining the determination of what a query means with the formulation of the DBMS query.

Semantic grammars are based on constituent categories that are chosen not for their ability to embody linguistic generalizations, but rather for the ease of parsing and interpretation that results when the grammar reflects the conceptual structure of the database domain. For example, instead of the general categories of "noun" and "verb phrase," semantic grammars may have categories such as "country" and "location specification." Such grammars are hopelessly tied to a single domain, and probably to a single database as well.

Efficiency also results from mapping a natural-language query directly into the code required for retrieving an answer from the database, but at the cost of being tied to a particular database. A number of database query systems (e.g., LADDER) construct a query directly while parsing the input with semantic grammar rules, but without building any other representation of what the query means.

Although the SODA query that results from the analysis of an English query represents, at least in some sense, the intended meaning of the latter, it does so in a way that directly reflects the structure of the database being queried. Consequently, if two databases encode the same information in different structures, the result will be two different database queries for the same English sentence. For example, if a user asks "How many Swiss mountains are there?" the database queries generated in response to his query can look very different, depending on whether the tuples representing Swiss peaks are distinguished from those representing other peaks by their membership in a different relation, or by the presence of the word "SWZ" in a COUNTRY field.

The problem this creates is not just an aesthetic one: to acquire the semantic and pragmatic rules necessary for generating a database query directly from an English query, TEAM would have to ask the DBE about far more than the structure and contents of the database. Answering the essential questions for such an acquisition would require the kind of expertise in natural-language processing that TEAM is intended to render unnecessary. Thus, the demands of transportability preclude use of the SODA language as the primary representation of the meaning of queries.[6]

2.2 Logical Form

Logical form plays a central role in TEAM: it mediates between the way an end user thinks about the information in a database, as revealed in his queries to the system, and the way information can be retrieved through queries in a formal database-query language. The predicates and terms in the logical form for a particular query are derived from information in the lexicon and conceptual schema;[7], hence, the choice of logical form indirectly affects the design of those components of the system and determines, in part, the information the DBE must supply.

The logical form employed by TEAM is first-order logic extended by certain intensional and higher-order operators and augmented with special quantifiers for definite determiners and interrogative determiners. Much research has been done to devise appropriate logical forms for many kinds of sentences [Moor81], but that investigation lies beyond the scope of this article.

[6] In addition, DIALOGIC was designed to be a general language understanding system that can be applied to tasks other than database querying. Therefore, it was undesirable to restrict its application by choosing an unsuitable semantic representation.

[7] As noted previously, the specific form depends also on general syntactic, semantic, and pragmatic rules for English that are encoded in the various components of DIALOGIC.

2.3 What Information Is Acquired

2.3.1 The Lexicon

The lexicon is a repository of the information about each word that is necessary for morphological, syntactic, and semantic analysis. There are two classes of lexical items: closed and open. Closed classes (e.g., pronouns, conjunctions, and determiners) contain only a finite, usually small number of lexical items. Typically, these words have complex and specialized grammatical functions, along with [at least some] fixed meanings that are independent of the domain. They are likely to occur with high frequency in queries to almost any database. Open classes (e.g., nouns, verbs, adjectives) are much larger and the meanings of their members tend to vary, depending on the particular database and domain. Therefore, most closed-class words are built into the initial TEAM lexicon, while open-class words are acquired for each domain separately. However, there are a number of open-class words, such as those corresponding to concepts in the initial conceptual schema (see Section 2.3.2) and words for common units of measure (e.g., "meter", "pound"), that are so broadly applicable to so many database domains that they are included in the initial lexicon as well.

Lexical entries include those for the names of file subjects (i.e., the entities about which some relation contains information—e.g., peaks for PEAK, and countries for WORLDC in the sample database illustrated in Figure 1.3), field names, and field values. In addition, the DBE can supply adjectives and verbs, as well as synonyms for words already acquired (see Section 2.4). Associated with every lexical entry is syntactic and semantic information for each of its senses. Syntactic information consists of its primary category (e.g., noun, verb, or adjective), subcategory (e.g., count, unit, or mass for nouns; object types for verbs), and morphology. Semantic information depends on the syntactic category. The entry for each noun includes the sort(s) or individual(s) in the conceptual schema (Section 2.3.2) to which that noun can refer. Entries for adjectives and verbs include the conceptual predicate to which they refer, plus information about how the various syntactic constituents of a sentence map onto arguments of the predicate. Scalar adjectives (e.g., "high") also include an indication of direction on the scale (plus or minus).

2.3.2 Conceptual Schema

The *conceptual schema* contains information about the objects, properties, and relations in the domain of the database. It includes sets of individuals, predicates, constraints on the arguments of predicates, and the information needed for certain pragmatic processing. The informational content is similar to that commonly encoded in semantic networks, but the apparatus used is more eclectic. The conceptual schema consists of a *sort hierarchy* and descriptions of various properties of nonsort predicates.

The sort hierarchy relates certain [monadic] predicates that play a primary role in categorizing individuals. These are called *sort predicates* (represented here in italics as in *PERSON*). TEAM was designed with a considerable amount of this conceptual information built in. Figure 3 illustrates a portion of this hierarchy. Each line connecting levels of the hierarchy signifies a set-subset relationship between two categories of individuals. The sorts connected by the small arcs directly below the nodes are disjoint; that is, no individual can be in two sorts joined in this manner. The sort hierarchy grows as information about a database is acquired. The DBE is required to position some of the newly acquired concepts in their appropriate places in the hierarchy.

Each field in the database is associated with the sort of objects that can appear in that field. Several additional properties are associated with the sorts derived from symbolic fields and from certain kinds of arithmetic fields.

With each sort obtained from a symbolic field, TEAM associates a predicate that encodes the relationship between that sort and the sort of the file subject. For example, for the relation WORLDC in Section 1.3, which includes information about capitals and continents, the system would link the sort *WORLDC-CAPITAL* with the predicate **WORLDC-CAPITAL-OF** (in this article, predicates are shown in boldface), which takes two arguments: the first of sort *WORLDC-CAPITAL*, the second of sort *COUNTRY*. This link is used in handling queries like "What is the capital of each country in Europe?" In particular, it is used to determine what it means for a capital to be "of" a country, or for a country to be "in" Europe. Additional properties of the sort indicate whether individual instances of it can modify or stand for instances of the sort of the file subject (e.g., "European countries," but not "Europeans" can be used to refer to the countries *c* satisfying the predication (**CONTINENT-OF** *c* EUROPE)).

Sorts that correspond to arithmetic fields containing measures (e.g., length, age) also include information about both the implicit unit of measurement (e.g., feet, years), and the kind of thing being measured (e.g., linear extent, temporal extent).

Several other kinds of information are associated with nonsort predicates. A *delineation* specifies the constraints on the sorts for each of a predicate's arguments; multiple delineations are supported but cannot be described in this brief format. Predicates corresponding to comparative-forming adjectives (e.g., "tall") have two additional properties: a link to the predicate that specifies the degree (e.g., **PEAK-HEIGHT** in our example), and an indication of polarity along the scale being measured (e.g., plus for **TALL**, minus for **SHORT**).

2.3.3 Associated Processes

Several general predicates have semantic and pragmatic specialists associated with them. The semantic specialists are Is-semantics and Degree-semantics; the pragmatic specialists are the Genitive, Noun-noun, Have, Of, General-preposition, Time, Location, Do-specialist, and Comparative.

The Is-semantics specialist is associated with the predicate **IS** and propagates sort restrictions across all the variables that are being equated by the **IS** assertion. This specialist is invoked prior to pragmatic processing (hence the "semantics" label); it attempts to reconcile any conflicts it detects and may revise some sort predications on variables in the process. For example, it is used in processing the query, "What is the area of Nepal?" to ascertain that the variable corresponding to the "what" is a *WORLDC-AREA*, not a *CONT-AREA*.

The Degree-semantics specialist replaces the general predicate **DEGREE-OF** with a more specific one. For example, by determining that predication (**DEGREE-OF** *peak1 x*) refers to the predicate **PEAK-HEIGHT**—i.e., that it is equivalent to the predication (**PEAK-HEIGHT-OF** *peak1 x*)—the specialist allows TEAM to further constrain the sort of *x* to be a *linear-measure*, thus allowing the comparative specialist invoked during pragmatic processing to make the right choice between the

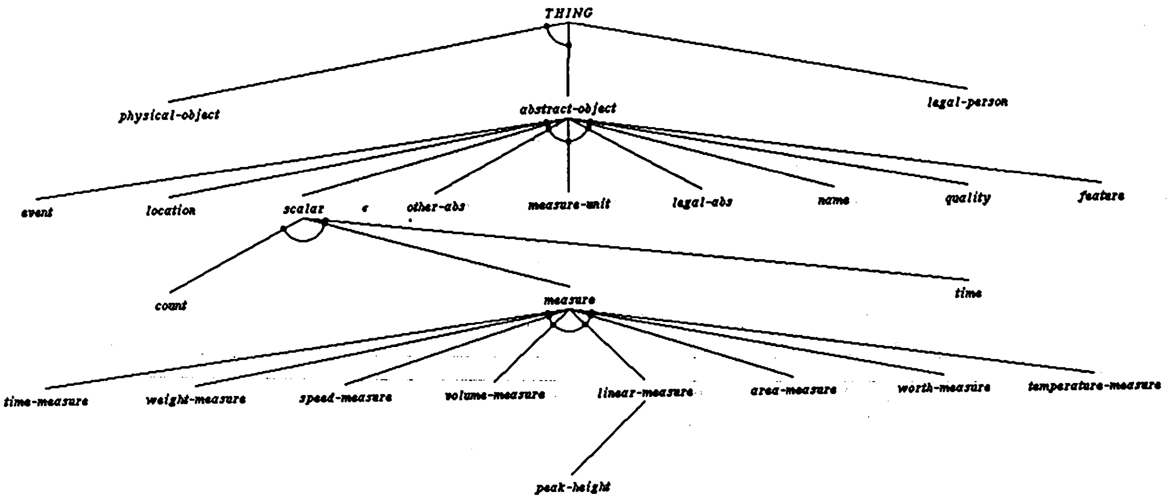

Figure 3: A Fragment of TEAM's Sort Hierarchy

alternatives of comparing the heights of two objects and comparing an object's height with a height value.

The Genitive, Noun-noun, Have, and Of specialists replace the vague predicates **GENITIVE**, **NN** (for noun-noun combinations), **HAVE**, and **OF** with more specific ones. The individual specialists differ only slightly, the differences reflecting the special restrictions associated with each construction.

The General-preposition specialist is associated with **ON**, **FROM**, **WITH**, and **IN**, converting these predicates into their appropriate domain-specific counterparts. For example, the Do-specialist determines that the phrase "countries in Asia" means those countries *c* for which the predication (**WORLDC-CONTINENT-OF** *c* **ASIA**) holds.

The Time-specialist and Location-specialist serve to map **TIME-OF** and **LOCATION-OF** into predicates that are appropriate for the database at hand. They can be invoked obliquely by the interrogative constructions "when" and "where."

The Do-specialist replaces the predicate **DO** (from the verb "do") with a more specific verb chosen from those acquired for a domain. Although "do" does not appear as the main verb very often in the database query task , the translators deduce its implied presence in some queries—for instance in such comparative questions as "What countries cover more area than Peru [does]?".

The comparative specialist examines the two arguments of a comparison to determine whether the comparison to be made is between two attribute values (e.g., Jack's height and seven feet) or between an entity and some value (e.g., Jack and seven feet). In the latter case, TEAM tries to identify the appropriate attribute of the entity (e.g., Jack's height).

2.3.4 Database Schema

The translation from logical form to SODA query requires knowing the exact structure of the target database and the manner in which the predicates appearing in the logical form are associated with the relations in the database. This information is provided by the *database schema*, which includes the following information[8]:

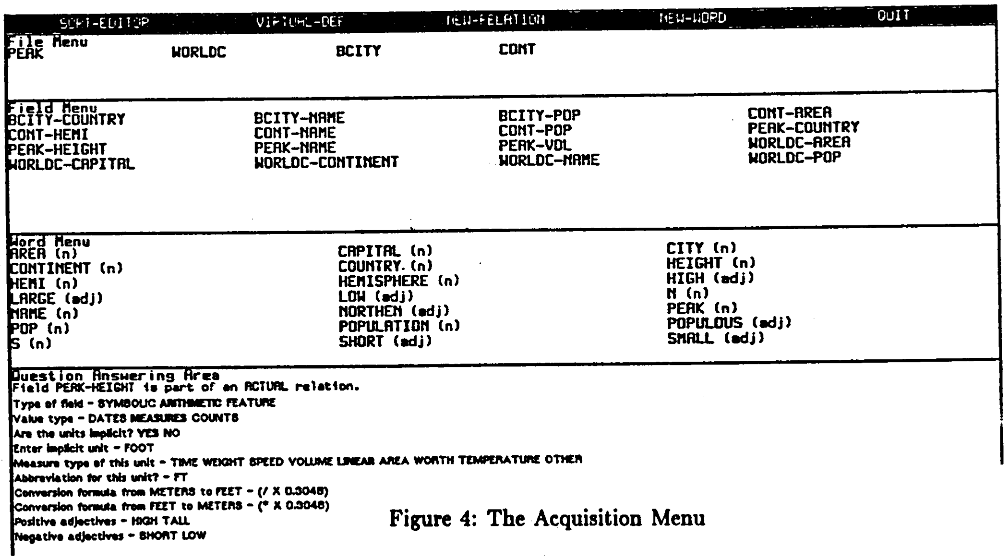
- Definition of sorts in terms of database relations (subject) or fields (and field value for sorts derived from feature fields).
- List of convenient identifying fields for each sort corresponding to a file subject or field.
- Definition of predicates in terms of actual database relations and attributes; this is done for predicates derived from both actual and virtual relations (for relation subjects and attributes).
- List of each relation's key fields.

The database schema relates all the predicates in the conceptual schema to their representation in a particular database. For each predicate, the database schema generates a logic formula defining the predicate in terms of database relations. For example, the predicate **WORLDC-CAPITAL-OF** has as its associated database schema a formula representing the fact that its first argument is taken from the WORLDC-CAPITAL field of a tuple of the WORLDC relation, and that its second argument comes from the WORLDC-NAME field of the same relation. If a predicate has multiple delineations—i.e., if it applies to different sorts of arguments (e.g., a **HEMISPHERE-OF** predicate could apply to both *COUNTRIES* and *CONTINENTS*)—the schema will include a separate definition for each set of arguments. In some cases (e.g., predicates resulting from the acquisition of some verbs and adjectives), the mapping associated with a predicate indicates that it is equivalent to another [conceptual schema] predicate with certain arguments set to fixed values.

2.4 Acquisition

The acquisition component of TEAM is crucial to its success as a transportable system. Recall that one constraint on TEAM is that the DBE not be required to have any knowledge of TEAM's internal workings, nor about the intricacies of the grammar, nor of computational linguistics in general. Yet detailed information, often necessarily linguistic in its orientation, must somehow be extracted from the DBE during an acquisition session. Furthermore, it is desirable that the acquisition component be designed to allow a DBE to change answers to questions and add information as he gains experience with TEAM and the types of questions that are asked by the end users.

[8] The schema translator also uses certain information in the conceptual schema, including taxonomic information in the sort hierarchy and delineation information associated with nonsort predicates.



Question Answering Area
Field PEAK-HEIGHT is part of an ACTUAL relation.
Type of field - SYMBOLIC ARITHMETIC FEATURE
Value type - DATES MEASURES COUNTS
Are the units implicit? YES NO
Enter implicit unit - FOOT
Measure type of this unit - TIME WEIGHT SPEED VOLUME LINEAR AREA WORTH TEMPERATURE OTHER
Abbreviation for this unit? - FT
Conversion formula from METERS to FEET - (/ X 0.3048)
Conversion formula from FEET to METERS - (* X 0.3048)
Positive adjectives - HIGH TALL
Negative adjectives - SHORT LOW

Figure 4: The Acquisition Menu

In an attempt to satisfy all these constraints, the menu-oriented system depicted in Figure 4 was developed. The acquisition system consists of a menu of general commands at the very top, three menus associated with relations, fields, and lexical items respectively, and, at the bottom, a window for questions and answers. When the DBE uses the mouse to select one of the items from the three menus, a set of questions appears in the question-answering area at the bottom of the display, to which he can then respond.

One of the general principles of acquisition is evident from this display, namely, that the acquisition is centered upon the relations and fields in the database, because this is the information most familiar to the DBE. The answers to each question can affect the lexicon, the conceptual schema, and the database schema. The DBE need not be aware of exactly why TEAM poses the questions it does—all he has to do is answer them correctly. Even the entries displayed in the word menu owe their presence to questions about the database. The DBE volunteers entries to this menu only in the case of verb acquisition, to supply an adjective corresponding to some noun already in TEAM's lexicon, or to enter a synonym for some lexicon-resident word.

The DBE is assumed not to have any knowledge of formal linguistics or of natural-language processing methods. He is assumed, however, to know some general facts about English—for example, what proper nouns, verbs, plurals, and tense are, but nothing more detailed than that. If more sophisticated linguistic information is required, as in the case of verb acquisition, TEAM proceeds by asking questions about sample sentences, allowing the DBE to rely on his intuition as a native speaker, and extracting the information it needs from his responses.

Virtual relations are specified iconically. The left side of Figure 5 shows the acquisition of a virtual relation that identifies the continent (PKCONT-CONTINENT, derived from WORLDC-CONTINENT) of a peak (PKCONT-NAME, from PEAK-NAME) by performing a database join on the PEAK-COUNTRY and WORLDC-CONTINENT fields. Similarly, the right side of Figure 5 shows the acquisition of the virtual relation that encodes the hemisphere (HEMIC-HEMI) of a country (HEMIC-NAME) by joining on the WORLDC-CONTINENT and CONT-NAME fields.

If he wishes, the DBE can change previous answers. Incremental updates are possible because most of the methods for updating the various TEAM structures (lexicon, schemata) were devised to undo the effects of previous answers before the effects of new answers could be asserted. Help information is always available to assist the DBE when he is unsure how to answer a question. Selecting the question text with the mouse produces a more elaborate description of the information TEAM is trying to elicit, usually accompanied by pertinent examples.

Finally, the acquisition component keeps track of what information remains to be supplied before TEAM has the minimum it needs to handle queries. The DBE does not have to determine himself how much information is sufficient; all he has to do is to perceive that no acquisition window indicates remaining unanswered questions. Of course, the DBE can always provide information beyond the minimum—for example, by supplying additional verbs, derived adjectives, or synonyms.

3 Conclusions

TEAM has been tested in a variety of multifile database domains by a fairly large number of people in addition to its original implementation team. While the testing has been much less rigorous than would be required for an actual product, enough has been learned to conclude that the basic ideas "work"—namely, that it is possible to build a natural-language interface that is general enough to allow its adaptation to new domains by users who are familiar with these domains, but are themselves neither experts on the system itself nor specialists in AI or linguistics.

TEAM handles a wide range of verbs, a capability that is absolutely essential for fluent natural-language communication. As it embodies no discourse model, its handling of pronoun resolution and determiner scoping is correspondingly limited. While its grammar coverage is quite extensive, the formalism used to represent it and the processes used to implement it are yielding to newer and more perspicuous designs[Shie84]. We are now investigating ways to provide transportability in natural-language systems that can interact with a variety of software services beyond database access and which more extensive discourse capabilities will be embodied.

Parallel Processing of a Knowledge-Based Vision System

D. I. Moldovan and C. I. Wu,

Department of Electrical Engineering -- Systems

University of Southern California

Los Angeles, CA 90089-0781

Abstract

A parallel processing algorithm and architecture for scene interpretation are presented in this paper. Scene interpretation and in particular, object classification, is an important aspect of high level image understanding. The algorithm for object classification presented in this paper is based on comparing image features with object models stored in a knowledge base and computing confidence values for object models. The algorithm is mapped into a multiprocessor system. Simulation results for this parallel processing technique are shown.

Index Terms: Symbolic processing, image understanding, knowledge-based parallel processing.

1. Introduction

A vision system consists of a number of numeric and symbolic algorithms aiming at understanding images. Although tremendous effort has been put in the image understanding field and many efficient algorithms have been developed, many fundamental problems still remain to be solved [Brad 82] [Wu 85]. Vision algorithms span the entire complexity range from simple purely numeric algorithms with small granularity to highly complex symbolic algorithms with large granularity for object classification [Neva 82] [Ball 82]. Historically, the focus of image understanding (IU) field has been directed more toward low level image processing [Dani 81] and consequently many parallel architectures have been proposed and built for these applications [Duff 81]. High level IU uses the results produced by image processing algorithms such as lines or regions and other features and through an inference process produces scene interpretations. This part of the vision system is more difficult and less explored than low level image processing [Wu 85]. It was believed by many that because of the symbolic nature of high level vision algorithms, parallelism was very limited in high level IU. In this paper we show that there is abundent parallelism in algorithms for object classification. We present a technique for scene analysis using the knowledge base approach and show the mapping of this algorithm into a parallel architecture.

A common technique used for knowledge processing is to compare the information on hand with a knowledge base. In the case of scene analysis the features extracted by image processing algorithms are constantly compared to known complex object models, and when the match is satisfactory and global consistency is achieved, the identity of image objects is found.

This paper is organized as follows: in section 2 an algorithm for object classification is presented followed by the description of the main processing modules, in section 3 the mapping of this algorithm into a multiprocessor system is shown, and in section 4 there are simulation results indicating the feasibility and the performance of this technique.

2. A Paradigm of Knowledge Based Vision Systems

2.1 System Organization

In figure 2-1 a flowchart of a vision system is shown [Binf 82]. The input consists of raw images provided by sensory devices. The purpose of this system is to obtain symbolic interpretations of images. The low and medium level processing such as early processing, segmentation, stereo, motion, occlusion, shading, etc. are responsible for extracting visual primitives from the original image such as regions, lines, and their attributes such as color, texture, size, shape, orientation, length, etc. Image interpretation is performed by grouping the visual primitives in various ways and attaching to them semantic labels under the constraints imposed by the knowledge base. As a result of this interpretation, object and scene descriptions are created which are constantly verified against expected object and scene models.

For our purpose the vision system from figure 2-1 may be partitioned into the following four main blocks: low level expert, short term memory, knowledge base, and high level expert. The *low level expert* incorporates all the modules required to transform raw images into intermediate symbolic representations. In early image processing, the nature of processing is iconic i.e. there is a direct relationship between physical storage location and image pixels [Rose 83]. The *short term memory* (STM) is the working memory of the vision system. It keeps all the symbolic representations made available by the low level expert and provides the processing environment for higher levels of abstractions [Mold 85a].

The *knowledge base* (KB), consisting of declarative and procedural knowledge, contains problem specific knowledge about the application domain. The declarative part is a collection of model objects and their relationships. Each model object is described by a frame and represents the classes of objects that are expected to be encountered during the processing of scenes. Model objects form an object hierarchy that plays the role of the hierarchical classifier. An unknown object is compared with each of the model objects and is classified to be the best matching class if evidence is sufficient. In this hierarchy, the scene object is the most general class and subsumes all other object classes in the image domain. The procedural part is linked to the declarative part by means of active demons in the frame structure and contains algorithms or production rules for computing attribute values, structures, and confidence scores. The *high level expert* (HLE) performs object classification through reasoning. It adaptively determines the appropriate levels of description based on the amount of information available. Once through the initial segmentation step, an input image is represented as a group of regions. Each region is represented as a frame with its own slot values for various region attributes such as area, centroid, and primary and secondary axes. Each region is initially classified as a scene object which is the most generic object class in the model object hierarchy. As the classification process proceeds, each region is further

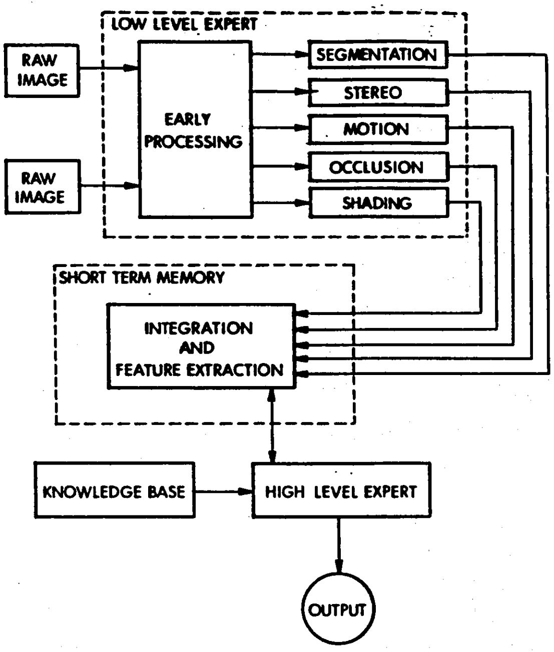

Figure 2-1: Main modules of a knowledge based vision system

hypothesized as subclasses of the established hypothesis. Then evidence is collected to confirm or deny these hypotheses. This cycle of hypothesis generation, evidence collecting, and confirmation or denial of hypothesis is repeated for each confirmed hypothesis until each region is classified as a terminal objects class of the object hierarchy, or no further subclassification is possible becaues of low confidence for the current classification. Then, as a second phase of scene analysis, the system checks for global hypothesis consistency. An object's class hypothesis is represented as an instance of the class model. Therefore, generation of a hypothesis corresponds to instantiation of the class model. The instantiation can be done in either a data driven or a model driven manner. In the data driven case, hypotheses are generated in an attempt to subclassify 'established' objects into their subclasses. In the model driven case, hypotheses are generated from the need to find new evidence for the existing hypotheses.

2.2 Classification Algorithm

The object classification algorithm can be summarized as the following six-step procedure where each step consists of one or more routines:

```
 Input: frame representation of image
        and frame representation of
        knowledge base;
Output: symbolic description of each
        image region;

Procedure:

Step 1: Hypothesis screener
        Perform a preliminary hypothesis
        check for each hypothesis to
        eliminate the apparently ridiculous
        image regions for each hypothesis;

Step 2: Evidence collection
        For each hypothesis perform specific
        image understanding algorithms to
        fill slot possibilities required to
        evaluate the confidence values;

Step 3: Establishment check
        Check if sufficient supporting evidenc
        exists for further classification usin
        a more specific hypothesis;

Step 4: Local confidence value evaluation
        Local confidence value is computed by
        optimizing the combination of slot
        possibilities;

Step 5: Subclassification
        Repeat recursively the classification
        algorithm for all the subclasses of
        this hypothesis;

Step 6: Global confidence value computation
        Compute the final confidence value for
        this hypothesis based on the local
        confidence value and the global confid
        values of its parent and children.
```

As an example, consider the classification of objects in the scene shown in figure 2-2. For processing this scene we use the knowledge base from figure 2-3. It is assumed that the image has been segmented into regions as shown in figure 2-4. The classification proceeds by applying the above procedure to each region. As a result of this process, each region is associated with a most likely frame from the knowledge base, and in the process it inherits the properties of all parent frames in the knowledge base hierarchy. For example, the path in the knowledge base most suitable to region 0 is 'scene-object', 'background', 'wood-object', and 'door'. In figure 2-5 are shown the confidence values [Shor 76] of all the frames in the model corresponding to region 0. The four numbers represent local measure of belief LMB, local measure of disbelief LMD, global measure of belief GMB, and global measure of disbelief GMD. The global confidence values (GCV) are computed as difference between the global measure of belief minus the global measure of disbelief.

$$GCV = GMB - GMD$$

The global measure of belief and disbelief are computed from local measure of belief and disbelief

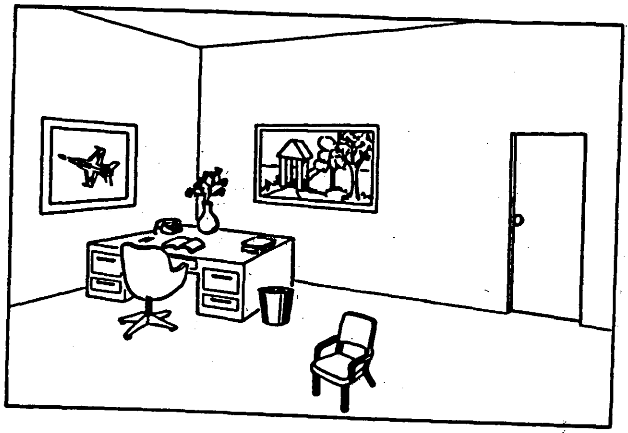

Figure 2-2: An example of scene

according to the formulas:

$$\mathrm{GMB} = \begin{cases} \mathtt{LMB,\ if\ this\ is\ a\ terminal\ node} \\ \mathtt{\Sigma LMB \oplus GMB(its\ children),\ \ otherwise} \end{cases}$$

$$\mathrm{GMD} = \begin{cases} \mathtt{LMD,\ if\ this\ is\ a\ root\ node} \\ \mathtt{\Sigma LMD \oplus GMD(its\ parent),\ \ otherwise} \end{cases}$$

$\mathtt{where}\ x \oplus y = x + y - x*y.$

The optimal path was selected by picking the model nodes with the largest global confidence value. The calculation of local confidence values is usually done in the short term memory by some vision algorithms. In this paper we do not discuss the processing performed.

Parallelism is achieved by simultaneous processing of many regions. After all the regions have been classified as described above, a global consistency check is necessary. If there are no conflicts the classification obtained holds, but if there are incompatibilities then more features are extracted from the image to help improve the decision process.

3. Mapping into hardware

Since the type of algorithms in various stages of a vision system varies considerable, no single parallel architecture can perform efficiently across the entire spectrum of vision algorithms. The architecture of a parallel processing system for the vision system described in the previous section is shown in figure 3-1. It consists of an intelligent memory [Fost 76], semantic network array processor (SNAP) [Mold 85b], a multiprocessor, and host computer. The host computer is mainly used to manage the vision tasks. The multiprocessor is a mesh-connected array of general purpose microprocessors. The SNAP consists of a square array of identical processing elements interconnected both locally and globally and having associative array capabilities. The multiprocessor acts as a controller for the SNAP array. The intelligent memory module can be accessed directly by the other three modules. The

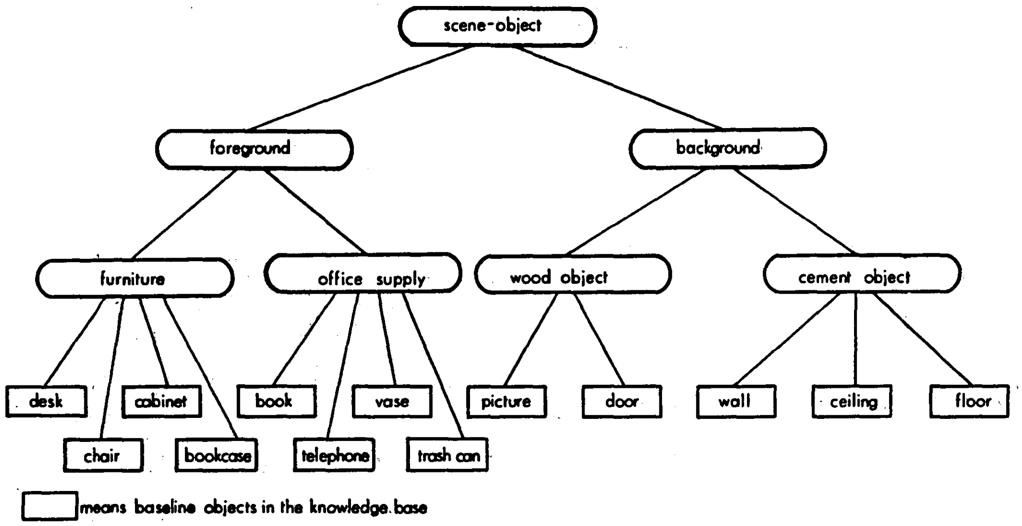

Figure 2-3: Model object hierarchy for office scene

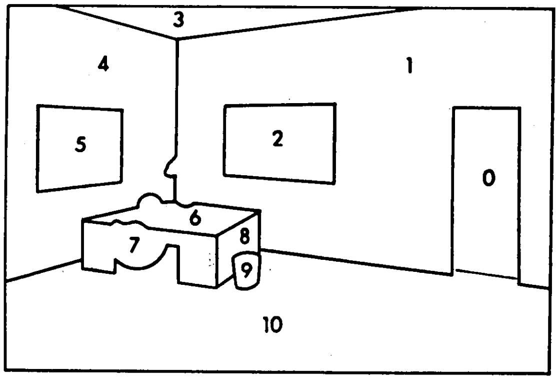

Figure 2-4: Segmented scene

intelligent memory consists of large number of processing cells with associative processing capabilities. The mapping of the vision system from figure 2-1 into this architecture is as follows: the low level expert is assigned to the intelligent memory [Rose 83]; the short term memory is assigned to the semantic network array processor [Dixi 84] [Mold 85a]; the high level expert and the knowledge base is distributed over the multiprocessor system. The SNAP and the multiprocessor perform symbolic functions while the intelligent memory performs most of the numeric functions. In this paper we are interested only in the operation of the multiprocessor system. Simulation results are described in the next section.

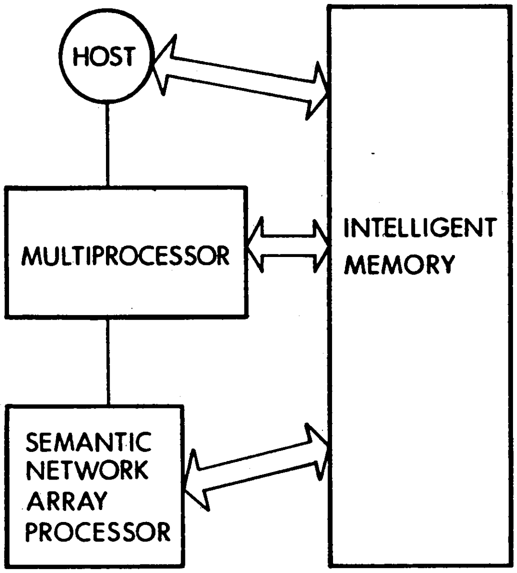

Figure 3-1: Vision Hardware System Architecture

4. Simulation Environment and Results

In this section we describe some simulation results obtained by implementing the knowledge based vision system on a multiprocessor. Through this simulation we want to demonstrate the feasibility of the

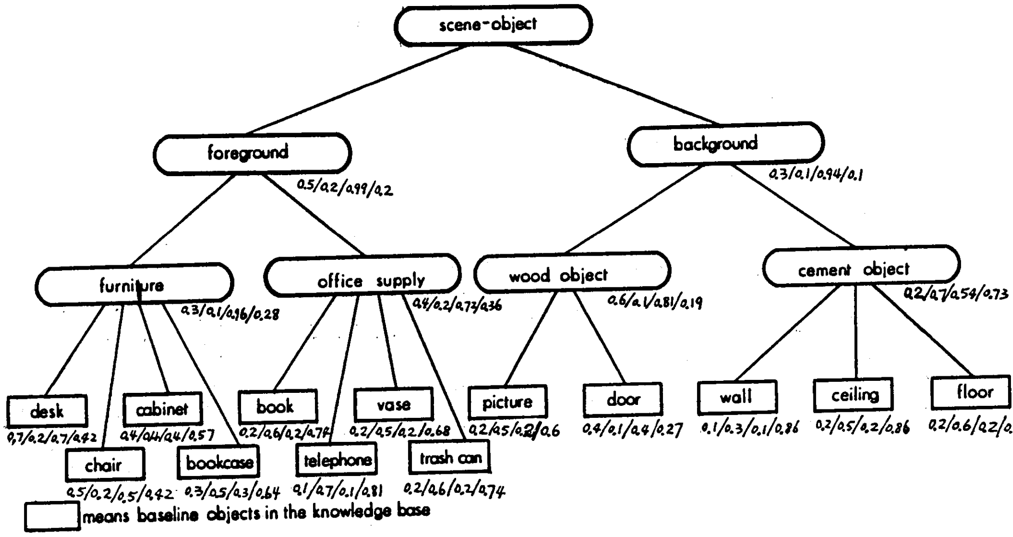

Figure 2-5: Confidence value for region 0 in figure 2-4

approach and to measure the speedup factor offered by the parallel scheme over the sequential processing. For this purpose we developed a program in Lisp [Gold 85]. This program simulates the operation of a four-node multiprocessor with mesh interconnection network. A system clock is used to coordinate all timing events. A time unit of system clock is defined as the time required to perform a simple arithmetic operation and transmit data between two adjacent processors. In each time unit it is determined if a processor is free or busy; if it is free and its queue contains a process then the processor is loaded, if busy it is determined what operation to be performed. A process consists of operations to instantiate a frame.

The inputs to the simulator are : (1) frame description of knowledge base vision system, (2) frame description of segmented scene, and (3) allocation policy of frames to processors. Three frame structures are used in our vision system: region frame, model frame and instance frame. The *region frame* is used to hold the spatial scene knowledge directly related with the image. The *model frame* contains domain knowledge and control knowledge as discussed before. The *instance frame* is the result of instantiating model frame and serves as the hypothesis of the region frame. In other words, the instance frame is the bridge between region frame and model frame. A sample structure of these three frames is shown in figure 4-1.

In its present form the simulator generates: (1) the final interpretation of the scene, (2) the parallel processing time and the sequential processing time, and (3) the utilization and load factors of each processor.

Simulation Example:

We simulated the interpretation of the scene shown in figure 2-2. For this purpose the knowledge base consisting of 20 frames was constructed as shown in figure 2-3. These frames were allocated to the four simulation processors according to three different allocation policies as indicated in table 4-1. In scheme (a) no parent and child or sibling frames are allocated to the same processor. In scheme (b) a totally random allocation was selected maintaining however a balanced load between processors. In scheme (c) an opposite policy from (a) was selected, in other words, as many related frames as possible were assigned to the same processor.

The simulator interpretes the scene by following the technique described in section 2. Each region is hypothesized on the hierarchical knowledge base and measure of belief and disbelief are computed for each instance. In step 1 of figure 4-2 is shown the sequence of instantiations for one region (region 0), and the belief and disbelief factors for each instance. The four numbers are in the following order: local measure of belief, local measure of disbelief, global measure of belief and global measure of disbelief. Based on the computed confidence value, the simulator computes the optimal path for each region, that is the path with the largest global confidence value. This is shown in step 2 of figure 4-2.

Figure 4-2: Sample of simulator printout result

The parallel processing time and the speedup factor obtained are summarized in table 4-2. The parallel processing time includes the parallel computation time as well as the interprocessor communication time. Preliminary simulations for more than four processors indicate that the speedup factor increases linearly as the number of processors increases.

The processor utilization time is defined here as the ratio between the "busy time" over the parallel processing time. The utilization factors obtained for this example under the three allocation schemes considered are shown in table 4-3.

ALLOCATION SCHEME	a	b	c	sequential
PROCESSING TIME	615	588	723	1637
SPEEDUP FACTOR	2.66	2.78	2.26	1

5. Conclusion

In this paper, a knowledge-based vision system was introduced and the emphasis was put on the parallel processing of object classification problem. The structure of the vision system proposed allows the extraction of some symbolic information from iconic domain at an early stage, and then provides the capability of performing complex symbolic processing in symbolic domain. Oftenly, because of the lack of a symbolic processor, in some IU systems many symbolic processing tasks are done in iconic domain. The proposed hierarchical architecture from section 3 is capable of performing a broad range of algorithms in image understanding. This system consists of an intelligent memory, a high level symbolic processor, a multiprocessor and a host computer. A possible mapping of a knowledge-based vision system into this architecture was proposed. We have also evaluated a portion of the architecture, the multiprocessor, using a software simulator. The results show the feasibility of parallel processing of a knowledge-based vision system. Work is in progress to simulate the operation of all the modules in the hierarchical architecture from figure 3-1 by implementing several algorithms from the vision system in figure 2-1.

A FAULT TOLERANT, BIT-PARALLEL, CELLULAR ARRAY PROCESSOR

Steven G. Morton

Staff Scientist, Central Research
ITT Advanced Technology Center
One Research Drive, Shelton, Connecticut 06484

ABSTRACT

We explore the question, "What are the effects of being able to build large, fault tolerant processor chips?" on a particular architecture, the SIMD, massively parallel, cellular array processor. The potential for high performance processor chips leads to a projected baseline configuration, a "personal supercomputer", that could be a coprocessor on a single plug-in board for a PC, that would provide peak performance of over 100 MFLOPS at 32-bits, or over 2,000 MIPS at 16-bits. The potential for low cost processor chips drives one to reduce costs throughout the system, including the extensive use of inexpensive DRAM, and lead to projections of price/performance with more than an order of magnitude improvement over alternative designs.

INTRODUCTION

The ITT Cellular Array Processor (CAP) architecture is characterized by its single-instruction stream, multiple-data stream (SIMD) design using bit-parallel, fault-tolerant, large area integration "array chips" for its parallel execution unit, and by its extensive use of low cost DRAM. In this paper we focus on the projected second generation, baseline design that would be a coprocessor occupying a single card slot in a PC. It would provide peak performance of over 100 MFLOPS at 32-bits or over 2,000 MIPS at 16-bits, as configured dynamically by software at runtime. A much lower performance, much larger, first generation prototype model has been demonstrated.

In this paper we emphasize the key issue of processor chip fault tolerance that we feel is the key to achieving the most compact, highest performance, lowest cost, most reliable, personal supercomputer for the image processing, scientific, and engineering marketplaces. The applications are characterized by matrix algebra, with either global operations, such as matrix multiply, for engineering and scientific processing, or many local operations, such as correlation windows, for image processing.

We particularly want to point out that we mean "personal supercomputer" in the sense of a significant fraction of a CRAY-1 or a Goodyear MPP on a desk top, as opposed to merely tens of MIPS or MFLOPS, as is getting to be the norm.

We have published several articles on various other aspects of CAP and its development, so we will only summarize that material in this paper. The instruction set, prototype model, and project evolution were covered in [1]. Details of the key prototype chip, array chip I, were covered in [2 - 5]. The logic simulation tools for chip development were covered in [6 - 7]. An application to image processing was given in [8].

This paper presents the projected second generation array chip and coprocessor design as viewed in early 1986. The technology continues to evolve in response to design and application experience. However, the underlying fault tolerant principles and their importance have not changed.

First, we compare well known cellular array processors to ours. Then we review our architecture, and explore the many effects of processor chip fault tolerance; fault tolerance that was a logical consequence of the tightly coupled, highly regular design, of a cellular array processor. Finally, we project where the next round of technology could take us.

COMPARATIVE CELLULAR ARRAY PROCESSORS

There are many parallel processors, but only a few cellular array processors. The Goodyear MPP (Massively Parallel Processor)[9], the ICL DAP (Distributed Array Processor)[10], and the Thinking Machines Connection Machine[11], are the most often mentioned machines in this class. The NCR GAPP (Geometric Arithmetic Parallel Processor) chip[12] (not a system) is unique in its diverse commercial application. Although the (ITT) CAP is similar to these machines in many ways, it also differs from them in these respects:

1. The CAP stores and processes the data stream differently. The other machines have 1-bit processor cells and are designed to operate in a bit-serial, word-parallel fashion. They store each word bit by bit through a succession of memory locations and increase word size in time. The second generation CAP, like the Illiac IV[13], has 16-bit processor cells and operates in a bit-parallel, word-parallel manner and increases word size in space, rather than in time. The first generation CAP, with 1-bit cells, is used as though it has 16-bit cells.

2. The CAP's parallel execution unit is fault tolerant at the level of a single cell. The MPP has limited fault tolerance, having four spare columns beyond is 128 minimum, but an entire column of 128 processors, not just one bad element, must be switched.

3. The CAP is a parallel reduced instruction set computer. Its assembly level programming model looks like a collection of conventional

CH2345-7/86/0000/0277$01.00 © 1986 IEEE

microprocessors working in lockstep. The MPP, DAP, and GAPP have single-bit oriented, even micro-, instruction sets.

4. The CAP interconnection architecture is an extension of other cellular array processors' nearest neighbor, except for the Connection Machine's hypercube. We use an x-y matrix of array chips II-M's, but since each array chip has 16 16-bit data processors, the x-dimension is nearest neighbor in 1 2-clock cycle, but the y-dimension requires 16 2-clock cycles to be nearest neighbor. This imbalance increases our packing density, reduces our pin count, and is coupled to our fault tolerant design, which enables defective elements to vanish from a one-dimensional array.

5. Due to both improved technology and fault-tolerant design, the second generation CAP would have 16 16-bit processors and large amounts (32+K bytes) of RAM on a single chip. The other machines integrate fewer processor bits with much smaller amounts of memory on a chip. This combination of large RAM and logic on a single chip increases the difficulty of chip design, both technically and administratively, but tremendously improves the price/performance and reduces the size of the system.

6. The CAP parallel execution unit has three levels of memory hierarchy, ranging from working registers to cache memory to external memory. The other machines have one level (GAPP and Connection Machine), or two levels (DAP and MPP), although the MPP also has a central, staging memory, as a global interconnect.

7. The CAP parallel execution unit has distributed memory addressing. The cache and external memory of each array chip have their address generated by the array chip. The other machines have only global addressing due to their single-bit architecture, making them prone to single-point failures in the address logic.

8. For a given total number of processor bits, the CAP is better suited to engineering applications than are the other machines, since the number of processors it provides is a better match to the dimensionality of many problems. Where the DAP would handle 4096 1-bit variables in bit-serial fashion, requiring enormous matrices for efficient use of the machine, a CAP with the same total number of processor bits would handle 128 32-bit variables in bit-parallel fashion. This provides efficient operation on much smaller matrices, as well as providing good processor utilization on more sizes of large matrices.

9. The CAP would have integrated, concurrent I/O so that data acquisition and computation may occur simultaneously. Multiple buffers would be provided in each processor cell so that interrupt service routines can provide direct memory access to the cache or external memory.

10. The MPP and Connection Machine processor cores occupy a volume over 1 m^3. The CAP would occupy less that 1% of that.

11. The primary application areas of the MPP, DAP, GAPP, and CAP are image processing, although the CAP targets engineering and scientific processing as well. The Connection Machine targets artificial intelligence - image understanding.

CAP ARCHITECTURE

OVERVIEW

The CAP employs a highly regular design based on an SIMD, cellular array architecture. A first generation prototype has been built from large (the largest logic chips in the U. S.), custom designed, CMOS chips that are feasible due to their fault tolerant design. A second generation design has been defined. The dominant chip, the

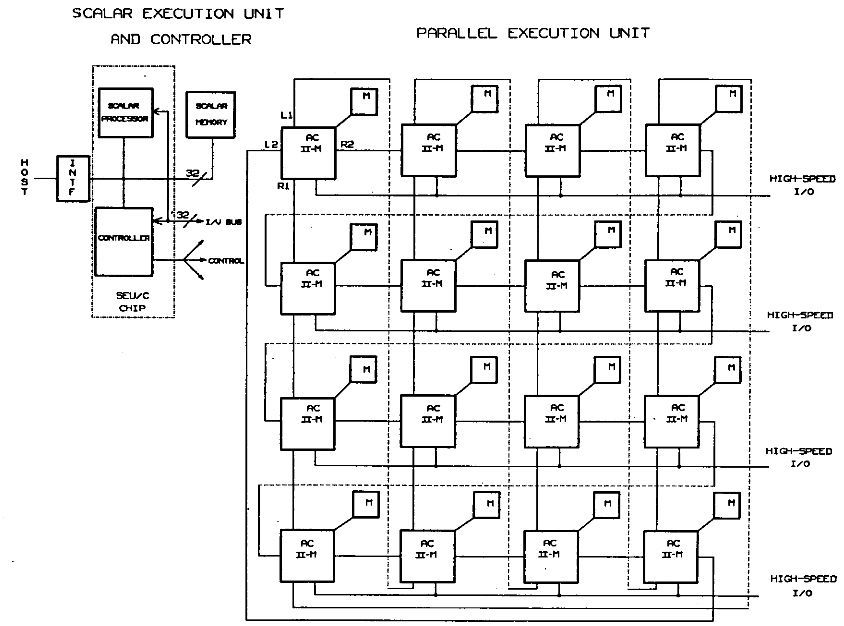

FIGURE 1 - PERSONAL SUPERCOMPUTER BLOCK DIAGRAM

array chip, has a simple, regular design that allows all processor elements, including a few spares, to be configured by software. In this way, words of varying size may be formed by cooperating processors, manufacturing defects may be overcome, and lifetime failures may be corrected.

A block diagram of the baseline, second generation personal supercomputer is shown in Figure 1. The scalar memory and scalar processor form the scalar execution unit (SEU). Scalar variables and all instructions are stored in the 32-bit wide scalar memory. A 32-bit wide scalar processor handles global address calculations, loop counts, and other scalar variables.

The parallel execution unit (PEU) contains a 4 x 4 matrix of array chip II-M's to provide 256 16-bit data processors, 128 32-bit processors, or 64 64-bit processors as configured by software at runtime. The array chips may be interconnected in many ways, but we will assume that they form 4 rows and 4 columns, with spiral connections between rows and between columns to form a modified nearest neighbor connection. The array may also be viewed one dimensionally as a single row.

Each array chip II-M in the PEU has 16 active 16-bit processors for data, 2 active 16-bit processors for address, 2 spare processors, plus on-chip RAM. The assignment of a processor, or cell, for address computation or data computation is made by configuration software at runtime. A 16-bit word is formed from a single cell. Thirty-two bit words are formed from a pair of adjacent good cells, possibly with a defective cell in the middle. Likewise, 64-bit words are formed from four good cells with intervening defective cells.

The on-chip RAM, nominally 1KW per processor, is a program - controlled cache; it is addressed by the 10 lsbs of the pair of address processors. The external DRAM, nominally 512KB per array chip, is for program-controllled page roll-in and roll-out of the cache, and is controlled by the pair of address processors, and may be viewed as a local staging memory.

The controller (C) provides instruction fetch and decode and drives the SEU and the PEU, providing a reduced instruction set for scalar and parallel processing. Operation of the SEU and PEU are mutually exclusive in order to simplify the design. Few applications seem to benefit significantly from their concurrentcy, and providing it is difficult.

We constructed a mechanical mockup of the CAP personal supercomputer to help us visualize the effect of surface mount technology. See Figure 2. The photograph was taken using a mirror so that components on both sides of the board may be seen. The two rows of eight large chips on the upper surface represent array chip II-M's. A combination scalar execution unit and controller (SEU/C) chip would also be on the upper surface. Four DRAM's external to each array chip would be on the lower surface, immediately behind the array chip.

The near-term technology projections for this second generation configuration design are shown in Table 1. A comparison of the first and second generation designs is given in Table 2.

Near-Term Technology Projections
for a Fault Tolerant CAP

11.Power Dissipation	250 watts	50 watts (est)

SYSTEM PERFORMANCE ESTIMATES

We calculate our architecture's maximum performance by assuming that all active parallel data processors are busy all of the time doing the quickest operation. Since this condition cannot occur indefinitely, due to the need for scalar operations, which are mutually exclusive with parallel operations, as well as iterative fixed-point operations and data-dependent masking, we derate the maximum to arrive at the peak values reported herein. We use a greater derating factor for fixed point than for floating point because the latter are inherently iterative but many fixed point are not.

For fixed-point operations:
256 16-bit processors x 12.5 MHz = 3,200 MIPS
Derating by 1/3 gives 2,000 MIPS
128 32-bit processors x 12.5 MHz = 1,600 MIPS
Derating by 1/3 gives 1,000 MIPS

For floating-point operations:
128 32-bit processors @ 1 MFLOP = 128 MFLOPS
Derating by 1/6 gives 100 MFLOPS
64 64-bit processors @ .375 MFLOP = 24 MFLOPS
Derating by 1/6 gives 20 MFLOPS

Performance estimates for 16-bit operations on a 256 by 256 data base are:

256 concurrent, 256-point complex FFTs - 7.5mS (rate of 1 per 30uS)
matrix transpose - 10mS
2-D FFT (real input) - 22mS
5 x 5 correlation - 2.5mS

ARRAY CHIP II-M

The basic idea for this chip is that one could take a DRAM, keep its common row decoder, strip off its column decoders, and directly couple a 256-bit wide bus to 16 16-bit processors, all on the same chip. Our fault tolerant design enables us to provide spare 16-bit processors and to widen the DRAM correspondingly in order to provide excellent chip yield, and thus keep the cost low. We would thus couple two fault tolerant designs, memory with spare rows and columns, and logic with spare processors.

Note, however, that there is common addressing for all of the memory on a chip. The address decoder is much too large to provide for each processor, plus it would be hard to have variable word sizes with matching memory addressing. Different chips may, however, may have different addresses. This is a compromise between the Goodyear MPP and the ICL DAP, where there is a single address for all of memory, since the memories are only one-bit wide, and loosely coupled microprocessors, where each processor can freely address its own memory. However, we do provide, at the expense of lowered efficiency, that processors on one chip may sequentially, independently, address the memory, as is valuable for matrix transpose operations.

Figure 3 shows the array chip II-M block diagram. We assume at least 256K bits of usable (320K bits total) on-chip DRAM are provided. The chip's key elements are the 20 (18 plus 2 spares) 16-bit processors, or logic cells, each of which is coupled to a 1K-word (or more) memory cell. All of the memory cells are addressed in parallel by the row decoder plus distributed group (1-of-4) decoders. The DRAM is used as a data cache and is program controlled.

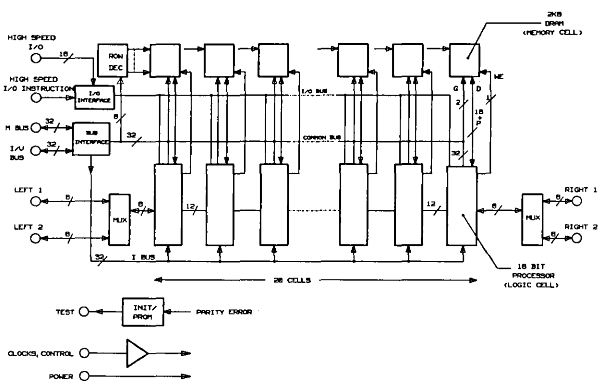

FIGURE 3

ARRAY CHIP II-M BLOCK DIAGRAM

We estimate that the array chip II-M/256K would contain 600,000 transistors, 2/3 of them in DRAM, and would have a die size of 500 x 600 mils in 1.25um double-metal CMOS. Later versions presumably would have a larger DRAM and thus substantially more (1,000,000+) transistors. While the typical process for a 256K DRAM is 1.5um, double poly, single-metal, we would use 1.25um and double-metal for the benefit of the logic cells.

The target clock rate is 12.5 MHz for a 32-bit, register-to-register ADD over 32 bits (two good cells with one bad in between). Iterative operations such as 2-bit multiply would use a 25 MHz clock. Note that we do word-serial arithmatic for multiply, divide and floating point operations, as explained later.

All memory cells simultaneously provide a word to their respective processor for a net transfer of 256 bits. In a conventional DRAM, many bits are fetched but only a few are output. This is terribly inefficient; the design of Video DRAMs recognizes this inefficiency. This combination of memory and logic on a single chip provides an enormous reduction in the number of chips and pins required to implement a system.

Manufacturing data, particularly the location of defects, would be stored in the INIT/PROM block at the time of factory testing. This data would be read by the system controller from each array chip II-M in turn when the system is turned on. Since the PEU is "defective", presumably having 1 or 2 bad cells per array chip, it must be "repaired"; the array chips do not repair themselves. Each array chip may be selected individually by an external decoder driving its chip select pin, and each cell may be selected by its physical address (0-19) in an array chip. Each cell in each array chip is turned off, to become invisible, or is set into the desired word configuration. The application may then refer to cells by their virtual address, 0-15, for data movement, independent of the physical locations of the defects. The configuration may also be changed as needed, such as following a diagnostic program that locates newly failed cells.

LOGIC CELL

The basic structure is a 16-bit slice, where in one cycle two operands are read from the multiport RAM (MPR), operated upon by the ALU and shift logic, and returned to the multiport RAM. The microinstruction set of array chip II-M (a "vector bit-slice" chip) resembles that of a collection of 64 AMD 2903 4-bit slice chips, plus memories and address logic. Register - to - register boolean operations are done in 80nS. Iterative multiply, divide, and floating point operations are done in a 40ns cycle. The logic cell block diagram is shown in Figure 4.

The path logic contains the mechanism for hiding defective cells, for connecting cells within a chip to form words longer than 16 bits, and for performing functions such as shift and rotate. A defective cell is bypassed, with data flowing over it as though it were not there. Extensive processor enable, or mask logic, controlling storage in both a logic and its memory cell, is also provided.

Words are configured by software at runtime by initializing the "configuration masks" in each logic cell. These masks are stored in the processor status word, along with the virtual cell ID, and control the flow of data within and between cells. The basic states of these masks are:

0. Inactive
1. 16-bit data
2. lsbs of 32-bit data
3. msbs of 32-bit data
4. lsbs of 32-bit address
5. msbs of 32-bit address

We have additional states to handle the assignment of a 16-bit cell to the 32-bit common bus, and to control the movement of data among processors.

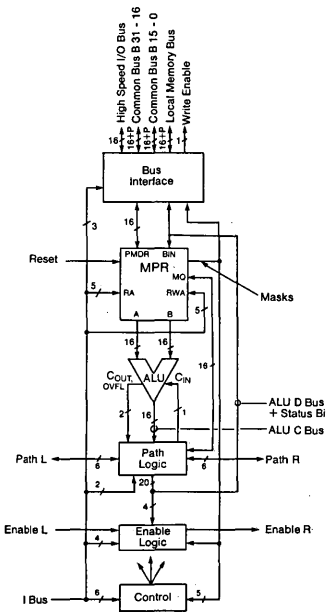

FIGURE 4

LOGIC CELL BLOCK DIAGRAM

MEMORY CELL

One memory cell, containing 2K bytes of storage, is provided for each logic cell. No provision is made for interconnection between one memory cell and other logic cells due to the complexity of interconnect that would arise. The memory cells share a common row decoder, as is found in ordinary DRAM designs. The two-bit group select from each logic cell selects one-of-four 17-bit groups (16-bits of data + 1-bit of parity) within a 256-row by 68-column memory cell. Spare rows, common to all cells, and a spare column per cell, improve the manufacturing yield. See Figure 5.

Although we assume the use of DRAM in this paper, the choice of DRAM or SRAM is based upon the availability of RAM technology to the design team, and the level of concern over soft errors. The general thought is that since no amount of memory is ever enough, the 4x (or higher for trench capacitors) density of DRAM over SRAM makes DRAM preferable.

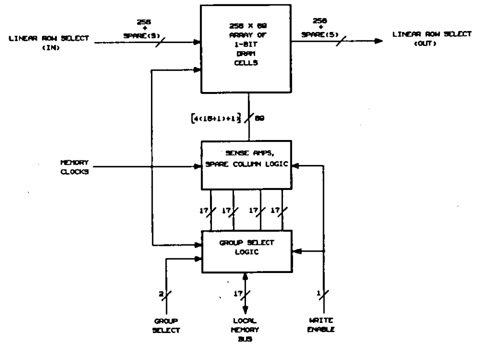

FIGURE 5

MEMORY CELL BLOCK DIAGRAM

PROGRAMMING MODEL

Unlike many array processors tnat are programmed only by microcode and are used to implement a library of Fortran-callable subroutines by a host, the CAP would run entire applications, written in assembly or high level language, often on live data. This would be possible because the CAP uses a simple, highly efficient, register-based, load/store architecture with deferred loads and jumps. The design of the instruction set is strongly influenced by the RISC[14] - reduced instruction set computer - philosophy. Our set contains only 33 basic instructions, including the load, store, arithmetic, logic, shift and program control. Instructions for configuration, scientific computation and SIMD support, such as interprocessor communication, are also provided.

From the system point of view, the programmer will begin a task on the host. The host would spawn a task that invokes a task on the CAP. The task on the CAP may be arbitrarily complex, accessing dedicated peripherals or communicating with the host operating system for file and user access.

Figure 6 shows a simplified programming model for the CAP. Each processor has sixteen registers, and each PEU processor has a local memory. All data processors have processor status words, and the PEU data processors have enabling masks (we call them vector if...else stacks - VIES). Notice the strong similarity to the programming models for ordinary, SISD, machines. This is in sharp contrast to today's supercomputers and array processors that have radically different programming models compared to SISD machines.

One easy way to visualize the CAP is as a collection of conventional SISD processors, each operating on its own data. The processors operate in lockstep and pass data to the left, right, up and down, to communicate in an organized fashion. Multiple concurrent FFTs or even recursive filters can be readily implemented. Fewer FFTs, each involving multiple processors, may also be done but with less efficiency. Implementing a perfect shuffle network on a fault tolerant grid is a problem that we have not solved.

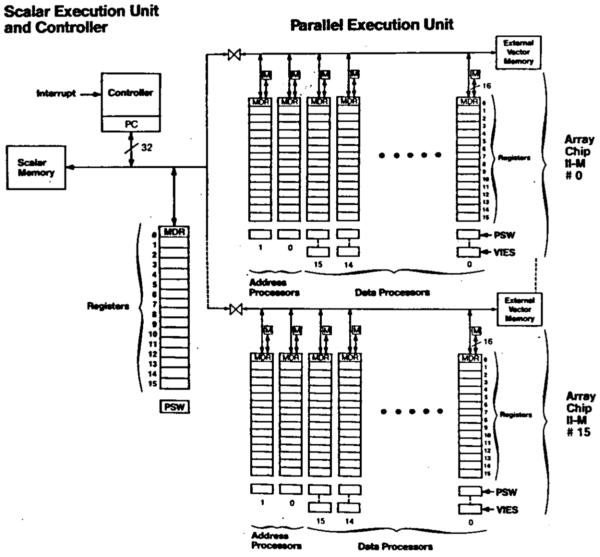

FIGURE 6

SIMPLIFIED PROGRAMMING MODEL

FAULT TOLERANCE IN THE CAP DESIGN

We recognized that the highly regular architecture of the parallel portion of a SIMD cellular array processor provides a design that is well suited to a fault tolerant design. (This realization occurred to us when our original chip design became too big to build any other way.) Just as DRAM's have employed spare elements for years, selected at the time of manufacture by a laser, our array chips provide a few spare elements selected at runtime by software. These spare elements may compensate not only for chip birth defects (from time of manufacture), but lifetime defects (wear out) as well, and are tied to our variable word size design.

Unfortunately, we have not found an efficient solution to the problem of fault tolerance in the common logic. Triple modular redundancy is too expensive for our tastes. Any failure in the scalar execution unit, controller, the power and clock distribution system, and the interconnections between chips will cause the failure of the system. We considered using error correcting codes on the microinstruction bus and data paths, but felt it was too much trouble. Furthermore, we have not found an efficient solution to detecting faults in the parallel execution unit other than running diagnostics. What we have done, however, is to use fault tolerance to reduce the cost of the largest portion of the system.

Having a few spare elements means we can increase the number of elements on a chip and maintain excellent yields. We thus need fewer chips, with fewer total interconnections to build a system. Mechanical connections, as from chip die to package to board, appear to be the least reliable portion of a system, so any attempt to reduce the number of connections should greatly improve reliability. The use of fault tolerance thus makes economic sense - it reduces the size and cost of our system.

ARRAY CHIP I

Array Chip I tested our fault tolerant technique. This device is our first-generation processor chip and is the basis for the prototype system we have built. See the chip photo in Figure 7. It uses 3um double metal CMOS technology and contains twenty 1-bit cells (in four groups of five cells for power distribution), of which only 16 are required for proper system operation, plus common logic and I/O buffers. Its block diagram is similar to the one for array chip II-M but without the DRAM, and its logic cell is similar to the one in array chip II-M, except the paths are 1-bit wide rather than 16. The locations of the bad cells are invisible to both the programmer, via cell bypass logic, and to the I/O pins, via an on-board, software - controlled, cellular switching matrix.

Array chip I has 120,000 transistors, 144 pins (many unused in our prototype system), a power consumption of about 500 mW, and a die size of 650 x 500 mils, the largest logic chip in the U.S. Any combination of word sizes, down to a single bit and upward without limit, extending across chip boundaries, may be selected by software with no external logic.

Its target clock rate for a 16-bit register-to-register ADD over 20 cells was 10 MHz, although its actual clock rate is closer to 3 MHz, due in part to miscalculated capacitive loading on clock buffers. Critical signal paths that use many pass transistors and that cross the entire chip make performance estimation particularly difficult. Our second generation, array chip II-M design, with closely contained critical paths, removes this latter difficulty.

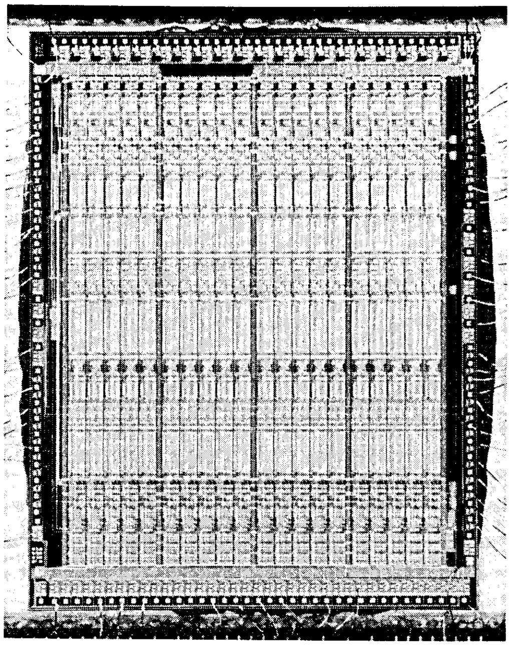

FIGURE 7

ARRAY CHIP I PHOTOGRAPH

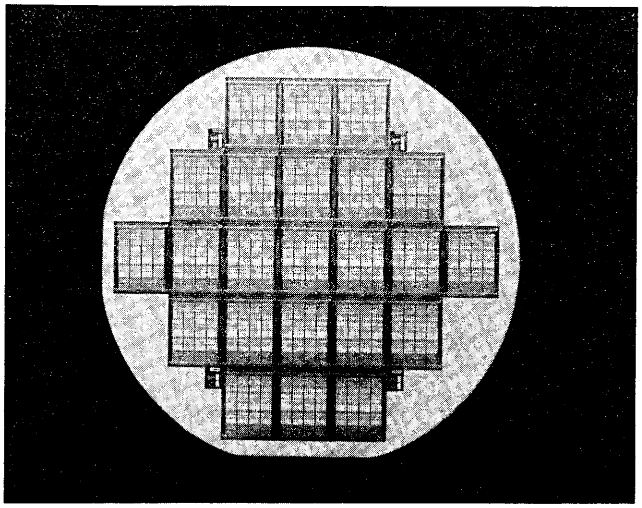

FIGURE 8

WAFER OF ARRAY CHIP I's

Array chip I may be viewed as 21 small chips rather than one large chip from a manufacturing yield point of view. Each of the 20 cells, plus one block of common logic, provide the 21 regions. Each cell area for yield analysis purposes is reduced by the small (10%) amount of critical logic area that must work, and the total amount of this critical logic area is added to the area of the non-fault tolerant common logic, which also must work. We estimated chip yields (at least 16 of 20 cells good) in the 25%-30% range, assuming 2 defects/cm^2, and we were happy to have this proven true. VLSI Technology Inc. fabricated our chips. The yield is the sum of all of the yields for the many combinations of 20 cells taken 16 at a time, times the yield of the common logic area.

A photograph of the array chip I wafer is shown in Figure 8, showing the large size of the dice. The 4" wafer contains only 23 array chip I dice (plus 4 small test dice), compared to a hundred or more for most designs.

Our first generation system prototype uses 36 array chip I's and has been in operation since late 1985. Four array chip I's form the scalar execution unit, providing 32-bit words for each of the address and data processors. Thirty-two array chips form the parallel execution unit, providing 16 16-bit processors, each with address and data units. A photograph of one of the wirewrap boards is shown in Figure 9. Twelve array chips I's, having large (and rotated) ceramic lids, form six of the parallel processors.

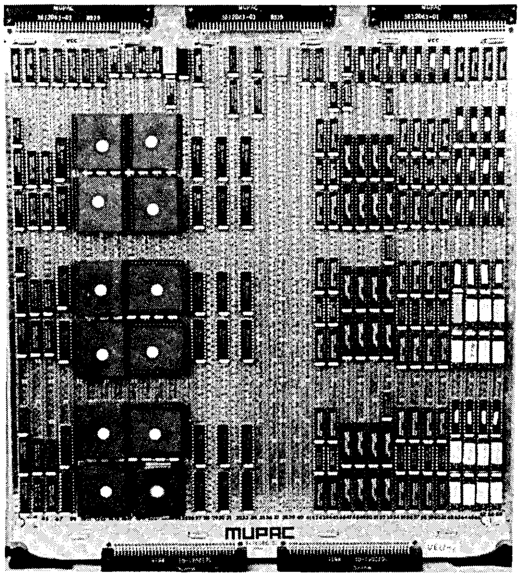

FIGURE 9

PROTOTYPE BOARD PHOTOGRAPH

EFFICIENCY OF DESIGN

We chose to use repetitive word-serial arithmetic for multiply, divide, and floating point operations. By word-serial we mean, for example, eight 2-bit ADD and SHIFT operations for a 16-bit by 16-bit multiply. This is in contrast to the parallel, often single-cycle, multipliers and floating point units that are common in many array processors. We did this for several reasons.

First, the amount of logic required and the amount of chip area required is much less for repetitive rather than parallel techniques. The yield of a processor element is inversely related exponentially to its size, so we want to keep the size small.

Second, we can support various word sizes. An add and shift structure grows linearly with the length of the word, requiring more cycles, whereas a parallel structure grows with the square of the word size. However, our throughput falls with the square of the word size for repetitive operations, since 2 cells are required for 32-bit operations, and twice as many cycles are required. Worse, we must lower the clock rate when switching from 32-bit words to 64-bit words. Our 16-bit timing is set at 32-bit cycle times because of instruction fetch limitations in the controller.

Third, the efficiency of a repetitive structure is higher than for a parallel structure. That is, there is a higher fraction of gates active for a larger portion of the time in a well-used repetitive structure than in a parallel structure. Consider a ripple-carry adder. Only one bit at a time is doing anything in the worst case carry propagation, as the carry flows from one bit to the next. There is no reasonable way to vary the clock rate depending upon when the summation is finished. Most of the adder is thus idle most of the time.

A parallel multiplier is similar. There is a wave of activity as the product formation flows through, but again, most of the gates are idle at any instant.

Thus, if one has a problem that can benefit from parallelism, the objective becomes to find a design that keeps most of the elements active and to increase the clock rate to get the most computation per unit area. This puts the speed burden on a small number of local registers, rather than on a larger, off chip memory.

This is an argument for memory hierarchy; the closer storage is to the arithmetic element, the smaller it may be and the faster it should operate. In array chip II-M we would have three levels: 16 registers, 1KW of cache, and 16KW of shared RAM, per parallel processor.

As a result of the increased number of processors that we may have per unit area of silicon because our structure is more efficient, we may keep more temporary variables in registers. This is a variation of the RISC philosophy. Thus instead of reading and writing vectors from and to RAM for each of a series of vector operations, we can be more like a systolic array, minimizing the number of memory transfers, by keeping temporaries in registers.

This enables us to use slower, denser, less expensive off-chip DRAMs rather than SRAMs. Further, the price and size disparity between SRAMs and DRAMs should be heightened as DRAMs become three - dimensional, using trench capacitors, for which there is no analogy in SRAMs.

NUMBER OF PROCESSORS PER CHIP

For a regular design that can use our cell bypass technique, one can increase the processing power per chip by increasing the number of cells so long as the I/O requirements to sustain those cells can be fulfilled. The memory on board array chip II-M, coupled to an I/O channel, is intended to help keep the cells busy.

Since the yield decreases as chip size increases for a non-fault tolerant chip, one may include some additional elements beyond the number required for a particular throughput. This further increases chip size, reducing the number of dice per wafer, but we found a broad range of choices. Better than a factor of ten improvement in yield may be observed. In addition, if one can use grade-outs, say chips with half of the cells good, one may opt for fewer spares. Thus we went from four spares to two in going from array chip I to array chip II-M, although decreased defect densities over the last few years increase our conviction for doing so.

A limit on chip size is set by the capability of the photolithographic equipment that exposes the wafers. In 1984, for 3um features as used by array chip I, one had 10x or 1x reticles; that is, the mask is ten times or one time the size of the die. A 10x wafer stepper can only build up to a 400 x 400 mil chip. A 1x stepper can build a chip the size of the wafer. For 1.25 um features, as would be used by array chip II-M, one generally uses a 5x stepper, limiting the size to 800 x 800 mils. Building a single device bigger than that size would require tiling the device with multiple sub-chips that are minimally interconnected due to alignment problems between them.

We might have built array chip I with few enough processors to achieve a chip size that was considered an upper limit, 400 x 400 mils. Instead, driven by an interest in wafer scale integration, we addressed the issue of what constitutes a limit on size. We were fortunate in being able to translate our interest in a highly regular, cellular array structure with bit-parallel, variable size words, into bypassable, fault tolerant cells.

NUMBER OF BITS PER PROCESSOR

The MPP, DAP, GAPP, and Connection Machine all have one bit per processor. Our array chip II-M would have 16 bits, and we use array chip I as though there is a single 16-bit processor.

We found how inefficient it is to build wide words in space from 1-bit cells. Holding fabrication technology constant, one can build a 16-bit cell in about twice the area of our 1-bit cell. The inefficiency in our one-bit cell results from the very high overhead that we paid to string one-bit cells side-by-side to build words of arbitrary size.

If, however, one is content to build long words in time, by using multiple cycles rather than multiple cells, which is better? The answer seems to lie in the amount of parallelism that one can use effectively, and the degree of freedom that one would like to have in addressing memory.

One reason that we went to 16-bit words was so we could afford some flexibility in addressing memory. We can accept having all parallel processors reference the same register, but having all the processors reference the same cache or bulk memory location severely limits the efficiency of many operations, such as matrix transpose, which needs a diagonal of addresses. No processor using 1-bit elements can afford to independently address each bit of memory. We can not afford in array chip II-M to have all processors independently address each 16-bit word, but at least each array chip may form a different address. We can then do time-division multiplexing between processors within an array chip, with 1/16 efficiency, to independently address the cache or external DRAM.

We also considered 8-bit and 32-bit cells. We had no applications for 8-bits, and the yield improvement of the smaller cell was insignificant. We liked 32-bits for floating point, but would have lost half our capability at 16-bits which we wanted for image processing, and the cell would have been bigger than we liked. So we chose 16 bits, with the provision that a pair of cells may work together to form 32-bit words, and the provision that a defective cell may be between them.

ONE-DIMENSIONAL FAULT TOLERANCE

The key to fault tolerance in array chip I and array chip II-M is that bad cells are invisible. Data flows across them from the left to right and vice-versa as though the cell were not there. Array chip I has five so-called horizontal paths, and array chip II-M would have twelve. These paths are local, from the left of cell N to the right of cell N+1, and are easily implemented. The implementation of a 2-dimensional bypass network, however, is extremely cumbersome as we found on the I/O pin reconfiguration logic on array chip I which connects good cells in one chip to good cells in another chip regardless of the locations of defects.

DIRECTIONS FOR FUTURE WORK

One of the most difficult problems is how to interconnect processors. We are currently limited to two-dimensional structures on the surface of a chip or board. The application of optical communication through stacks of wafers, unknown today, would give us a third dimension and should pave the way for far more powerful and more compact structures. Enormously parallel processors with capabilities in the near teraFLOP region and with multi-gigabit I/O rates, dissipating only 10KW, and contained in a liquid-cooled, six inch diameter cylinder six inches long are conceivable[15].

CONCLUSION

We have demonstrated a first generation, and defined a second generation, cellular array processor using large area integration chips for the parallel execution unit - the bulk of the system. These chips are feasible only because of their fault tolerant design. We believe that the high performance, low cost, and small size that result from the use of these or like chips will dramatically improve the price, performance, and reliability of cellular array processors.

ACKNOWLEDGEMENTS

Many people contributed to the project from its inception in 1981 until its prototype

demonstration in 1985. Figure 10 shows the team that was closely involved at the time of the demo. Particular recognition goes to the project founder, Jack Cotton (not shown), and the division director, Santanu Das (not shown) for their belief in the project.

BIOGRAPHY

Steven G. Morton was born in Yokosuka, Japan, in 1949. He is a member of the IEEE and is married, has two children, and lives in Oxford, Connecticut. He is the architect of the CAP on which he has filed for 15 patents. He joined ITT in 1979, and his first responsibility was the construction of a digital signal processor for the ITT System 12 Digital Switch. Prior to ITT, he was with the MIT Lincoln Laboratory where he worked on attitude control and ground - based telemetry systems for the LES-8 and LES-9 Air Force communication satellites. He received his BSEE and MSEE from MIT in 1972, where he specialized in computer architecture. He is now in Central Research at ITT studying the limits of optoelectronics.

IMPLEMENTATION OF PARALLEL PROLOG ON TREE MACHINES

Abstract

In this paper, parallel algorithms to control the execution of Prolog programs on tree machines are proposed, and their efficiencies are compared through simulation experiments. The model of the tree machine used in this experiment consists of a single-tree engine, a multiplexer, and a system controller. The single-tree engine is a common part of tree machines and has generality. From the experimental results through simulation, it appears that if the given problem has enough parallelism, then high performance can be obtained by the algorithms proposed in this paper. While a better utilization of processing elements and a better load balancing are future research problems, tree machines are found to be suitable for parallel implementation of Prolog.

Key Terms: Prolog, knowledge-based problems, tree machines, logic programming, multiprocessor systems, parallel algorithms.

I. Introduction

Logic programming is one of the best methods to formalize and solve knowledge-based problems [Nils80]. Prolog is a logic programming language based on first order logic [Kowa79], where knowledge is represented by a set of facts and a set of inference rules. The ICOT (Institute for New Generation Computer Technology) started its research project for the Fifth Generation Computing Systems (FGCS) in 1982 under the auspices of MITI (Ministry of International Trade and Industry) of Japan [Moto82], [Feig83]. Prolog is supposed to be the kernel language of the new computer systems in its project.

One of the main difficulties in solving knowledge-based problems is that many of them are NP-hard, that is, the computation time needed to solve these problems on a conventional sequential computer will increase exponentially as the problem size increases. One of the best solutions to overcome this difficulty is to implement special purpose multiprocessor systems for logic programming. If the problem has enough parallelism, the computation time to solve these problems on such systems will be effectively reduced as the number of processing elements (PE's) is increased.

Multiprocessor systems can be classified in two categories. The first includes **tightly coupled systems** where PE's are connected through shared common memories; and the second includes **loosely coupled systems**, where PE's are connected through message links.

One of the advantages of tightly coupled systems is that the communication between PE's can be quickly executed if the number of PE's is small. However, if the number of PE's is large, the performance of communication among PE's tends to be reduced due to memory access contention. Another disadvantage of tightly coupled systems is that their system software tends to be harder to design and implement compared to the loosely coupled systems. As a consequence, the construction of efficient tightly coupled systems that have a large number of PE's is more difficult.

Loosely coupled systems are designed to avoid these problems. Though the message transfer rate between PE's of these systems is slower than that of tightly coupled systems with a small number of PE's, loosely coupled systems have some advantages. One is that access contention for message transfer can be reduced; and another is that system software is relatively easy to design and implement due to its modularity. Therefore, it is easier to construct loosely coupled systems that have a large number of PE's.

The choice of interconnection topology is one of the critical problems in constructing efficient loosely coupled systems. In regard to the interconnection topologies for loosely coupled systems, various possibilities have been proposed. They include: ring, mesh, hypercube, and tree structures. Interconnection topologies based on tree structure seem to be efficient for solving knowledge-based problems because the computation process for solving these problems can be naturally represented in the form of a tree.

Another important key to constructing efficient loosely coupled systems is the design of parallel algorithms that fit the interconnection topology of the system. In this paper, several parallel algorithms to control the execution of Prolog programs on tree machines are proposed, and their efficiencies are compared through simulation experiments.

The model of the tree machine used in this experiment consists of a single-tree engine, a multiplexer, and a system controller. The single-tree engine is a common part of tree machines and has generality. From the experimental results through simulation, it appears that if the given problem has enough parallelism, then high performance can be obtained by the algorithms proposed in this paper. While a better utilization of Processing Elements and a better load balancing are future research problems, tree machines are found to be suitable for parallel implementation of Prolog.

II. Parallel Processing Schemes for Prolog

2.1 Prolog Programs

A Prolog program consists of a database and a question. The database consists of a set of facts, which represent properties of objects and/or relations among objects, and a set of inference rules, which are used to obtain an answer to the question. As an example, consider the following database.

Example 1

```
1:   offspring (John, Matt).
2:   offspring (Matt, Don).
3:   descendant (*X, *Y) :-
          offspring (*X, *Y).
4:   descendant (*X, *Y) :-
          offspring (*X, *Z),
          descendant (*Z, *Y). []
```

In this example, constant objects (John, Matt, and Don) are assumed to begin with alphabets, while variables (*X, *Y, and *Z) are assumed to begin with an asterisk.

The database in Example 1 describes the facts (lines 1 and 2):

1: "Matt" is an offspring of "John";
2: "Don" is an offspring of "Matt";

and the inference rules (lines 3 and 4):

3: If *Y is an offspring of *X,
then *Y is a descendant of *X;
4: If, for some *Z, *Z is an offspring of *X
and *Y is a descendant of *Z,
then *Y is a descendant of *X.

A question to the database is of the form like:

?- descendant (John, *A),

which means "Who are descendants of John?" The answer to this question will be:

*A=Matt;
*A=Don;

which means "Matt and Don are." And if a question:

?- descendant (John, Don),

which means "Is Don a descendant of John?" is given, the Prolog system will reply:

yes.

A question to the Prolog system is also called a **goal clause.**

2.2 Parallel Processing Schemes

An inference process in Prolog can be represented in the form of a state space search tree. As an example, the state space search tree that corresponds to the question "?- des(John, *A)" to the database of Example 1 is shown in Figure 1. In this figure, each node (box) represents a sub-goal of the given goal (or in other word, a sub-question of the given question). Each edge represents the super/sub relation between two goals; and the number on the right hand side of each edge represents the applied rule number. Here, "off" and "des" represent the relations "offspring" and "descendant" respectively.

Several parallel schemes for processing Prolog programs have been studied. They include: **OR-Parallel Scheme, AND-Parallel Scheme, Stream-Parallel Scheme,** and **Search-Parallel Scheme** [Cone81]. The basic idea of the **OR-Parallel Scheme** can be explained in the following way. The sub-goals in the state space search tree can be solved independently if there is no side effect; that is, each fact and inference rule can be unified at the same time. For example, clauses "off(John,*A)" and "off(John,*Z), des(*Z,*A)" in Figure 1 can be processed simultaneously.

In the **AND-Parallel Scheme,** all literals in the goal clause are unified to the corresponding literals in the right hand side of a inference rule. For example, two literals "off(John,*Z)" and des(*Z,*A)" in the clause

"off(John,*Z), des(*Z,*A)"

of Figure 1 can be unified at the same time. While this scheme introduces more parallelism then the OR-Parallel Scheme, this scheme could be inefficient because all possible combinations of values should be assigned to the variables included in the literals and investigated whether or not the assignment causes a contradiction.

The **Stream-Parallel Scheme** is one of the methods to realize the AND-Parallel Scheme. In this scheme, every literal is treated as an independent process, and each common variable is treated as a message channel. For example, "off(John,*Z)" and "des(*Z,*A)" in the "off(John,*Z), des(*Z,*A)" are considered as two independent processes, and "*Z" is considered as a message channel. However, efficient implementation of this scheme awaits future research.

In the **Search-Parallel Scheme**, the database is decomposed into subsets and they are placed in different PE's. The goal clause is sent to each PE and then examined simultaneously.

Because the OR-Parallel Scheme is the easiest to implement, many parallel Prolog systems are based on this scheme [Aida83], [Yasu83], [Maru84]. However, parallel Prolog systems based on the Stream-Parallel Scheme are also studied [Ito_84], [Onou85]. These systems are supposed to execute the programs written in Concurrent Prolog [Shap83].

```

III. Tree Machine Model

3.1 Conventional Tree Machines

Tree machines are loosely coupled systems where PE's are connected to form a tree structure. In these machines, each PE has its own local memory unit and works independently. Messages are transferred between PE's through message links that connect them. One of the advantages of tree machines in problem solving is that the structure of these machines fit the state space search trees of problems.

Though tree machines fit state space trees, there are several drawbacks to tree machines. One of them is that the load tends to concentrate at PE's near the root of the tree. Load balancing is one of the critical problems in designing efficient algorithms for tree machines.

Typical structures of tree machines are shown in Figure 2. In this figure, circles and rectangles denote PE's, and arrows denote the message links. Messages are transferred along the direction of these arrows. System (a) is the simplest model called a single-tree machine [Brow80], [Taka81], [Shaw81], and [Stol82]. DADO [Stol82] and NON-VON [Shaw81] are designed for production systems and expert systems. System (b) and (c) are called double-tree machines, which include Bentley's machine (b) for database operations such as sorting and searching [Bent79], and the DON System (c) for combinational optimization problems [Imai84].

The double-tree machines have several advantages over the single-tree machines. In the single-tree machines, messages are transferred in both directions of the message links, while they are transferred in only one direction of the message links in the double-tree machines. As a result, effective bandwidth of a message link in the double-tree machines is twice as wide as that in the single-tree machines. And it is easier to implement algorithms that have pipeline features on double tree machines than single-tree machines. Therefore, double-tree machines will have better performance than single-tree machines. Other advantages of double-tree machines are discussed in the literature [Imai84].

3.2 The Tree Machine Model

The model of the tree machine used in the simulation experiment is shown in Figure 3, which consists of a single-tree engine, a multiplexer, and a system controller. The reason behind the selection of this model is that the single-tree engine is a common part to all tree machines and has generality. The system controller is involved in this model in order to improve the efficiency of the tree machine.

In this model, it is assumed that messages can be transferred through the multiplexer quickly enough not to affect the efficiency of the computation in the single-tree engine and the system controller. Note that this model is more efficient than other tree machines under this assumption.

Especially, in the single-tree machine, messages must be transferred in both direction of the message links, which causes conflicts at PE's. Therefore, single-tree machines will be less efficient than this tree machine model. And double-tree machines will be about as efficient as this tree machine model.

IV. Prolog Implementation on Tree Machines

4.1 Observation

The process in which a Prolog program is executed can be represented in the form of a state space search tree like Figure 1. Comparing the structure of this tree with the interconnection topology of the tree machines, the following observations can be made. First, while the number of successors of a node in the state space search tree is indefinite, internal PE's of the tree machines have up to two successors or up to two predecessors (in the case of double tree machines).

Secondly, the depth of a leaf node of a search tree is also indefinite. As a consequence, it would not be effective to map a search tree directly to a tree machine, because some of the nodes of the search tree could not be assigned to PE's and the load of PE's would not be balanced. Therefore, it is important to design efficient algorithms that distribute the load to the PE's as evenly as possible.

4.2 Assumptions

For the rest of this paper, the OR-Parallel Scheme is implemented because the OR-Parallel Scheme is the easiest to implement on multiprocessor systems. The purpose of the simulation experiment is to investigate the efficiency of tree machines in the application to parallel Prolog implementation. Evaluation of other parallel schemes awaits future work.

The implementation of Prolog in this paper is an extension of the scheme for the DON System as proposed by Sano, et al. [Sano84]. In this scheme, programs are written in "pure Prolog," where no side effect is allowed and no "cut operator" is used. The outline of the OR-Parallel Scheme used in this experiment is as follows. Further details of this Scheme are shown in the literature [Miur85].

(1) The unification operation is executed simultaneously in each PE and the database of the program is stored in each PE prior to the execution.

(2) Each PE has an input queue to store the messages. A message sent from the predecessor PE is placed at the tail of the input queue, and the PE gets a message from the head of the queue in the order of arrival.

(3) If the depth of the state space search tree is deeper than that of the processor tree, the unsolved sub-goals are resent to the root PE and processed in the processor tree in the pipeline manner.

(4) The Prolog interpreter uses the "copy method" instead of the "structure sharing method." The source program is converted into an intermediate form. The goal clause is also converted into the intermediate form.

4.3 Decomposition of the Set of Unifiable Clauses

When a goal clause is examined in the tree machine, the set of unifiable clauses is decomposed into two or three subsets in order to make the load of each PE balanced. There are two decomposition methods used in the experiments.

Method D-2 (Decomposition into two):

Decompose the set of unifiable clauses into two subsets that have as equal a number of clauses as possible; then, send them to successors. []

Method D-3 (Decomposition into three):

Keep one of the clauses for the PE, and decompose the rest of the clauses into two subsets that have as equal a number of clauses as possible; then send the subsets of clauses to successors. []

The difference between Methods D-3 and D-2 is that one of the unifiable clauses is kept for the PE in Method D-3. As an example, suppose that a goal clause can be unified with clauses #1 through #5. In Method D-2 (decomposition into two), clauses #1 through #3 will be sent to the left successor and clauses #4 and #5 will be sent to the right successor. On the other hand, in Method D-3 (decomposition into three), clause #1 is kept for the PE, clauses #2 and #3 are sent to the left successor, and clauses #4 and #5 are sent to the right successor.

4.4 Control Procedures

Though the use of Method D-3 is expected to reduce the message transfer overhead, it is possible that the PE's near the root of the tree become a bottleneck. To avoid such a situation, the control procedures switch the use of these decomposition methods according to the following information:

(1) Depth of the PE, and
(2) Number of goal clauses stored in message queues.

However, in the leaf PE's, Method D-3 is always applied in order to make the leaf PE's as busy as possible. Because the number of leaf PE's is about the half of that of all PE's in the system, this strategy will yield a better utilization of PE's.

Definition

Let d(i) be the depth of PE#i, which is defined as the path length from the root PE to PE#i. And let q(i) be the number of goal clauses stored in the message queue of PE#i. []

Three control procedures D, Q1, and Q2 for the non-leaf PE's are given in the following way.

(1) Control Procedure D

The basic idea of procedure D is to divide the set of PE's into two subsets. Then, Method D-2 is used in the PE's which are near to the root PE, while Method D-3 is used in the PE's which are far from the root PE. More formally, this procedure is described as follows.

Control Procedure D:

```
Let $D_t$ be a positive parameter.
If $d(i) \geq D_t$ then use Method D-3;
otherwise, use Method D-2. []
```

(2) Control Procedure Q1

In procedures Q1 and Q2, the number of messages in PE's are used to switch the decomposition procedures. In procedure Q1, if the number of messages in the PE does not exceed the given threshold, then Method D-3 is used; otherwise Method D-2 is used. Procedure Q1 is described as follows.

Control Procedure Q1:

```
Let $Q_t$ be a positive parameter.
If $q(i) \leq Q_t$ then use Method D-3;
otherwise, use Method D-2. []
```

(3) Control Procedure Q2

Control procedure Q2 takes advantage of the number of messages in the successor PE's. Let PE#j and PE#k be the successor PE's of PE#i. The number of messages in the message queues of the PE#i, PE#j, and PE#k are used to switch the decomposition method. After the decomposition, sub-goals are sent to the successors so that the number of messages in the message queues of PE's #j and #k becomes as equal as possible. There are three variations of this method.

Procedure Q2-a:

```
If $q(i) \leq q(j)$ or $q(i) \leq q(k)$
then use Method D-3;
otherwise, use Method D-2. []
```

Procedure Q2-b:

```
If $q(i) \leq q(j) + q(k)$ then use Method D-3;
otherwise, use Method D-2. []
```

Procedure Q2-c:

```
If $q(i) \leq \min[\, q(j), q(k) \,]$
then use Method D-3;
otherwise, use Method D-2. []
```

V. Simulation Experiments

5.1 Assumptions

Simulation experiments have been conducted to investigate the efficiency of the tree machines that execute Prolog programs. The following assumptions have been made in the simulation experiments:

Assumption 1
Any number of messages can be stored in an input queue of a PE. []

Assumption 2
The computation time needed to manipulate the message queue (such as insert and remove) is small enough to ignore compared to the computation time needed to process a clause. []

The unit of the computation time is the time needed to move one Byte of data between memory cells. The computation time needed to compare two data items (one Byte each) is assumed to take **one unit** of time, and the computation time to transfer one Byte of data item between adjacent PE's is assumed to take **two units** of time because the message link is slower than the internal bus in a PE.

Let T(n) be the computation time required to solve a problem by a tree machine that has n PE's. Then the **speedup rate Rs**(n) of the tree machine is defined by:

$$Rs(n) = T(1) / T(n)$$

Note that the minimum configuration of the single-tree engine has only one PE.

The following test problems were solved in the simulation experiments:

(1) Quicksort for 50 items [Okun84],
(2) Ancestor/descendant database search problems [Sano84],
and
(3) N-Queens problems [Okun84], where all solutions are searched.

5.2 Experimental Results

Experimental results for the above problems are summarized in Figures 4 through 7. In each figure, the x coordinate denotes the number of PE's in the single-tree engine of the tree machine model, on a log scale; and the y coordinate denotes the average speedup rate (Rs), also on a log scale. From these figures, the following observations can be made.

(1) Quicksort

The results for the quicksort problem for the control procedure Q1 are summarized in Figure 4. The speedup rate of the system did not exceed 1.5, due to the lack of parallelism in the quicksort algorithm. The results when control procedures D and Q2 are used are almost the same as those shown in Figure 4.

(2) Ancestor/Descendant Database Search

The results are summarized in Figure 5. Here, the results for the control procedure D are shown in Figure 5 (a), and the one for the control procedure Q1 are shown in Figure 5 (b).

When control procedure D is used, the best speedup rate was obtained by setting $D_t = 1$. And better speedup rates were obtained by setting $D_t = 2$, 0, and 3, in this order. When control procedure Q1 is used, almost the same best speedup rate was obtained by setting $Q_t = 1$, 2, or 3, except 0. The results when control procedure Q2 is used are almost the same as those shown in Figure 5 (b).

(3) N-Queens Problems

The results for the 5-Queens problem are summarized in Figure 6. Here, the results for the control procedure D are shown in Figure 6 (a), and the one for the control procedure Q1 are shown in Figure 6 (b). When control procedure D is used, the best speedup rate was obtained by setting $D_t = 3$.

When control procedure Q1 is used, the speedup rate was only slightly affected by the value of parameter Q_t. The results when control procedure Q2 is used are almost the same as those shown in Figure 6 (b).

(4) The Effect of the Amount of Parallelism in the Problems

The efficiency of the control procedure is affected by the properties of problems being solved. The speedup rates of the tree machine for the 5-Queens Problem and the 6-Queens Problem are shown in Figure 7. The control procedure used in this experiment is Q1 with $Q_t = 0$.

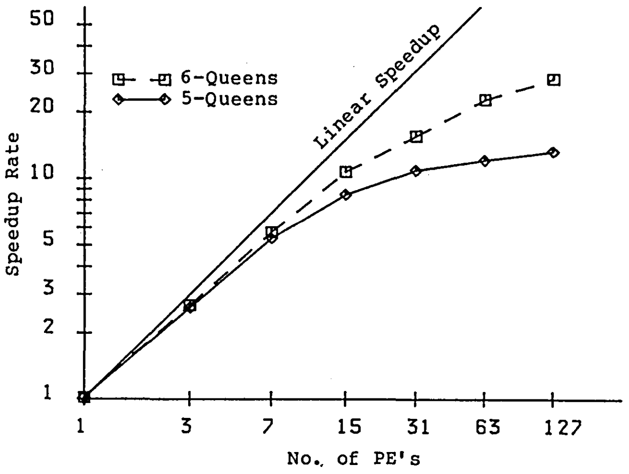

Figure 7 - Comparison of the Speedup Rates for 5-Queens Problem and 6-Queens Problem
(Control Procedure Q1 with $Q_t = 0$)

5.3 Discussion

From the above observations, the following discussion can be made.

(1) The Choice of Control Procedure

Comparing this result with that of the database search problems, it is known that the optimum value of parameter D_t changes depending on the problems to be solved. And the efficiency of control procedure D is also affected by the types of problems to be solved. Though this procedure might bring the best results by chance, it does not steadily yield a good efficiency. Therefore, it is not considered the best method.

On the other hand, control procedures Q1, Q2-a, Q2-b, and Q2-c show similar results. The value of the parameter Q_t slightly affects the efficiency of the control procedure Q1. In regard to the ancestor/descendant relation database search problem, procedure Q1 is a little more efficient than Q2 procedures. In conclusion, control procedure Q1 is considered the best method among procedures D, Q1, and Q2's.

(2) The Effect of the Amount of Parallelism in Problems

Comparing the results of the Quicksort Problem (Figure 4), 5-Queens Problem, and 6-Queens Problem

(Figure 7) with each other, it is known that the speedup rate of the tree machines is improved for larger problems which have more parallelism. The efficiency of the tree machine is affected by the possible parallelism included in the problems to be solved. If the problems have enough parallelism, the tree machines show a good speedup rate compared to the number of PE's.

(3) Comparison with Other Machines

The speedup rate of the tree machine model is comparable to that of another parallel inference machine PIM-R designed by ICOT [Onou85], where the speedup rate of the PIM-R machine is up to three times as fast for nine PE's. Comparison with other machines, such as DADO or NON-VON, awaits future work.

(4) Load Balancing

In regard to the load balancing, the load tends to be concentrated at PE's near the root of the tree, depending on the problems being solved. Especially, in problems like the Ancestor/Descendant Database Search Problems where the branching factor is large, the load still tends to be concentrated at the root PE.

For example, according to the simulation results, when these problems are solved on the tree machine with 127 PE's (except the system controller) with the control procedure Q1 ($Q_t = 0$), the maximum and average number of messages stored in the message queue of the root PE were 39 and 14 respectively.

Accordingly, the efficiency of the tree machines could be improved by developing more sophisticated control procedures than those proposed in this paper. The improvement of algorithms is one of the future research problems.

VI. Conclusion

In this paper, a tree machine model was described to implement parallel Prolog schemes. Then, an OR-parallel Scheme for Prolog implementation was shown, and several control procedures were proposed in order to make the load better balanced. Finally, the efficiencies of these control procedures were compared through simulation experiments.

Among the proposed control procedures, Procedure Q1 showed the best results, which switches the decomposition methods according to the number of messages in the message queue. Though the efficiency of the tree machine is affected by the potential parallelism included in the problems, if the problems have enough parallelism, the speedup rate of tree machines is comparable to that of other multiprocessor systems that have been investigated.

In conclusion, tree machines are promising candidates for future super computer systems that solve complicated knowledge-based problems.

The following will be included in future research projects:

(1) Introduction of control structures to Prolog which play the role of the "cut" operator.
(2) Study on the implementation of the predicates that cause side effects, such as database manipulation operations.
(3) Development of more sophisticated algorithms that achieve better load balancing and better utilization.
(4) Study on the implementation of the AND-Parallel Scheme, in particular the Stream-Parallel Scheme, on tree machines.
(5) Study on the parallel Prolog machines based on the Search-Parallel Scheme, that have a distributed database system.

Acknowledgements

The authors would like to thank Mr. Sano of Sony Corp. who designed the preliminary version of the simulation program as a part of his Master's project. The authors are also grateful to President Honda of Toyohashi University of Technology and Prof. M. Everson of Nagoya University for their helpful comments and encouragement. OPTIMAL GRANULARITY OF PARALLEL EVALUATION OF AND TREES

ABSTRACT

AND-tree evaluation is an important technique in artificial intelligence and operations research. An example is the divide-and-conquer algorithm, which can be considered as the evaluation of a precedence graph consisting of two opposing AND-trees. In this paper, the optimal granularity of parallelism of AND-tree computations is quantitatively analyzed. The efficiency analysis is based on both preemptive and nonpreemptive critical-path scheduling algorithms. It is found that the optimal grain depends on the complexity of the problem to be solved, the shape of the precedence graph, and the task-time distribution along each path. The major results consist of tight bounds on the number of processors, within which the optimal grain can be sought efficiently. In view of the optimal granularity, architectural requirements for parallel AND-tree evaluations are also discussed.

INDEX TERMS: AND trees, critical-path scheduling, divide-and-conquer algorithms, granularity, processor-time efficiency, processor utilization.

1. INTRODUCTION

A wide class of problems arising in artificial intelligence, operations research, decision making, and various scientific and engineering fields involve finding a solution of a problem, which is made up of a large number of subproblems to be solved. Solving these subproblems can be represented as AND-tree computations. Examples include evaluating arithmetic expressions, searching possible solution trees of logic programs, evaluating functional programs, scheduling operations in assembly lines, finding the extremum, merge-sorting, and quick-sorting.

There are two kinds of AND-trees, *intrees* and *outtrees*. In an intree (resp. outtree), each node has at most one immediate successor (resp. predecessor), and the root is an exit node (resp. entry node). The intrees and outtrees specify the precedence relationships among the nodes. Every node is reachable from the entry node for an outtree or can reach the exit node for an intree. In recursive computations, such as divide-and-conquer algorithms, a problem is partitioned into smaller and distinct subproblems, and the solutions are found for the subproblems and are combined into a solution for the original problem. The procedure is applied recursively until the subproblems are so small that they can be solved directly. In this way, the evaluation can be viewed as a process with two phases, the decomposition of subproblems based on an outtree and the composition of results based on an intree. Hence, the precedence graph is composed of an intree and an outtree. We call this particular graph an *outin tree*. Deterministic programs can be represented by outin trees. Functional programming, which is considered as an important programming style to resolve the von-Neumann bottleneck, deals exclusively with AND-graphs [1]. Similarly, data-flow graphs are AND-graphs [7].

Outin trees have the following characteristics. First, there is no cycle in an outin tree. Second, in contrast to general forests, an outin tree consists of one outtree and one intree and have a one-to-one correspondence of all the leaves in the two trees. We call these leaves the ***leaves of the outin tree***. In this paper, we will mainly discuss outin trees. However, the results derived apply to intrees and outtrees as well. Here, AND-trees and outin trees are used synonymously. Figure 1(a) illustrates an outin tree, which reflects the precedence relationships among tasks in a merge-sort problem shown in Figure 1(b) to sort six elements. The nonterminal nodes in the outtree part represent decompositions, each of which split a (sub-)list into two smaller sublists, whereas the nonterminal nodes in the intree part represent composition, each of which generate a sorted list based on two smaller sorted sublists.

Evaluation of outin trees naturally suggests implementation on parallel computers due to the independence of subproblems. AND-tree evaluations are important in evaluating logic programs, especially when parallel processing is used [5]. Studies conducted on parallel computers for executing divide-and-conquer algorithms can be classified into three types. First, multiprocessors that are connected in the form of a tree, especially a binary tree, can be used to exploit the potential parallelism of divide-and-conquer algorithms [13, 23]. A second approach is the virtual tree machine [2], which consists of a number of processors with private memory connected by an interconnection network, such as the binary n-cube, and a suitable algorithm to decide when and where each subproblem should be solved. The third approach is a variation of the above approaches using a common memory. All processors are connected to the memory by a common bus [14].

To evaluate an AND-tree in parallel, it is necessary to schedule the subproblems to achieve high throughput and processor utilization. An important problem is to determine the proper granularity of parallelism, that is, the minimum size of a subproblem that should be computed by a single processor. If the grain is too large, then the processors can be loosely coupled but may be under-utilized. In contrast, if the grain is too small, then the processors can be better utilized, but tight coupling may be necessary, and the communication overhead may be prohibitive. The grain must be properly chosen to obtain a proper balance between processor utilization and communication overhead.

In previous studies, one can find different points of view on the issue of granularity. Some researchers advocate a fine grain, while others suggest a coarse grain. For example, in designing the FFP machine [21], a small grain is chosen based on the hypothesis that appropriately designed small-grain multiprocessors will prove superior to large-grain ones in supporting ease and generality of parallel computations. In contrast, in

Figure 1. The merge-sort problem represented as an outin tree.

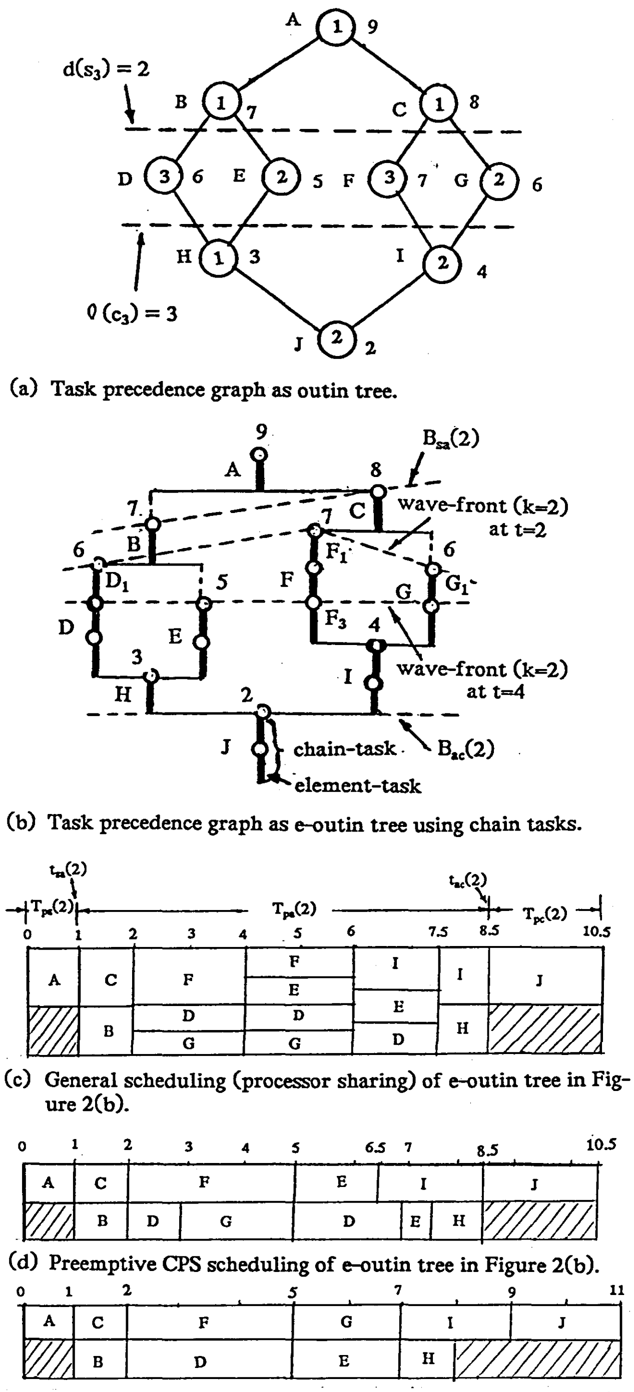
Rediflow [17], large-grain parallelism is used to minimize communication overheads. Moreover, most previous studies on granularity were discussed qualitatively. In this paper, we will analyze the optimal granularity of parallel evaluation of outin trees quantitatively. We will identify the factors that influence the optimal grain, in particular, the relationship between the optimal granularity and the problem complexity.

2. SCHEDULING PARALLEL OUTIN-TREE EVALUATIONS

To analyze the optimal granularity of parallel evaluation of outin trees, an asynchronous model for parallel computation is adopted here. The precedence graph of an outin tree is oriented such that the entry node is at the top of the figure and the exit node is at the bottom. An arc is assumed to be always directed towards the bottom of the graph. The number inside a node is the task execution time, while the number next to a node, called its *length*, is the sum of the task execution times for nodes in the longest path from this node to the exit node. Figure 2(a) is an example of an outin tree.

The execution time of a task can be interpreted as either its maximum processing time or its expected processing time. In the former case, the worst-case time to complete the schedule is considered, while in the latter case the length of the schedule represents a rough estimate of the average time of computation. In some outin-tree problems, the execution time of each task can be predicted quite accurately. For example, in evaluating arithmetic expressions, the time to execute a primitive operation, such as a multiplication, is known. In other cases, the average execution times may have to be estimated from statistics or from previous experience. In all cases, the communication overhead is non-trivial when preemptions are allowed, and the task time should also include the overhead of preemptions.

Our goal is to choose an algorithm that minimizes the maximum completion time for scheduling outin trees on a set of P identical processors, and to find the optimal granularity based on



(a) Task precedence graph as outin tree.

(b) Task precedence graph as e-outin tree using chain tasks.

(c) General scheduling (processor sharing) of e-outin tree in Figure 2(b).

(d) Preemptive CPS scheduling of e-outin tree in Figure 2(b).

Figure 2. Outin tree and CPS scheduling.

this scheduling algorithm. Our scheduling problem is similar to the P/tree/C_{max} scheduling problem in which tree precedence graphs are considered [12, 6, 4]. Note that the proper granularity is related to the scheduling algorithm. If the underlying scheduling algorithm does not minimize the completion time, then the granularity found with respect to this scheduling algorithm is suboptimal. In this paper, our analysis of optimal granularity is based on optimal scheduling algorithms. The method of granularity analysis used here can be applied to choosing the best grain for other scheduling algorithms.

If preemption is allowed, P/preemption,intree/C_{max} can be solved optimally either by Muntz and Coffman's Critical Path Scheduling (CPS) algorithm in O(N) time [22], or by other polynomial-time algorithms [9]. In the CPS algorithm, the next job chosen is the one with the longest length of unexecuted jobs. This longest path is called the *critical path*. If preemption is not allowed, then optimal scheduling algorithms have been obtained only for two cases: (a) all tasks have equal execution times and the precedence relationships are in the form of an intree (Hu's algorithm) [15] and (b) when two processors are used [3]. Hu's optimal scheduling algorithm is indeed a CPS algorithm. Many other cases have been proved to be NP-hard [25, 19]. Besides efficient and optimal, the CPS algorithm is easy to implement and, consequently, is one of the most common scheduling algorithms [20, 18].

In case that the precedence graph is a tree, that all processors are identical, and that each task requires t_i, $0<t_i \leqslant t_{max}$, units of time to complete, the nonpreemptive CPS algorithm turns out to be almost-optimal in the sense that

$$T_p(k) \leqslant T_{np}(k) \leqslant T_p(k) + t_{max} \qquad (2.1)$$

where $T_{np}(k)$ and $T_p(k)$ are, respectively, the total times required by the nonpreemptive and preemptive CPS algorithms using k processors [16]. Some researchers have strived for nonpreemptive scheduling algorithms to solve scheduling problems with tree precedence [12, 8, 18]. Recently, Garey, Dolev, et al. have studied the scheduling of forests consisting of intrees and outtrees. Given a fixed number of processors, polynomial algorithms with high complexities to find an optimal schedule of these forests have been developed [10, 8].

In our research, we are interested in a special, but widely used, case of outin trees. From the point of view of optimal granularity, evaluating an outin tree can be divided into the *splitting*, *all-busy*, and *combining* phases with respect to k, the fixed number of processors. In the splitting phase, the problem is decomposed, and the number of busy processors is increased from one up to at most k−1 (the number of busy processors must always be less than k if the number of available tasks at any time is less than k). In the combining phase, the subproblems are composed, and the number of busy processors is decreased from at most k−1 to one. During these two phases, some processors are idle. In contrast, in the all-busy phase, all the k processors are busy. Schindler has proved that the schedule of a precedence graph is optimal if either the computations can be completed in only the all-busy or combining phase, or it can be partitioned into the all-busy and combining phases by a "heightline" [24]. We will show that this result can be extented to scheduling outin trees, and that the CPS algorithm guarantees the optimal preemptive scheduling and near-optimal nonpreemptive scheduling of outin-tree evaluations.

To analyze the properties of *preemptive CPS*, in short, *PCPS*, algorithms, it will be more convenient to represent a task (a node of the outin tree) of execution time t_i by a chain-task, which is t_i *element-tasks* (or *element-nodes*, or in short, *e-tasks* or *e-nodes*), each of which has one unit of execution time (see Figure 2(b)). We will use a subscript i in the task identifier to indicate the i'th e-task in the chain-task. Hence, F_2 is the second e-task of task F. The new outin tree is called the *element-outin tree* (or *e-outin tree*). For each chain-task, the e-task farthest from the exit e-node of the e-outin tree is called a *task-head* e-node. It is easy to verify that the length of the task-head e-node is the same as the length of the original multiunit task. Two e-nodes are said to be in the *same e-level* of the e-outin tree if their lengths are identical, that is, the e-level number of an e-node is equal to its length assuming that the exit e-node is in Level 0. To distinguish between nodes and levels in the original outin tree (as exemplified by Figure 2(a)) and in the e-outin tree (as exemplified by Figure 2(b)), we will use *tasks* and *levels* with respect to the original outin tree and *e-task* and *e-level* with respect to the e-outin tree in subsequent discussions.

There is another variation of preemptive scheduling algorithms called General Scheduling (GS) discipline [22], which is extremely useful in studying the granularity of parallel outin-tree evaluations. In the GS algorithm, each processor in the system is considered to have a certain amount of computing capacity rather than as a discrete unit, and this computing capacity can be assigned to tasks in any amount between zero and the equivalence of one processor. For example, if we assign half of a processor to task P_i with execution time t_i, then it will take $2 \cdot t_i$ units of time to complete P_i. In the GS discipline, one processor is assigned to each of the k e-nodes farthest from the exit e-node of the e-outin tree to be evaluated. If there is a tie in the lengths among u e-nodes for the last v, u>v, processors, then v/u of a processor is assigned to each of these u e-nodes. Each time when either (a) a chain-task of the e-outin tree is completed, or (b) a point is reached where, if we continue with the present assignment, some e-nodes will be computed at a faster rate than other e-nodes that are farther from the exit e-node, then the processors are reassigned to the remaining tree according to the CPS principle. Situation (b) occurs when an e-node that is being computed has the same length as that of some unexecuted task-head e-node(s). In this case, one (or part of a) processor must be assigned to the unexecuted task-head e-node.

The GS discipline is illustrated in Figure 2(c). Muntz and Coffman have proved the equivalence between the GS and PCPS algorithms [22]. That is, if preemptions are permitted, then the "processor-sharing" capability is not needed for optimal scheduling. To illustrate this equivalence, Figure 2(d) shows the preemptive schedule for the corresponding e-outin tree in Figure 2(b). Note that in the scheduling algorithms discussed in this paper, all idle processors, if any, must be used to compute an available executable task.

In practice, preemptions are usually restricted at the beginning of a time unit, so the overhead of a practical PCPS algorithm is equal to that of Hu's algorithm, which assumes that tasks have unit execution times. From Eq. (2.1), we have [22]

$$T_p(k) = T_{gs}(k) \leqslant T_h(k) \leqslant [T_{gs}(k) + 1] = [T_p(k) + 1] \quad (2.2)$$

where $T_h(k)$ and $T_{gs}(k)$ are the times required by Hu's and GS algorithms, respectively. Eq. (2.2) shows that the behavior of GS is very close to that of any PCPS algorithm that only allows preemptions at the beginning of a time unit. In subsequent discussions, the results will be derived without any restriction on the allowable times for preemptions. Moreover, we will use GS as a model to analyze the properties of PCPS algorithms. The granularities derived are the same as those when the PCPS algorithm is used.

At time t, an e-node is said to be *active* if either a processor or part of a processor is assigned to it. The total number of active e-nodes may be greater than the number of processors since some e-nodes may share processors. All active e-nodes form a wave-front in the e-outin-tree evaluation. Two particular times of the wave-front are of special interest: $t_{sa}(k)$ and $t_{ac}(k)$. The computation enters the all-busy phase at $t_{sa}(k)$ and enters the combining phase at $t_{ac}(k)$. In both times, the wave-fronts serve as phase-boundaries. We call the former phase-boundary $B_{sa}(k)$ and the latter $B_{ac}(k)$.

For the task graph in Figure 2(a), if the PCPS algorithm is employed, then $t_{sa}(2)$=1 and $t_{ac}(2)$=8.5 (see Figures 2(c) and 2(d)). The corresponding phase-boundaries $B_{sa}(2)$ and $B_{ac}(2)$ are indicated in Figure 2(b).

If a preemptive (resp. nonpreemptive[*]) CPS algorithm is applied, then the computational times required by k processors to complete the splitting, all-busy and combining phases are denoted by $T_{ps}(k)$, $T_{pa}(k)$ and $T_{pc}(k)$ (resp. $T_{nps}(k)$, $T_{npa}(k)$ and $T_{npc}(k)$). In the intree part of an e-outin tree, each e-node corresponds to a path to the exit e-node, while each e-node in the outtree part may have more than one path to the exit e-node. The longest path from an e-node to the exit e-node is selected as the *execution-path* through this e-node. For an e-node, if more than one such longest path exist, then a left-to-right orientation or any tie-breaking rule is used to break the tie. In the outtree part, if an e-node has q immediate successors, one of which is in its execution-path called the *immediate execution-successor*, then the other q−1 immediate successors serve as heads of new execution-paths, called *path-heads*. As a result, each active e-node corresponds to a unique execution-path to the exit e-node.

For example, in Figure 2(b), the execution-path from e-node A_1 is (A_1, C_1, F_1, F_2, F_3, I_1, I_2, J_1, J_2) and e-node B_1 is the head of the execution-path (B_1, D_1, D_2, D_3, H_1, J_1, J_2). Note that when k processors are used, only the topmost k−1 path-heads are active in the splitting phase. Other path-heads are active in the all-busy phase.

Let A(t,k) be the set of active e-nodes at time t when k processors are used. This set can be divided into two classes in terms of the lengths of the corresponding execution-paths. At time t, the active e-nodes whose execution-paths are the shortest among all active e-nodes belong to a subset $A_s(t,k)$, and lie in a single e-level, called the *minimal active e-level*. The other active e-nodes belong to another subset $A_h(t,k)$. (If t and k are obvious in the context, they will be omitted for brevity). For example, in Figure 2(b), when t is 2, e-nodes D_1 and G_1 belong to $A_s(2,2)$, and e-node F_1 belongs to $A_h(2,2)$.

In the following four propositions, we will show the properties of the PCPS algorithm, which are related to the optimal granularity of parallel outin-tree evaluations. It is easy to observe that the active e-nodes are executed at different rates depending on whether the assigned processor is shared or not. Let $r_i(t)$ be the processing rate in e-node per time unit of active e-node i at time t. The following proposition distinguishes the processing rates under various conditions.

Proposition 2.1: During a parallel evaluation of an outin tree with k processors, $r_i(t)$, the processing rate of active e-node i at time t, satisfies the following equations.

$$r_i(t) \begin{cases} = 1 & \text{if e-node } i \in A_h(t,k) \text{ or } |A(t,k)| \leqslant k \\ < 1 & \text{otherwise} \end{cases}$$

where |A(t,k)| is the number of active e-nodes in the set A(t,k).
Proof: This follows from the GS strategy immediately. □

Proposition 2.1 reflects the following facts. First, in the splitting and combining phases, the processing rate for any e-node is one, that is, an e-node is processed in each time unit. Second, if an active e-node is not in the minimal active e-level, then one processor (rather than part of a processor) has to be assigned to it, that is, its corresponding processing rate is one. Third, in the all-busy phase, if the number of active e-nodes is equal to the number of processors, then the processing rates for e-nodes in the minimal active e-level is also one. Only when the number of active e-nodes is larger than the number of processors used, the processing rates of e-nodes in the minimal active e-level are less than one.

Let h_{max} be the length of the critical path in the outin tree to be evaluated. Since at least one time unit is needed to complete each e-node, it is evident for any scheduling algorithm that

$$T(k) \geqslant h_{max} \tag{2.3}$$

where T(k) is the completion time using k processors under a preemptive or nonpreemptive scheduling discipline. The following proposition shows the relationship between $T_p(k)$ and the shape of the phase-boundary.

Proposition 2.2:[**] (a) $T_p(k) > h_{max}$ implies that all active e-nodes on the phase-boundary B_{ac} are located in the same e-level. (b) If an active e-node on the phase-boundary B_{ac} belongs to A_h, then $T_p(k) = h_{max}$.

The example in Figure 2 illustrates Property (a) above. At time t=4, e-node G_1 in the critical path "enters" the set A_s, and hereafter all active e-nodes are in the same e-level. Proposition 2.2 reflects the fact that preemptive scheduling algorithms distribute work uniformly among the available processors, thereby reducing the computational time required in the combining phase. This is the reason for a preemptive algorithm to run faster than the nonpreemptive counterpart.

To investigate the optimal granularity, we need to examine the phase-boundaries when different numbers of processors are used. The following proposition compares two boundaries with respect to k and k+1 processors. In subsequent discussions, the phase-boundary in a *single e-level* will mean that all active e-nodes on this boundary have execution-paths with the same length.

Proposition 2.3:[**] If phase-boundary $B_{ac}(k+1)$ is in a single e-level, then the phase-boundary $B_{ac}(k)$ must be in a single e-level.

If the phase-boundary $B_{ac}(k+1)$ is not in a single e-level, then there are k,' 0<k'<k, active e-nodes belonging to $A_h(k+1)$ on this phase-boundary. During the splitting and all-busy phases, we can partition the (k+1) processors into two groups. The first group consists of k' processors that only evaluate e-nodes in the k' execution-paths from the topmost k' path-heads to the k' e-nodes. Other (k+1−k') processors constitute the second group, which evaluate all e-nodes in the two phases except for e-nodes in the aforementioned k' execution-paths. Accordingly, we can prove the following proposition.

Proposition 2.4:[**] If an outin tree is evaluated by the PCPS algorithm, then $T_{ps}(k+1) \geqslant T_{ps}(k)$, and $T_{pc}(k+1) \geqslant T_{pc}(k)$.

The following theorem shows that the PCPS algorithm can be used to find the optimal preemptive schedule for outin trees.

Theorem 2.1.: PCPS is a minimum-completion-time scheduling algorithm for an outin tree.
Proof: Let $\Phi_{ps}(k)$ and $\Phi_{pc}(k)$ be the total amount of idle times in the splitting and combining phases when the PCPS algorithm is applied and k processors are used. Clearly,

$$T_p(k) = \frac{\Phi_{ps}(k) + T(1) + \Phi_{pc}(k)}{k} \tag{2.4}$$

Minimizing $T_p(k)$ implies minimizing ($\Phi_{ps}+\Phi_{pc}$). In the PCPS algorithm, once an e-node is available, that is, its predecessor node has been finished, a processor is assigned to it immediately. The time spent in the splitting phase for any schedule cannot be shorter than that in the PCPS algorithm. It also means that Φ_{ps} for the PCPS algorithm is the minimum. We now consider Φ_{pc}. If the phase-boundary B_{ac} is not in a single e-level, then $T_p(k)=h_{max}$ according to Proposition 2.2. That is, the PCPS algorithm achieves the minimum computational time T(k) according to Eq. (2.3). What we need to consider is the case when the phase-boundary B_{ac} is in a single e-level. This boundary is indicated by a dark line B in Figure 3.

Suppose that an arbitrary scheduling algorithm is used, the corresponding phase-boundary is denoted by B', which is shown as a dashed line in Figure 3. Note that it is impossible for all e-nodes on boundary B' to be beneath boundary B, otherwise at least one processor is idle before the wave-front achieves B,' which implies that B' is not a phase-boundary. In other words, at least one e-node on boundary B' is above or on boundary B_{ac}. Similarly, it is impossible for all e-nodes of boundary B' to be

[*] We will discuss nonpreemptive CPS algorithms in Section 4.

[**] Due to space limitation, the proofs of Propositions 2.2 thru 2.4, Lemmas 3.1 thru 3.4, and all lemmas and theorems in Section 4 are omitted.

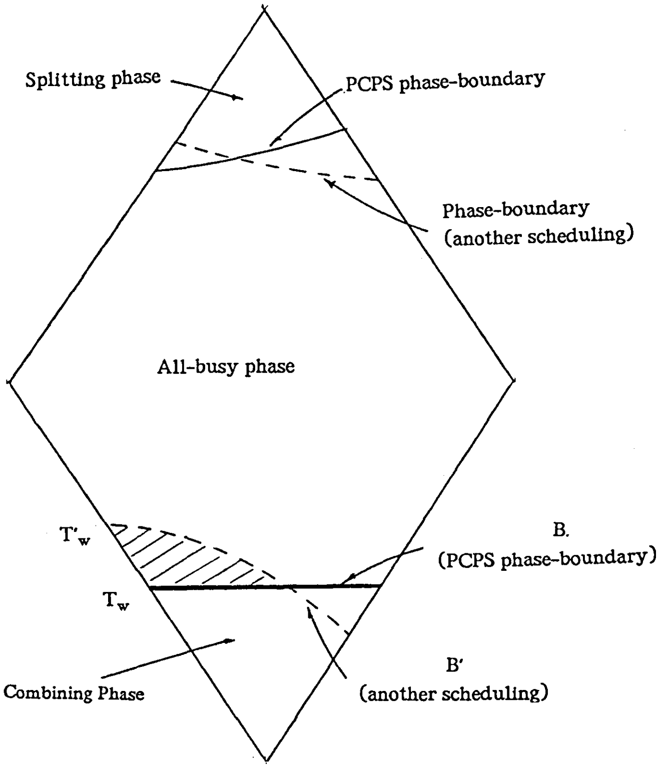

Figure 3. Proof of Theorem 2.1.

above boundary B.

Let N_{pc} and N_c' be the amount of task times in the combining phase of the PCPS and another scheduling algorithm. Let $T_c'(k)$ and $\Phi_c'(k)$ be the computational time and the total idle time in the combining phase when an arbitrary scheduling algorithm using k processors is adopted. If $T_{pc}(k)$ equals $T_c'(k)$, then $N_{pc}(k) \geqslant N_c'(k)$, hence, $(\Phi_c' - \Phi_{pc}) = (N_{pc} - N_c') \geqslant 0$. If $T_{pc}(k)$ is less than $T_c'(k)$, since at least one e-node on boundary B' is beneath or on boundary B_{ac}, $(N_c' - N_{pc})$ cannot be larger than the amount of task times for e-tasks beneath B' and above B (the shaded area in Figure 3). Since, from Proposition 2.1, the processing rate for any path in the combining phase is one, then after $(T_c' - T_{pc})$ time units, all e-nodes in the shaded area in Figure 3 must be completed. As less than k e-nodes can be completed during a time-unit in the combining phase, the amount of e-nodes in the shaded area must be less than $k(T_c' - T_{pc})$. Therefore,

$$(\Phi_c' - \Phi_{pc}) = [k(T_c' - T_{pc}) - (N_c' - N_{pc})] > 0.$$

This means that Φ_{pc}, the total idle time in the combining phase, is also minimum for the PCPS algorithm. The proof does not imply that the PCPS algorithm is the unique optimal algorithm, but rather that the amount of idle times introduced by the PCPS algorithm is the minimum. □

3. OPTIMAL GRANULARITY IN PREEMPTIVE SCHEDULING

The criteria generally used to define the optimal granularity are the processor utilization (PU), kT^2, and AT^2, where k is the number of processors, T is the computational time, and A is the area of a VLSI implementation. The complexity of divide-and-conquer algorithms in an SIMD model and the conditions to assure the optimal processor utilization have been studied [14]. However, processor utilization increases monotonically with decreasing number of processors, which means that PU achieves the maximum when one processor is used. Hence, PU is not an adequate measure for the effects of parallel processing. A more appropriate measure is the kT^2 criterion, which considers both PU and computational time, since

$$kT^2(k) = \frac{T(1)T(k)}{PU} \quad \text{where } PU = \frac{\text{speedup}}{k} \text{ and } T(k) = \frac{T(1)}{\text{speedup}}$$

To minimize kT^2 means to reduce the computational time and to maximize the processor utilization. kT^2 is linearly related to AT^2 if the area of connection wires is proportional to the area of processing elements, as in systolic arrays. Both computational time and processor utilization are important in many applications, hence, kT^2 is a good criterion to optimize. In other applications, such as real-time processing, the completion time may be more critical and the PU is a secondary consideration. In this case, a different optimization criterion may have to be used.

In this paper, we have adopted kT^2 as a criterion of processor-time efficiency to derive the optimal granularity for parallel outin-tree evaluations. That is, given an outin-tree, we need to either choose k to minimize kT^2, or given a fixed k, determine the type of outin trees (their shapes, complexities, etc.) and its proper size that can be solved most efficiently by this system.

It is difficult to find the optimal granularity with respect to kT^2 directly because the optimal granularity depends on the execution time of each task and the shape of the outin tree. We now try to find an efficient and systematic method to determine the optimal grain via an intermediate variable, the total idle time. Let $\Phi_p(k)$ (resp. $\Phi_{np}(k)$) be the total amount of idle times when a preemptive (resp. nonpreemptive) scheduling algorithm with k processors is used. $\Phi_p(k)$ takes into account the idle times in both the splitting and combining phases. Clearly, $\Phi_p(k) = [\Phi_{ps}(k) + \Phi_{pc}(k)]$ and

$$kT(k) = T(1) + \Phi(k) \qquad (3.1)$$

Eq. (3.1) holds for both preemptive and nonpreemptive scheduling algorithms.

The total idle time $\Phi_p(k)$ is related to both k and kT^2. The following two lemmas show the difference between the total idle times when different number of processors are used.

Lemma 3.1:** Suppose that an outin tree is evaluated by the PCPS algorithm, then

$$[\Phi_p(k+1) - \Phi_p(k)] \leqslant h_{max} \qquad (3.2)$$

where h_{max} is the length of the critical path.

Lemma 3.2:** Suppose that an outin tree is evaluated by the PCPS algorithm, then

$$[\Phi_p(k+1) - \Phi_p(k)] \geqslant [T_{ps}(k) + T_{pc}(k)] > 0 \qquad (3.3)$$

Lemma 3.3:** Suppose that an outin tree is evaluated by the PCPS algorithm, then

$$T_p(k+1) \leqslant T_p(k)$$

The above lemmas reveal that when the number of processors used are increased, the total idle times must increase, and the difference of the total idle times with respect to k_1 and k_2 processors is bounded by $(k_2 - k_1)[T_{ps}(k) + T_{pc}(k)]$ and $(k_2 - k_1) \cdot h_{max}$, respectively. From these facts, we can determine the conditions under which kT^2 is either monotonically increasing or decreasing with respect to k. The following theorem shows the relation between $\Phi_p(k)$ and kT^2.

Theorem 3.1: Suppose that an outin tree is evaluated by the PCPS algorithm. $kT_p^2(k)$ is monotonically increasing with k if $[\Phi_p(k+1) - \Phi_p(k)] > T_p(k)/2$. $kT_p^2(k)$ is monotonically decreasing with k if $[\Phi_p(k+1) - \Phi_p(k)] < T_p(k)/(2 + 1/k)$.

Proof: By Eq. (3.1), we get

$$(k+1)T_p^2(k+1) - kT_p^2(k) \qquad (3.4)$$
$$= \frac{[T_p(1) + \Phi_p(k+1)]^2}{k+1} - \frac{[T_p(1) + \Phi_p(k)]^2}{k}$$
$$= \frac{k[T_p(1)+\Phi_p(k+1)]^2 - k[T_p(1)+\Phi_p(k)]^2 - [T_p(1)+\Phi_p(k)]^2}{k(k+1)}$$
$$= \frac{[\Phi_p(k+1)-\Phi_p(k)]\,[2T_p(1)+\Phi_p(k+1)+\Phi_p(k)] - kT_p^2(k)}{k+1}$$
$$= \frac{[\Phi_p(k+1)-\Phi_p(k)]\,[(k+1)T_p(k+1)+kT_p(k)] - kT_p^2(k)}{k+1}$$

Since, from Lemma 3.2, $\Phi_p(k+1) > \Phi_p(k)$, hence

$$(k+1)T_p(k+1) = [T_p(1)+\Phi_p(k+1)] \qquad (3.5)$$
$$> [T_p(1)+\Phi_p(k)] = kT_p(k)$$

From Eq's (3.4) and (3.5), we conclude that if $[\Phi_p(k+1)-\Phi_p(k)] > T_p(k)/2$, then $(k+1)T_p^2(k+1) > kT_p^2(k)$. By Lemma 3.1, Eq's (3.4) and (2.3), we obtain the following condition.

$$\text{If} \quad [\Phi_p(k+1) - \Phi_p(k)] < \frac{T_p(k)}{2 + 1/k},$$
$$\text{then} \quad [(k+1)T_p^2(k+1) - kT_p^2(k)]$$
$$< \left| \frac{kT_p(k)}{2k+1} [2kT_p(k)+T_p(k)] - kT_p^2(k) \right| = 0 \quad \square$$

Theorem 3.1 restricts the region within which we need to find a value k that minimizes $kT_p^2(k)$. In other words, the approximate condition that adding a processor will not degrade the processor-time efficiency is that all processors will be busy at least half of the time.

In the example shown in Figure 2, $T_p(1) = 18$, $T_p(2) = 10.5$, $\Phi_p(2) = 3$, $T_p(3) = 9$, and $\Phi_p(3) = 9$. (Readers are suggested to schedule this outin tree with three processors). Since $\Phi_p(2) = 3 < T_p(1)/3 = 6$, and $[\Phi_p(3) - \Phi_p(2)] = 6 > T_p(2)/2 = 5.25$, according to Theorem 3.1, we can conclude that the use of two processors minimizes kT^2 for this outin tree.

A question about the monotonicity of $[kT_p^2(k+1) - kT_p^2(k)]$ now arises naturally. If $[kT_p^2(k+1) - kT_p^2(k)]$ is increasing monotonically with k, then $kT_p^2(k)$ is a unimodal function of k, and the optimal value of k can be found easily. This monotonicity will be proved in the following theorem.

Theorem 3.2: Suppose that an outin tree is evaluated by the PCPS algorithm, then $kT_p^2(k)$ is a concave function of k, that is, $kT^2(k)$ achieves the minimum when $k = k$,' and $kT^2(k)$ is monotonically decreasing (resp. increasing) with k when $k < k'$ (resp. $k > k'$).

Proof: To show $kT_p^2(k)$ is a concave function of k, we need to prove that its second-order difference is positive, namely, $[(k+2)T_p^2(k+2) - (k+1)T_p^2(k+1)] > [(k+1)T_p^2(k+1) - kT_p^2(k)]$. Let $\Delta(kT_p^2(k)$ denote $[(k+1)T_p^2(k+1) - kT_p^2(k)]$. Then

$$\Delta(kT_p^2(k)) = k[T_p^2(k+1) - T_p^2(k)] + T_p^2(k+1) \qquad (3.6)$$

$$\Delta((k+1)T_p^2(k+1)) = (k+1)[T_p^2(k+2)-T_p^2(k+1)]+T_p^2(k+2) \qquad (3.7)$$

Subtracting Eq. (3.6) from Eq. (3.7) and applying Eq. (3.1) yields

$$\Delta((k+1)T_p^2(k+1)) - \Delta(kT_p^2(k)) \qquad (3.8)$$
$$= (k+2)[T_p^2(k+2) - T_p^2(k+1)] - k[T_p^2(k+1) - T_p^2(k)]$$
$$= [T_p(k+2) + T_p(k+1)]\,[\Phi_p(k+2) - \Phi_p(k+1) - T_p(k+1)]$$
$$- [T_p(k+1) + T_p(k)]\,[\Phi_p(k+1) - \Phi_p(k) - T_p(k+1)]$$

From Eq's (2.3) and (3.8) and Lemmas 3.1, 3.2 and 3.3, we conclude that $\{\Delta((k+1)T_p^2(k+1)) - \Delta(kT_p^2(k))\} > 0$. □

We have found the condition under which kT_p^2 is increased or decreased based on the intermediate variable, $\Phi_p(k)$, and that kT_p^2 is a concave function. Next, we will determine the number of processors such that kT_p^2 is minimum for a given outin tree.

Note that in the original outin tree (see Figure 2(a)), each node is a multiunit task, and tasks in a level may have different lengths. If there are m(i) tasks in level i, then there are m(i) paths from level i to the exit node. Among these paths, the minimum length is denoted by ℓ (i). Similarly, we can define the *depth* of a node as the sum of task-times along a path from the entry node to and including this node, and denote the shortest depth from the entry node to level i by d(i).

Given k processors, we can find c_k, a particular level in the intree part of the original outin tree, such that $m(c_k)$, the number of tasks in this level, is less than k, but $m(c_k+1) \geqslant k$. This particular level is called the *minimum-all-busy level*. Likewise, in the outtree part, there is a level called the *maximum-all-busy level* and denoted by s_k, such that $m(s_k) < k$ and $m(s_k-1) \geqslant k$. By recognizing the minimum-all-busy and maximum-all-busy levels, we can roughly estimate the locations of the phase-boundaries. Recall from Proposition 2.2 that $T_p(k) = h_{max}$ if the phase-boundary B_{ac} is not in a single e-level. In this case, $(k+1)T_p^2(k+1) > kT_p^2(k)$. To achieve the minimum $kT_p^2(k)$, the number of processors should be reduced until the phase-boundary appear in a single e-level. (When $B_{ac}(k)$ is not in a single e-level but $B_{ac}(k-1)$ is, $kT_p^2(k)$ may be minimum.) This observation shows that the use of the minimum-all-busy level to estimate T_{pc} is accurate in most cases. The following lemma shows that the shortest length from the minimum-all-busy (resp. maximum-all-busy) level to the exit (resp. entry) node gives the lower-bound computational time in the combining (resp. splitting) phase.

Lemma 3.4:** Suppose that an outin tree is evaluated by k processors. If s_k and c_k are the maximum-all-busy and minimum-all-busy levels, then (a) $T_{ps}(k) \geqslant d(s_k)$, and (b) $T_{pc}(k) \geqslant \ell(c_k)$. Further, if the phase-boundary $B_{ac}(k)$ lies in a single e-level, then $T_{pc} = \ell(c_k)$.

This lemma is illustrated by the example in Figure 2(a). Suppose that three processors are used, the maximum-all-busy level contains tasks B and C, and the minimum-all-busy level contains tasks H and I. $T_{ps}(3)$ (resp. $T_{pc}(3)$) cannot be less than 2 (resp. 3) because if either task B or C, which are associated with the shortest depth from the entry node to this level, is not finished, then the computation cannot enter the all-busy phase. Likewise, if task H has been assigned to a processor, then the computation must have entered the combining phase. Since $B_{ac}(2)$ lies in a single e-level, $T_{pc}(2) = \ell(c_2) = 3$.

For an arbitrary outin tree,

$$T_{ps} \geqslant t_{en}, \; T_{pc} \geqslant t_{ex}, \text{ and } \Phi_p \geqslant (t_{en} + t_{ex}) \qquad (3.9)$$

where t_{en} and t_{ex} are the task times of the entry and exit nodes, respectively.

When more than one processor are used, some processors must be idle when the entry and exit nodes are evaluated. If the times spent in evaluating the entry and exit nodes dominate over all other computations, then parallel processing is definitely inefficient. The following corollary identifies the condition under which sequential computation is better than parallel processing.

Corollary 3.1: Suppose that an outin tree is scheduled by the PCPS algorithm and $(t_{en}+t_{ex}) > T(1)/2$, then sequential processing, i.e., $k=1$, achieves the minimum kT^2.

Proof: This follows from Theorem 3.1 immediately. □

Having proved a series of propositions, lemmas, and theorems, the main theorem to derive the optimal granularity under the PCPS scheduling algorithm can be obtained now. In the following theorem, the region on k in which we can find the optimal granularity of parallel outin-tree evaluation is given.

Theorem 3.3: Suppose that an AND-tree is evaluated by the PCPS algorithm and $k > 1$, then

$$(k+1)T_p^2(k+1) > kT_p^2(k) \text{ if } k > \frac{2T_p(1)}{h_{max}} \text{ and} \tag{3.10}$$

$$(k+1)T_p^2(k+1) < kT_p^2(k) \text{ if } k < \left\{\frac{T_p(1)+t_{en}+t_{ex}}{2h_{max}} - \frac{1}{2}\right\} \tag{3.11}$$

Proof: From Lemma 3.2,

$$\Delta\Phi_p(k) \geqslant T_{ps}(k) + T_{pc}(k). \tag{3.12}$$

Since the idle time of each processor cannot be larger than $(T_{ps}+T_{pc})$, we have

$$\Phi_p(k) \leqslant (k-1)\,[T_{ps}(k) + T_{pc}(k)] \tag{3.13}$$

By Theorem 3.1, Eq's (3.1), (3.12) and (3.13), the condition that guarantees the monotonic increase of $kT_p^2(k)$ with k is

$$(k+1)T_p^2(k+1) > kT_p^2(k) \tag{3.14}$$

$$\text{if } [T_{ps}(k)+T_{pc}(k)] > \frac{T_p(1) + (k-1)[T_{ps}(k)+T_{pc}(k)]}{2k}.$$

On the other hand, when all tasks but those in the critical path can be completed by (k-1) processors during $h_{max} - [T_{ps}(k)+T_{pc}(k)]$ time-units, i.e.,

$$(k-1) > \frac{T_p(1) - h_{max}}{h_{max} - [T_{ps}(k)+T_{pc}(k)]}, \tag{3.15}$$

the phase-boundary B_{ac} must not be in a single e-level. As discussed before, the optimal grain cannot be larger than the RHS of Eq. (3.15) plus one. By Lemma 3.4, Eq's (3.14) and (3.15),

$$(k+1)T_p^2(k+1) > kT_p^2(k) \text{ if}$$

$$k > \min\left\{\frac{T_p(1)}{d(s_k)+\ell\,(c_k)} - 1,\ \frac{T_p(1)}{h_{max} - [d(s_k)+\ell\,(c_k)]}\right\} \tag{3.16}$$

The condition described in Eq. (3.10) is obtained from Eq. (3.16).

Note that $\Delta\Phi_p(k) \leqslant h_{max}$, and that $kT_p(k) > [T_p(1)+t_{en}+t_{ex}]$ according to Lemma 3.1, Eq's (3.1) and (3.9). By Theorem 3.1, the following result can be derived.

$$(k+1)T_p^2(k+1) < kT_p^2(k) \text{ if } h_{max} < \frac{T_p(1) + t_{en} + t_{ex}}{2k+1}$$

which is equivalent to Eq. (3.11). □

To find optimal granularity, we need to search the small region of k defined by Theorem 3.3. The lower and upper bounds of this region are, respectively, $\{T_p(1)/(2h_{max}) - 1\}$ and $\{2T_p(1)/(h_{max}) + 1\}$. Note that we have not made any assumption about the distribution of task times in deriving these bounds. Since kT_p^2 is a concave function of k (Theorem 3.2), the desirable number of processors can be found easily by a binary search. The binary search can be completed within about $\log_2(T_p(1)/h_{max})$ steps. Each step in the binary search tests whether $\Delta(kT_p^2(k))$ is positive. If it is, then a smaller value of k will be checked in the next step, otherwise, a larger k will be tested.

For any k inside the search region, the phase-boundary $B_{ac}(k)$ is in a single e-level, hence the location of $B_{ac}(k)$ can be uniquely determined without knowing the detailed schedule. Accordingly,

$$\Phi_p(k) = k[T_{ps}(k) + T_{pc}(k)] - [N_{ps}(k) + N_{pc}(k)]$$

where $N_{ps}(k)$ and $N_{pc}(k)$ are the amount of task times in the splitting and combining phases. From Lemma 3.4, $T_{pc}(k) = \ell\,(c_k)$, and $T_{ps}(k)$ can be found directly from the e-outin tree. As a result,

$$kT_p^2(k) = \frac{[T_p(1) + \Phi_p(k)]^2}{k}$$

For instance, suppose that N items need to be sorted. It is well-known that $T(1) = N{\cdot}\log_2 N$ if a merge-sort algorithm is used. In this case, the overhead in the intree part dominates that of the outtree part. For the intree part, $h_{max} = N + N/2 + \cdots + 1 = 2N-1$, so the lower and upper bounds of the search region can be determined from Theorem 3.3, which are close to $(\log_2 N)/4$ and $\log_2 N$, respectively. Since there are only $(3{\cdot}\log_2 N)/4$ candidate values in this search region, $\log_2\log_2 N$ steps of a binary search can guarantee to find the optimal grain of parallel merge sorting. For problems such as evaluating numerical or logic expressions and finding the maximum (or minimum) value, all task times are identical. Theorem 3.3 predicts that the optimal grain is between $N/(2{\cdot}\log_2 N)$ and $2N/\log_2 N$. Figure 4 shows the simulation results of applying a nonpreemptive CPS algorithm to a binary intree of 4096 terminal notes and t_i=1 for all i. Since all tasks have unit execution times, the performance of the nonpreemptive CPS algorithm is very close to that of GS algorithm (see Eq. (2.2)). In this example, kT^2 is minimum when 431 processors are used, which is between $N/(2{\cdot}\log_s N)$ (=170) and $2N/\log_2 N$ (=683).

The above analysis reveals that the optimal grain of an outin-tree evaluation is related to the following parameters:

(a) T(1), the time required by a sequential evaluation, which is the sum of all task times in the outin tree;
(b) h_{max}, the length of the critical path;
(c) $d(s_k)$, the shortest depth from the entry node to s_k, the maximum-all-busy level; and
(d) $\ell\,(c_k)$, the shortest length from c_k, the minimum-all-busy level, to the exit node (recall that c_k and s_k depend on k).

$T(1)/h_{max}$ reflects the shape of the outin tree, while $T(1)/d(s_k)$ and $T(1)/\ell\,(s_k)$ reflect the distribution of the task-times. If the outin tree is "wide" and nearly balanced, i.e., $T_p(1)/h_{max}$ is large, then a fine grain is more appropriate, otherwise, a coarse grain is more suitable. Further, if tasks in levels closer to the entry and exit nodes have longer execution times, i.e., $T_p(1)/[d(s_k)_+\ell\,(c_k)]$ is small, then the optimal grain should be larger, otherwise, a finer grain is better with respect to kT^2. Both $T(1)/h_{max}$ and $T(1)/[d(s_k)+\ell\,(c_k)]$ are related to the problem complexity. We will again show the influence of problem complexity on the

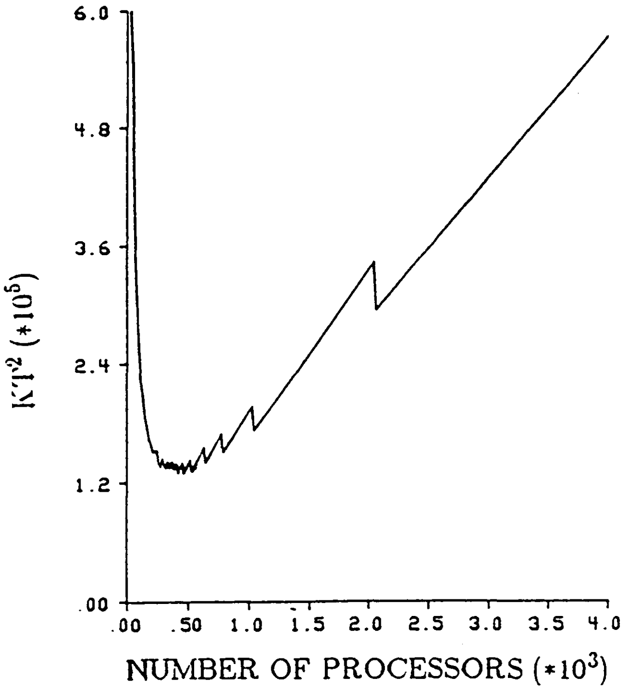

Figure 4. Simulation results to find the optimal granularity of evaluating an intree with 4096 leaves and unit execution times for all nodes.

optimal granularity in the next section, where nonpreemptive algorithms will be used.

4. OPTIMAL GRANULARITY IN NONPREEMPTIVE SCHEDULING

Nonpreemptive CPS algorithms are similar to the PCPS algorithm except that preemption is not allowed. In the nonpreemptive CPS algorithm, one processor is assigned to each of the k nodes farthest from the exit node. If there is a tie in lengths among more than one node, then a left-to-right tie-breaking rule is used to assign a processor to one of these nodes. When a task of the outin tree is completed, the free processor is assigned to the node farthest from the root in the remaining outin tree to be evaluated. Figure 2(e) illustrates an example of nonpreemptive CPS scheduling. In general, nonpreemptive scheduling is more practical due to the smaller task-switching overheads; however, it is more difficult to predict its performance and determine the optimal grain in parallel processing.

The problem of determining the optimal granularity of nonpreemptive CPS algorithm is complicated by its anomalous behavior. Graham has proved that if an AND-tree is evaluated twice by using k_1 and k_2 processors, respectively [11], then

$$\frac{T_{np}(k_1)}{T_{np}(k_2)} \leqslant \left\{ 1 + \frac{k_2 - 1}{k_1} \right\}$$

The above inequality implies that the anomaly $T_{np}(k+1)/T_{np}(k) < k/(k+1)$ is possible. In other words, $kT_{np}^2(k)$ is generally not a concave function of k and cannot be searched by a binary search or other efficient search methods.

In a special case, if the execution times of tasks of an outtree are monotonically decreasing as the tree is decomposed, then it will be shown below that $\Phi_{np}(k_2) > \Phi_{np}(k_1)$ holds for $k_2 > 2k_1$. Likewise, the same relation holds for the case when the execution times of tasks of an intree are monotonically increasing as the tree is composed. Here, the optimal granularity of outin-tree computations based on a nonpreemptive CPS algorithm can be bounded in a relatively small region. The assumption on monotonic distribution of task times is valid in divide-and-conquer algorithms.

In this section, we will develop conditions under which kT^2 is monotonically increasing or decreasing with k for the special case in which the task times are monotonically decreasing in the outtree and monotonically increasing in the intree. We will investigate the difference of the total idle times with respect to different number of processors under nonpreemptive CPS. The following lemma gives the lower and upper bounds of $[\Phi_{np}(k_2) - \Phi_{np}(k_1)]$.

Lemma 4.1:** Suppose that an outin tree is scheduled by a nonpreemptive CPS algorithm and that $t_i > t_j$ if task i is a predecessor (resp. successor) of task j in the outtree (resp. intree) part, then

$$[\Phi_{np}(k_2) - \Phi_{np}(k_1)] \geqslant \{(k_2 - k_1)[T_{ps}(k_1) + T_{pc}(k_1)] - k_1 t_{npa}(k_1)\} > 0 \quad \text{if } k_2 > 2k_1 \qquad (4.1)$$

$$[\Phi_{np}(k_2) - \Phi_{np}(k_2)] \leqslant \{(k_2 - k_1)[T_{ps}(k_2) + T_{pc}(k_2)] + k_2 t_{npa}(k_2)\} \quad \text{if } k_2 > k_1 \qquad (4.2)$$

where $t_{npa}(k)$ is the longest task-time among all tasks in the all-busy phase when k processors are used.

We should point out that the above lemma holds for the case in which a part of the phase-boundary is in the intree and another part is in the outtree. The above lemma is true because the task time of a node in the all-busy phase is less than either T_{ps} or T_{pc} from the assumption of monotonically distributed task times. That is, $[T_{ps}(k_1) + T_{pc}(k_1)] > t_{npa}(k_1)$ is always true regardless the location of the phase-boundary.

Similar to Theorem 3.1, we first study the relationship between kT^2 and the idle times. The following theorem gives the conditions under which kT^2 is monotonically increasing or decreasing based on the intermediate variable $\Phi_{np}(k)$.

Theorem 4.1:** Suppose that an outin tree is scheduled by a nonpreemptive CPS algorithm and that $t_i > t_j$ if task i is a predecessor (resp. successor) of task j in the outtree (resp. intree) part, then

$$k_2 T_{np}^2(k_2) > k_1 T_{np}^2(k_1) \text{ if } [\Phi_{np}(k_2) - \Phi_{np}(k_1)] > \left| \frac{k_2 - k_1}{2} T_{np}(k_1) \right| \text{ and } k_2 > 2k_1; \qquad (4.7)$$

$$k_2 T_{np}^2(k_2) < k_1 T_{np}^2(k_1) \text{ if } [\Phi_{np}(k_2) - \Phi_{np}(k_1)] < \left| \frac{2(k_2 - k_1)k_1}{2k_1 + 3k_2} T_{np}(k_1) \right| \text{ and } k_2 > k_1 \qquad (4.8)$$

The main theorem to find the optimal granularity can be derived from Theorem 4.1. Before this theorem is proved, the following lemma is needed.

Lemma 4.2:** For a given outin tree, suppose that both PCPS and nonpreemptive CPS algorithms are applied, then $[T_{nps}(k) + T_{npc}(k)] \leqslant [T_{ps}(k) + T_{pc}(k) + t_{npa}(k)]$.

The example in Figure 2 illustrates this lemma. Here, $[(T_{nps} + T_{npc}) - (T_{ps} + T_{pc})] = 1$, which is less than t_{npa} (=3).

Theorem 4.2:** Suppose that an outin tree is scheduled by a nonpreemptive CPS algorithm and that $t_i > t_j$ if task i is a predecessor (resp. successor) of task j in the outtree (resp. intree) part, then k, the number of processors that minimizes $kT_{np}^2(k)$, is bounded between $[T_{np}(1) + t_{en} + t_{ex}]/(8h_{max})$ and $3T_{np}(1) /[d(s_k) + \ell(c_k) - 2t_{npa}(k)]$

As an example, we can determine the area within which the optimal granularity can be found for the parallel merge-sort of N elements. In this problem, the computational overhead in the intree is dominant, so only the part of the intree has to be considered in the scheduling. From Theorem 4.2, the lower bound of the search region is $(\log_2 N)/16$, since $T_{np}(1) = N \cdot \log_2 N$ and $h_{max} < 2N$. If N is large enough, then $[d(s_k) + \ell(c_k) - 2t_{npa}(k)]$ will be larger than 1.5N, hence, the upper bound of the search region is $2 \cdot \log_2 N$.

Comparing these bounds with Theorem 3.3, we see that the range within which an optimal-grain for a nonpreemptive schedule can be found is larger than that of a preemptive schedule. Moreover, kT^2 is not monotonically decreasing or increasing with k for nonpreemptive scheduling, i.e., kT^2 is not a unimodal function of k, hence, an exhaustive search is required to find the optimal grain.

To predict the optimal order-of-magnitude granularity in general, we now briefly discuss the asymptotically optimal granularity of parallel outin-tree evaluations with nonpreemptive CPS algorithm. Let C(n) be the overhead of a node in the intree, which has n leaves rooted by this node. C(n) represents the overhead of combining the results from its immediate predecessor nodes in the intree. Likewise, let D(n) be the overhead of a node in the outtree, which has n leaves rooted by this node. D(n) represents the overhead of decomposing the given node into its immediate successor nodes in the outtree. For an outin tree with N leaves, C(N) and D(N) represent the overheads of the exit and entry nodes, respectively. Let Θ be the set of functions of the same order. For problems such as summing a set of numbers, finding the maximum of N numbers, and returning logical values to the main goal in evaluating logic programs, $C(n) = \Theta(1)$. In quicksort and merge sort, $C(n) + D(n) = \Theta(n)$.

The asymptotically optimal grain depends on the complexities of C(n) and D(n). The higher the order-of-magnitude complexity of C(n) and D(n) are, the larger the granularity is. When the order-of magnitude complexity of C(n) (and/or D(n)) is large, the time spent in the combining (and/or splitting) phase is dominating the time in the all-busy phase, and the performance gain in the all-busy phase with finer grains is negligible. In other words, a small granularity may result in underutilization of processors.

To isolate the impact of the complexities C(n) and D(n) on the optimal granularity from the shape of the outin tree, we discuss the complete binary outin tree, and assume that, for all nodes in a level of the intree (resp. outtree) part, the order-of-magnitude complexities of C(n) (resp. D(n)) are identical. This assumption enables us to estimate T(1). The following theorem gives the condition under which the asymptotically minimum kT^2 is achieved for various complexities of C(n) and D(n).

Theorem 4.3:** Suppose that a nonpreemptive CPS algorithm is applied to evaluate an outin tree of N leaves by k processors. Assume that, for all nodes in a level of outin tree, the order-of-magnitude complexities of C(n) (and D(n)) are the same and that $t_i > t_j$, if task i is a predecessor (resp. successor) of task j in the part of the outtree (resp. intree). Then the order-of-magnitude $kT_k^2(N)$ is the minimum if $\Theta(T_{npa}(k(N))) = \Theta(T_{nps}(k(N))+T_{npc}(k(N)))$.

The above theorem shows that if the number of leaves of an outin tree is very large, then, to achieve the minimum $kT_p^2(k)$, the number of processors should be chosen such that the times required by the all-busy phase and the total times required by the other two phases are approximately equal. This result also shows the relationship between the processor utilization and kT^2. Let N_{sc} be the amount of task-time in the splitting and combining phases, and $T_{npa}(k) = [T_{nps}(k)+T_{npc}(k)]$. Then, for arbitrary outin tree computations, an asymptotically optimal granularity is achieved when

$$PU(k) = \frac{kT_{npa}(k) + N_{sc}}{2kT_{npa}(k)}$$

Since $T_{npa}(k) \leqslant N_{sc} \leqslant (k-1)T_{npa}(k)$, we conclude that the corresponding processor utilization is between 0.5 and 1. In other words, when a problem is solved by a parallel divide-and-conquer algorithm and there are a large number of leaves in its outin-tree representation, to pursue more than 50% processor utilization will reduce the utilization-time efficiency. According to Theorem 4.3, the asymptotically optimal granularities with respect to various C(n)+D(n) are summarized in Table 1.

Complexity of C(n)+D(n) $1 \leqslant n \leqslant N$	Optimal Granularity	Architectural Requirements
$\Theta(\log_2^s n)$ $s \geqslant 0$	$\Theta\left(\frac{N}{\log_2^{s+1} N}\right)$	A very large number of processors; tree or other efficient interconnection
$\Theta(n^r \log_2^s n)$ $0 < r < 1$ $s \geqslant 0$	$\Theta\left(\frac{N^{1-r}}{\log_2^s N}\right)$	A large number of processors; tree or other efficient interconnection
$\Theta(n \log_2^s n)$ $s \geqslant 0$	$\Theta(\log_2 N)$	A small number of processors; loosely coupled; simple interconnection
$\Theta(n^p)$ $p > 1$	$\Theta(1)$	Single or few processors; shared memory

Table 1. Asymptotically optimal granularities in parallel processing of outin trees with respect to order-of-magnitude kT^2 (N is the number of leaves of the outin tree).

5. CONCLUDING REMARKS

In this paper, we have derived tight bounds within which the optimal granularity of parallel AND-tree evaluations under preemptive and nonpreemptive critical path scheduling can be found. For nonpreemptive scheduling, the asymptotically optimal granularities with respect to various problem complexities have been derived. These theoretical results provide an upper bound on the number of processors to achieve the minimum kT^2 criterion.

According to our efficiency analysis, we found that the optimal granularity depends on the problem complexity, the shape of the precedence graph (balanced or skewed), and the task-time distribution along each path (random or monotonic). It is usually difficult to predict the shape and the task-time distribution. One possible way is by statistical analysis. In contrast, the complexity of a problem to be solved is generally known before the problem is solved.

The complexity of each node in the outin tree is an important factor that influences the optimal granularity. As illustrated in Table 1, if C(n)+D(n) is $\Theta(n^p)$, $p>1$, and a large number of processors are used, then the processor-time efficiency, kT^2, must be poor regardless of the capacity of the interconnection network. In this case, the time needed to evaluate a subproblem will be increased quickly during the decomposition process in the outtree and the composition process in the intree. Hence, the root and exit nodes of the tree are obvious bottlenecks. In contrast, if C(n) and D(n) are $\Theta(1)$, then the time needed to evaluate any subproblem is bounded by a constant, and the root and exit nodes will not be bottlenecks. Examples of this kind of problems include finding the maximum and evaluating an arithmetic expression. Here, a fine-grain architecture is appropriate, and a large speedup will be obtained by using a large number of processors. Tree-structured computer architectures [13, 21] and virtual-tree computers [2] are good candidates in these applications. In cases when C(n) equals either $\Theta(n)$ or $\Theta(\log^s n)$, $s \geqslant 0$, the time needed to evaluate a subproblem is increased slowly during the decomposition process in the outtree and the composition process in the intree. A medium-grain architecture will be more cost-effective. For example, to sort 4000 elements by a parallel merge-sort algorithm, using ten to twelve processors will be a good choice. For many practical problems, especially when divide-and-conquer algorithms are used, the precedence graph is nearly balanced, and the task-times of all nodes in each level are approximately equal, hence, the nonpreemptive critical path scheduling algorithm may be viewed as a parallel breadth-first search. In this case, well balanced workloads with overlapped process communications can be assigned to the processors working under an SIMD model. The optimal grains will, therefore, be close to the theoretical ones predicted in Sections Three and Four. The architectural requirements for various cases are summarized in Table 1.

In many problems, the order-of-magnitude complexities of C(n) and D(n) may be different. For example, for the quicksort algorithm, $C(n)=\Theta(1)$ and $D(n)=\Theta(n)$, that is, most of the computational overhead is spent in the decomposition phase, and the composition operation is trivial. In contrast, for the merge-sort algorithm, $C(n)=\Theta(n)$ and $D(n)=\Theta(1)$. In many logical and functional programs, the return operation is usually simple, i.e., $C(n)=\Theta(1)$, but the complexity of a subgoal or function call depends on the number of the parameters passed and the method of copying data. For these problems, the optimal grain can be determined by the part of the tree that has dominant overhead.

The shape of the AND-tree and its task-time distribution are also important factors to be considered. Let $T_p(1)/h_{max}$ be "average width" of an AND-tree. The optimal granularity is found to depend strongly on the average width. If the AND-tree is "wide," then the degree of parallelism is high and the granularity can be small. On the other hand, if the AND-tree is "narrow," then the degree of parallelism is low and the granularity is necessarily large. Here, the tree may have to be restructured to arrive at a different representation.

In many problems involving AND-trees, the trees are usually irregular, and the workloads may be data dependent. An important functional requirement is, therefore, the ability to dynamically distribute the workload in the architecture. For a computer architecture with a small granularity, an efficient interconnection network is needed. In a loosely coupled system with a coarse grain, an effective load balancing mechanism is necessary. Here, process communications may not be well overlapped with computations, and the corresponding task-times should include the communication overhead. As a result, the optimal number of processors may be less than the theoretical values predicted in Sections Three and Four.

Abstract

Finite-element analysis requires extensive computations in the preprocessing and postprocessing stages, which could become the real bottleneck. This paper presents a multiprocessing and macropipelining approach to overcome this difficulty. We demonstrate through timing analysis that using a linear array of processors in a macropipelined fashion, one can achieve a significant throughput improvement in preprocessing the data elements and outputing the results after a finite-element analysis. We provide analytical methods for matching the processing bandwidths among the host computer, the preprocessor, the linear system solver, and the postprocessor. The time savings in these preprocessing and postprocessing steps will greatly improve the overall system performance.

1. Introduction

The Finite Element Method (FEM) for solving Partial Differential Equations (PDE) consists of three phases : the input of data elements, the solution of a linear system of equations, and the output of analytical results[1]. In the past, most efforts have concentrated in the middle phase of solving a linear system of equations Kx = f, where K is an nxn stiffness matrix obtained by discretizing the given PDEs. Very little has been done in the speedup of the input and output phases.

Finite-element analysts often refer to the input phase as *preprocessing* and the output phase as *postprocessing*. Besides I/O of elemental data and results, computations are also needed in these two phases in order to produce the stiffness matrix and to display graphically the analytical results obtained in the middle phase. In this article, we propose a pipelined approach for speeding up the extensive computations involved in the preprocessing and postprocessing phases.

Finite-element discretization often yields a linear system of equations with $n = 10^5$ or more unknowns in structural engineering. In most cases, the stiffness matrices obtained are highly sparse and symmetric positive definite. Sequential algorithms such as adaptive *Successive Over Relaxation* (SOR), preconditioned *Conjugate Gradient* (CG) methods[2] have been developed for solving sparse linear systems on conventional uniprocessor computers. These algorithms can produce the solution in $O(n^{1.5})$ time, contributed by $O(n^{0.5})$ iterations with O(n) time required for each iteration[3].

Pipelined vector processors have been used in supporting computations of this type[4, 5]. Solving a linear system with $n=10^6$ unknowns can now be done in minutes using a Cray X-MP or a Floating-Point Systems attached processor[5, 6]. However, these sequential algorithms do not fully exploit parallelism contained in all three phases.

The parallel algorithm obtained by Pan and Reif[7] decomposes a stiffness matrix into recursively nested dissections, which requires $O(\log^3 n)$ time and $O(n^{1.5})$ processors. After the decomposition, $O(\log^2 n)$ time and O(n) processors are needed to solve the linear system of equations. In order to match the high speed of parallel computations performed in the middle phase, special hardware is needed to speedup the preprocessing and postprocessing phases. This will be crucial to the overall system performance.

In this paper, we propose a method to speedup the pre/postprocessing steps. We present the limitations in speeding up the pre/postprocessing using a data-transfer model. A linear array of processors is used to yield optimal performance under the revealed limitations on I/O bandwidths.

2. The System Architecture

A finite-element machine consists of five major components: the host computer, the preprocessor, the interface unit, the parallel linear system solver, and the postprocessor as shown in Fig. 1. The host computer generates finite elements by applying a discretization algorithm to the space domain. The preprocessor

[1] The research was supported in part by NSF grant DMC-84-21022 and in part by AFOSR grant 86-0008

generates elemental stiffness matrices and corresponding force vectors. The interface unit assembles elemental stiffness matrices and force vectors to yield the global stiffness matrix K and force vector f.

The linear system solver solves the system Kx = f for the unknown vector x. The results are then sent back to the interface unit, which associates finite elements with their solved nodal values and sends the combined terms to the postprocessor. The postprocessor interpolates the final results and sends them back to the host computer. The host computer then displays the final solution to the user.

The use of the host computer, the interface unit, and the highly parallel linear system solver have been similarly practiced in the MPP[8], the connection machine[9], and the finite-element machine[10]. What we propose here is an architectural setup for faster preprocessing and postprocessing. The intention is to match the processing bandwidth of all the component subsystems involved in finite-element analysis. The parallel system solver demands the use of a large memory space to accommodate the huge stiffness matrix involved. The interface unit demands also a large memory space to accommodate the discretized space domains and their relations to the stiffness matrix. The pre/postprocessors are designed as functional units with a small working memory.

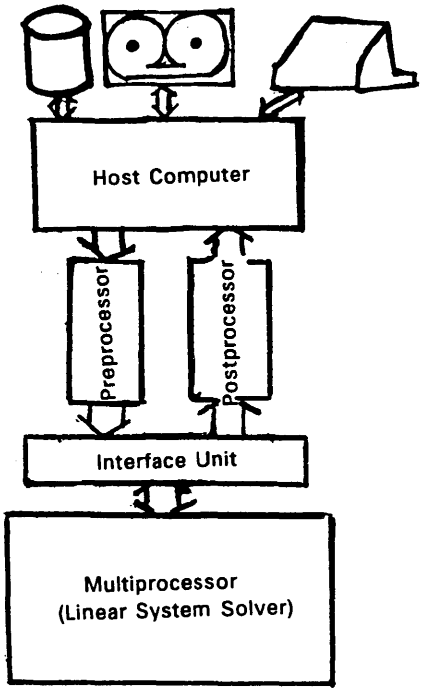

Figure 1: The system architecture of a parallel FEM-PDE solver

3. Preprocessing and Postprocessing in the FEM

Pre/postprocessings are essential in supporting real-time input of data elements and the generation of 3-D graphic displays. Most simulation studies in structural analysis, flight control, oil reservoir modeling, biological and seismological experiments demand a heavy degree of pre/processing. We define an *elemental computation* as follows : Consider an element E_i in the discretized domain, Let X be the input set , Y be the output set and F be a function independent of the index i. Then we have Y = F(X) associated with element E_i.

In preprocessing, the set X is generated from the host computer, and the set Y is sent to the interface unit. In postprocessing, X is generated from the interface unit, and Y is destined to the host computer. These elemental computations are performed repeatedly for the generation of elemental stiffness matrices and force vectors , the derivation of dependent variables, graphical curve interpolations, and geometrical transformations. All of them are main operations contained in the pre/postprocessing phases.

There is no data dependence between different elemental computations This implies the existence of massive parallelism in these elemental computations. However, the limited data transfer bandwidth between system components constrains this parallelism. We define several parameters below which will be used in the architectural designs of the preprocessor and the postprocessor. :

T_i The average time for transferring one elemental data set from the host computer to the preprocessor.

T_o The average time for transferring one elemental data set from the the postprocessor to the host computer.

T_c The preprocessing time of one element.

T_c' The postprocessing time of one element.

N_e The number of elements in a discretized PDE problem.

P The number of processors used in the preprocessor.

P' The number of processors used in the postprocessor.

Let T be the total time required for a preprocessing procedure and T' be that for a postprocessing procedure. Then we can prove that:

$$T > N_e T_i \quad \text{and} \quad T' > N_e T_o \qquad (1)$$

where, N_eT_i is the minimum time required to transfer all data from the host computer to the preprocessor. Since the overall processing time must be larger than the time for loading the data from the host computer, the inequality is thus obvious. Similar arguments hold for the postprocessing. Furthermore, one can easily show that:

$$T > (N_eT_c)/P \quad \text{and} \quad T' > (N_eT_c')/P', \qquad (2)$$

where $(N_eT_c)/P$ is the minimum time required if P processors are used in preprocessing. P' is the number of processors used in postprocessing.

For the best performance, the above results lead to the use of $P = N_eT_c/T$ and $P' = N_eT_c'/T'$ respectively. This leads to the following conditions:

$$T = (N_eT_c)/P \quad \text{if} \quad T_c > T_iP$$

$$T' = (N_eT_c')/P' \quad \text{if} \quad T_c' > T_oP' \qquad (3)$$

These findings reveal that the maximum speedups obtainable in pre/postprocessing are T_c/T_i and T_c'/T_o respectively. If the speedup factor does not match with the speed of the linear system solver, multiple lines of pre/postprocessors may be needed to support parallel data streams flowing between the host and interface unit. We concentrate on a single stream of pre/postprocessors in this study.

4. Linear Array and Macropipelining

A simple linear array of processors is proposed in Fig.2 for either preprocessing or postprocessing. Linearly connected processors requires minimum communication links between adjacent processors. The linear array can be designed to be modularly extensible, easily synchronizable[11], and fault tolerant[12]. In order to avoid the use of a large amount of data memory in the array, systolic processing is preferable. Most computations for FEM pre/postprocessing are complex, they may not map nicely with a linear systolic array. For this reason, we propose a *macropipelining* approach to achieve a pseudo systolic data flow. Macropipelining refers to the practice of pipelining in the processor level, as originally suggested in Händler[13] and Briggs, et al[14].

In macropipelining, the data context of each element are processed on the fly similarly to that of a systolic array. Once a processor receives the data context of an element, it continues the computation of the element for T_c/P (or T_c'/P') time and passes the partial results to the next processor. The processors in the linear array pass the results to the interface unit in preprocessing stage or to the host computer in postprocessing stage. The purpose is to average the load of all processors involved and to achieve an optimal pipeline rate.

The original sequential program is repeated in each processor, no recoding is needed. Only a hardware timer is required in each processor for generating interrupt signals every T_c/P time to pass the elemental context between processors. Only a small amount of memory is used in each processor to accommodate the context of three elements, one being received, one being processed, and the third one being sent out.

The pipelining of multiple processors into a macropipeline demands a special processor architecture as suggested in Fig.3. The *dual port* memory uses one port for data transfer between processors, and the other for data processing within the processor. The numerical processing unit performs floating point arithmetic. The input/output of data are done through parallel data channels. The input/output link processors contain data buffers to interface communicating processors in the array.

Besides parallel data links between processors, there are links connecting the control units of each processor. These interprocessor control links are used to synchronize the computations and communications along the linear array. The control unit sequences the local operations in each processor and communicates with the neighboring processors. The timer is designed to support macropipelining, which generates interrupt signals to the control unit and initiates the context switching between processors.

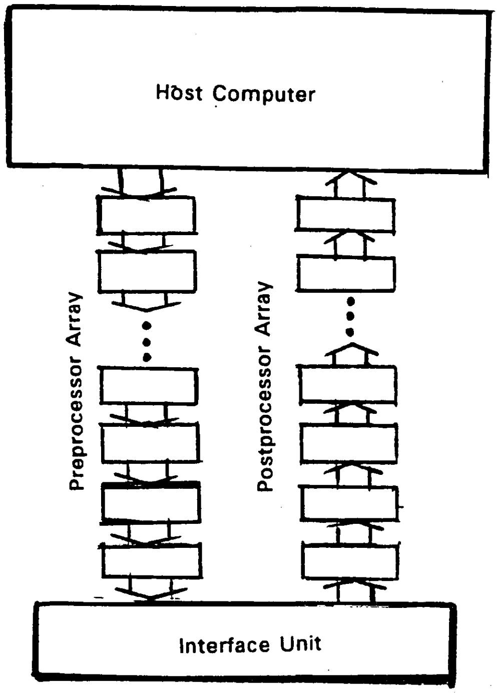

Figure 2: Suggested processor architecture for the construction of I/O processing units

Macropipelining is limited by excessive context size of each element. A large context size may create a data transfer bottleneck in the array. This interprocessor data transfer rate may substantially limit the throughput of the linear array. Several parameters thus are crucial to the performance of the preprocessor array are defined below.

t_1 The average time for transferring one byte through the data links between adjacent processors in the linear array.

n_c The size of the context of an element, measured by bytes.

t_i The average time for transferring one byte through the data channel between host computer and the preprocessor.

n_i The size of input data set of each element, measured by bytes. Note that $T_i = t_in_i$.

Using the above parameters, we found the following conditions for optimal design of the preprocessor array:

$$T_c > Pn_ct_1 \qquad (4)$$

This condition implies that T_c/P delay is needed in processing each element in a processor, where n_ct_1 is the time required to transfer the context of each element between adjacent processors in the macropipeline. Similarly, to yield optimal performance in the postprocessor array, we need to satisfy:

$$n_it_i/n_ct_1 > 1 \qquad (5)$$

This condition leads to the maximum speedup T_c/T_i, where $T_i = n_it_i$ and $T_c > (T_c/T_i)n_ct_1$.

We define a *software ratio* $\alpha = n_i/n_c$ between the size of input data set and the size of context per element, and a *hardware ratio* $\beta = (t_i/t_1)$ between interprocessor link bandwidth and the host-preprocessor channel bandwidth. These two ratios are crucial to the performance of the two arrays used. In most cases, $\alpha < 1$, since the context must contain the input data set. The value of α provides a guideline for choosing the hardware parameter β. In practice, we prefer the use of smaller value of β, say $\beta < 8$.

The condition $\alpha\beta > 1$ is necessary in applying macropipelining in the preprocessor array to achieve maximum speedup. However, if the number of processors available in the system is less than T_c/T_i, we have a loose condition for obtaining optimal performance from macropipelining as specified above. The performance of the preprocessing macropipeline is analyzed below under two assumptions, $T_c > PT_i$ and $T_c > Pn_ct_1$. The total processing time of the preprocessing array is:

$$T = T_c + Pn_ct_1 + (T_c/P)N_e < 2T_c + (T_cN_e)/P, \qquad (6),$$

where $T_c + Pn_ct_1$ is the time for the interface unit to receive the first output, it is the pipeline startup time. The throughput of the liner pipeline is T_c/P. As a result, it takes $(T_c/P)N_e$ to process the last elements. The total processing time is thus $T_c + Pn_ct_1 + (T_c/P)N_e$. The condition $T_c > Pn_ct_1$ leads to the inequality in Eq. 6.

The above result shows that macropipelining often results in a nearly optimal performance with small start up overhead. Once a solution vector is produced by the linear system solver, it needs to be displayed graphically. To generate graphical primitives from the discretized solutions, one need to perform geographical transformations, perspective transformations, and polynomial interpolations. The outputs from the postprocessor array are mainly the graphic primitives needed by the host computer for display purpose.

Macropipelining can be similarly used in the postprocessor array, To measure the performance of the postprocessor array, the following parameters are used:

t_o the average time of transferring one byte between the postprocessor and the host computer.

n_o the size of the output data set of each element transferred to the host computer, measured by bytes.
Note that, $T_o=t_on_o$.

n_c' the size of the data context of an element in postprocessing, measured by bytes.

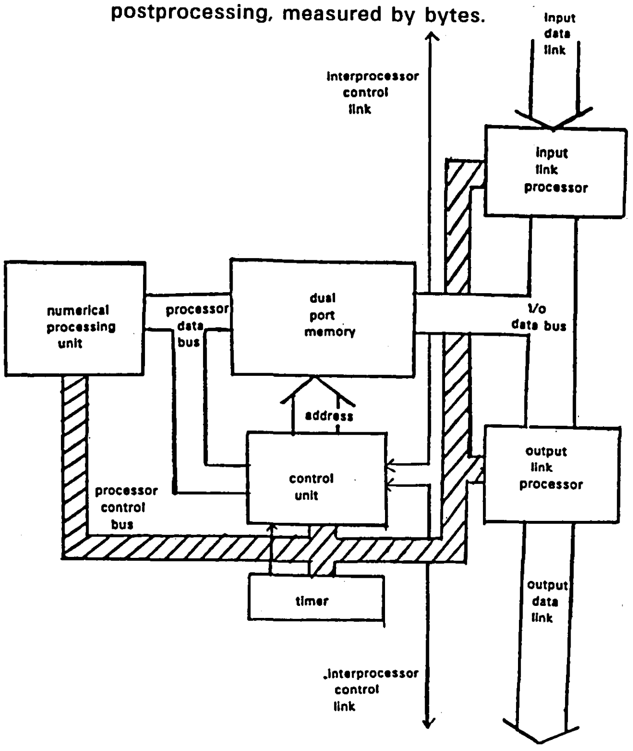

Figure 3: Proposed architecture of the processors used in the preprocessing and postprocessing arrays

α' the ratio of n_o/n_c.

β' the ratio of t_o/t_1.

In case $T_c' > T_oP'$ and $T_c' > Pn_c't_1$, the total postprocessing time $T' < 2T_c' + (N_eT_c')/P'$ can be similarly derived.

The use of a linear array of processors can achieve a nearly optimal speedup in FEM pre/postprocessing. However, the conditions for achieving this performance, $T_c > Pn_ct_1$ ($T_c' > P'n_c't_1$) and $\alpha\beta > 1$ ($\alpha'\beta' > 1$) should be carefully examined in real applications. The gains from exploiting overlapped parallelism in these I/O operations must be balanced by the increased cost of the pre/processors arrays.

5. Parallel Elemental Computations

Examples of FEM pre/postprocessing are given below. We consider first the computational demand in FEM preprocessing, namely for the generation of elemental stiffness matrices and elemental force vectors. To simplify the explanation, consider a 2-D 4-node quadrilateral Lagrange element for a poisson equation :

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = f(x, y) \tag{7}$$

The elemental stiffness matrix $K = [k_{ij}]$ is an 4x4 matrix defined by the following equation :

$$k_{ij} = \int\int [\frac{\partial \psi_i}{\partial x}, \frac{\partial \psi_i}{\partial y}] [\frac{\partial \psi_j}{\partial x}, \frac{\partial \psi_j}{\partial y}]^T \ dxdy \tag{8}$$

where ψ_i's are the basic shape functions associated with each node. These shape functions are predefined from a standard square element on a *natural coordinate system* (ξ, η). The standard element and a real element are linked by an isoparametric transformation between the two coordinate systems (ξ, η) and (x, y) as illustrated in Fig.4 . To perform the integration, Gauss quadrature is performed as follows:

$$K = \sum_{k=1}^{2} \sum_{l=1}^{2} B(\xi_k,\eta_l)^T B(\xi_k,\eta_l) \det(J(\xi_k,\eta_l)) W_{kl} \tag{9}$$

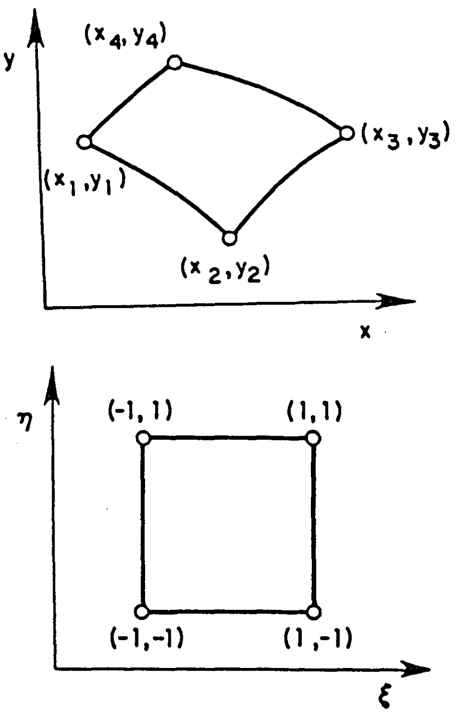
where (ξ_k, η_l) are the Gauss points inside an element. In the above example 2 x 2 Gauss points are used. J is a 2x2 Jacobian matrix on the Gauss point, which depends on 4 nodal coordinates of real elements. B is a 2x4 matrix defined on each Gauss points by the following equation :

$$B=J^{-1}N, \quad N_{2x4} = [n_{ij}] \tag{10}$$

$$n_{1j}=\frac{\partial \psi_j}{\partial \xi} \qquad n_{2j}=\frac{\partial \psi_j}{\partial \eta}$$

N is a precomputed constant matrix for the standard square element. The computations involved are elemental. The inputs are the nodal coordinates of each real element, and the outputs are the elemental stiffness matrices. Since the stiffness matrix is symmetric, only the diagonal and upper triangle of the stiffness matrix need to be computed. The values of n_i and n_c are estimated to yield the ratio α. With the ratio α determined, the ratio β for macropipelining can be determined accordingly.

The input data set corresponds to the coordinates of 4 nodal points, which requires 8 words or n_i = 32 bytes. The context of the computation includes the input coordinates of 4 nodal points, the diagonal and upper triangle of the stiffness matrix, the Jacobian matrix, the B matrix, auxiliary integer indexes and other temporary variables. A context of 32 words is large enough for the given example, which makes n_c = 128 bytes. Note that, the constants are part of the program which does not belong to the context of an element. The ratio $\alpha = n_i/n_c = 1/4$ implies that $\beta > 4$ is required to achieve maximum speedup.



$$x = \sum_{i=1}^{4} a_i\phi_i(\xi, \eta) \qquad y = \sum_{i=1}^{4} b_i\phi_i(\xi, \eta)$$

Figure 4: The isoparametric transformation of a quadralateral finite element

The total number of floating point operations involved determines the ratio T_c/T_i, which corresponds to the maximum parallelism achievable in the preprocessing array. Two parameters are used :

n_f The total number of floating point operations (multiplication or addition) used in the element based computation for an element.

t_f The average processing time of a floating point operation in a processor.

Since most operations involved in the stiffness matrix generation are floating point computations, T_c is estimated to be $n_f t_f$. The speedup for the given example is thus upper bounded by

$$T_c/T_i=(n_f/n_i)(t_f/t_i)=\theta\gamma \qquad (11)$$

The ratio $\theta = (n_f/n_i)$ is a *software parameter* independent of the hardware configuration. The larger is the value of θ, the higher parallelism is available in the preprocessing phase. The ratio $\gamma = t_f/t_i$ is a *hardware parameter* that reflects the hardware configuration used in the linear array. Since a fast communication channel is assumed in the system architecture, we can assume $\gamma >> 1$. An estimation of n_f for the given example is 640, which implies θ=20. In case γ = 10, a speedup of 200 is possible in the preprocessing stage.

The computational properties of various finite elements in solving a linear elastic problem are given below for a 3-D problem.

$$\varepsilon_x = \frac{\partial u}{\partial x} \qquad \varepsilon_y=\frac{\partial v}{\partial y} \qquad \varepsilon_z=\frac{\partial w}{\partial z}$$

$$\varepsilon_{xy} = \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \qquad \varepsilon_{xz} = \frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \qquad \varepsilon_{yz} = \frac{\partial v}{\partial z} + \frac{\partial w}{\partial y}$$

$$\frac{\partial \sigma_x}{\partial x} + \frac{\partial \tau_{xy}}{\partial y} + \frac{\partial \tau_{xz}}{\partial z} = -f_x$$

$$\frac{\partial \tau_{yx}}{\partial x} + \frac{\partial \sigma_y}{\partial y} + \frac{\partial \tau_{yz}}{\partial z} = -f_y \qquad (12)$$

$$\frac{\partial \tau_{zx}}{\partial x} + \frac{\partial \tau_{zy}}{\partial y} + \frac{\partial \sigma_z}{\partial z} = -f_z$$

$$[\sigma_x, \sigma_y, \sigma_z, \tau_{xy}, \tau_{xz}, \tau_{yz}]^T = E[\varepsilon_x, \varepsilon_y, \varepsilon_z, \varepsilon_{xy}, \varepsilon_{xz}, \varepsilon_{yz}]^T$$

where E is a 6x6 constant matrix. For structures of thin thickness, it can be simplified to a 2-D problem and qudrilateral plane element can be applied in discretization. For a general problem, a 3-D cubic solid element needs to be used for the discretization. To generate the local stiffness matrix K and force vector f, two numerical integrations are performed:

$$K = \int_0^1\int_0^1\int_0^1 B^T E B \det[J] \; d\xi d\eta d\zeta$$

$$f = \int_0^1\int_0^1\int_0^1 (B^T E \{\varepsilon_0\} - B^T\{\sigma_0\} + N^T\{f_0\})\det[J] \; d\xi d\eta d\zeta \qquad (13)$$

where matrix B depends on nodal coordinates of an element, J is the the Jacobian matrix which links the real coordinate system (x, y, z) to the natural coordinate system (ξ, η, ζ). Matrix N depends on the shape functions used. The size of matrices B and N depends on the number of nodal points used to model the elements. To compute this integration numerically, the Gauss Quadrature method is applied. The number of Gauss points used for the numerical integration depends on the order of the shape function.

In Table.1, we summarize the computational properties for various elements used in a linear elastic structural analysis. These properties correspond to the hardware independent parameters which are used in the performance analysis and design of the preprocessor. The geometrical shapes of these elements are shown in Fig.5 . In all cases the value of α and θ are large enough to justify the use of a linear array as a preprocessor.

Table 1: Computational Properties For Preprocessing Of Various Finite Elements in Fig.4

2-D plane elements

nodes	d.o.f	G-points	n_c	n_i	n_f	α	θ
4	8	2x2	512	176	2400	0.34	13.6
4	8	3x3	512	176	5400	0.34	30.7
4	8	4x4	512	176	9600	0.34	54.5
8	16	3x3	1120	352	10,800	0.31	30.7

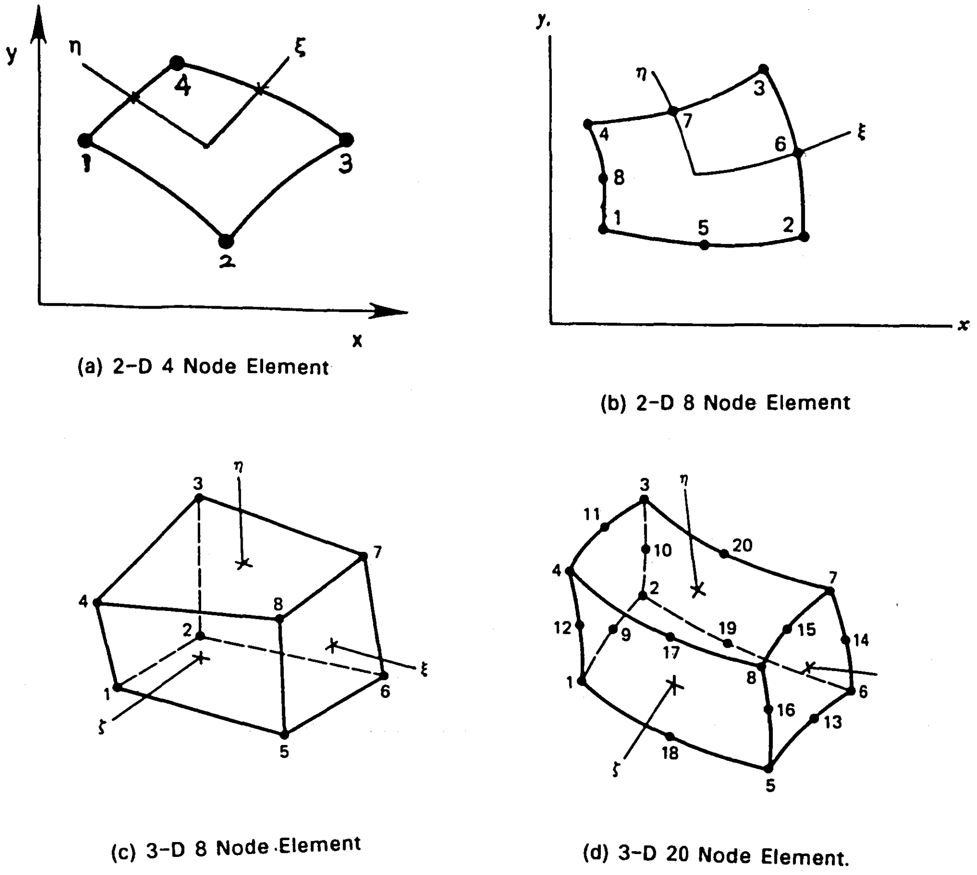
8	16	5x5	1120	352	21,000	0.31	59.6

3-D solid elements

nodes	d.o.f.	G-points	n_c	n_i	n_f	α	θ
8	24	3x3x3	3136	672	135,000	0.21	200
8	24	4x4x4	3136	672	320,000	0.21	476
20	60	4x4x4	12,000	1680	768,000	0.14	457
20	60	5x5x5	12,000	1680	1,500,000	0.14	893

Note that :
nodes : number of nodes used in one element.
d.o.f. : degree of freedom in the finite element.
G-points : number of Gauss points used in each dimension.



(a) 2-D 4 Node Element

(b) 2-D 8 Node Element

(c) 3-D 8 Node Element

(d) 3-D 20 Node Element.

Figure 5: Various finite elements for an elastic structural analysis defined in Eq. (12)

Using the same linear elastic elements, consider a simple postprocessing algorithm which interpolates the solution vector, generates the graphical primitives, and sends them to the host computer. The interpolated picture provides a clear contour of the solution vector or the derived solution vector. The software parameter θ'is determined to examine achievable speedup. The value θ' can be estimated from the computation performed to generate one interpolation point and the number of bytes used for coding one such point in graphics. For example, to interpolate the solution for a point (ξ_p, η_p) in a 2-D element, first the norm of the interpolated solution at point P (u_p, v_p) needs to be computed :

$$u_p = \sum_{k=1}^{\text{nodes}} u_k \psi_k(\xi_p, \eta_p)$$
$$v_p = \sum_{k=1}^{\text{nodes}} v_k \psi_k(\xi_p, \eta_p) \qquad (14)$$
$$c_p = (u_p^2 + v_p^2)^{1/2}$$

Then the natural coordinate of point $P(\xi_p, \eta_p)$ is transformed into its real coordinate (x_p, y_p) by :

$$x_p = \sum_{k=1}^{\text{nodes}} x_k \psi_k(\xi_p, \eta_p)$$
$$y_p = \sum_{k=1}^{\text{nodes}} y_k \psi_k(\xi_p, \eta_p) \qquad (15)$$

Then the value of (x_p, y_p, v_p) is scaled into integers corresponding to the graphical primitives. Table 2 lists the 2-D elastic elements discussed in the previous section with an estimated θ' value. The estimations are based on the fact that 4 bytes are used to code one interpolation points inside an element. The estimated θ' value for 3-D elements are also given in the table. In all cases, α' are greater than 1/2. This implies that the hardware with β'= 2 is good for achieving the maximum speedup. Again, the table justifies the choice of a linear array for FEM postprocessing.

Table 2: Computational Properties For Postprocessing Of Various Elastic Finite Elements in Fig.4

2-D plane elements

nodes	d.o.f.	deg(ψ)	θ'
4	8	2	10
4	8	3	12
4	8	4	14
4	16	3	29
4	16	4	33

3-D solid element

nodes	d.o.f.	deg(ψ)	θ'
8	24	3	26
8	24	4	30
20	60	4	72
20	60	5	82

Note that :
deg(ψ) : the degree of the shape functions as a polynomial.

6. Conclusions

The importance of using fast pre/postprocessing systolic arrays in a finite-element machine becomes apparent with the increasing use of highly parallel linear system solvers. Computational properties of FEM pre/postprocessing steps reveal that linear arrays are indeed a good choice for these steps. The hardware demand is low and the array is modularly expandable. Macropipelining avoids the problem of software recoding. Our case studies reveal that high speedup factors of 100 or 1000 (assuming γ=10) can be achieved with the macropipelining approach. To reach the maximum speedup, the data transfer rate between processors should be 4 to 8 times faster than the host computer channel speed. The results being presented should be useful to those who are involved in developing efficient I/O and parallel PDE solvers on a multiprocessor supercomputer[15].

ABSTRACT

A new class of parallel algorithms for solving linear tridiagonal systems, which compares very favorably with the existing parallel algorithms, is described.

1. INTRODUCTION

There are basically two classes of methods for solving linear tridiagonal systems in parallel. The first of these due to Stone [4,5] is called the method of recursive doubling. This method introduces parallelism in the now-classical Gaussian elimination algorithm. The second method is called the method of cyclic reduction and is due to Hockney [1,9]. There are in fact two versions of this algorithm: one is called the odd-even reduction [3] (also known as serial cyclic reduction [1]) and the other is called the odd-even elimination [3] (also known as parallel cyclic reduction [1]). A version of the recursive doubling given in [1] takes 24logn (all logarithms are to base 2) units of time using a parallelism of size n. Refer to Table 1. The odd-even reduction, on the other hand, takes only 19logn units of time using a parallelism of size $n'/2$ where $n'=n+1=2^t$ for some $t\geq 1$ [1]. The odd-even elimination, however, using a parallelism of size n', takes only $14\log n'$ units of time. It can be easily shown that both the recursive doubling and odd-even elimination require a total of O(nlogn) scalar operations but odd-even reduction needs only O(n) (that is, about 19n) scalar operations. Thus, for large n, when the available parallelism is limited, the odd-even reduction is widely recommended [3]. For a succinct summary of these and many other parallel algorithms, refer to the survey by Heller [3]. The performance of these algorithms on vector machines has been thoroughly analyzed in Stone [5] and Lambiotte and Voigt [11].

In this paper, we describe a new class of parallel algorithms for solving linear tridiagonal systems. Like the method of recursive doubling, this method also introduces parallelism in the solution of the recurrences arising from the Gaussian elimination algorithm. Our method is very flexible, permits vector or multi-processor or a combination of vector and multiprocessor implementations and is adaptable to a wide range of the size of parallelism. This new algorithm is based on the shared memory model called PRAM [10] which allows simultaneous read but only single write in the same memory location. More specifically, it is shown that a linear tridiagonal system of size n can be solved in $(n/p[(32/3)+6\log p]-3$ units of time using $(3/2)p$ processors where $n=2mp$ for m, a multiple of 3, and $p=2^k$ for some $k\geq 1$. Thus, using only 3 processors (p=2) this method takes only 8.33n-3 units but the widely preferred odd-even reduction needs 9n units of time. When p=n/3, that is, using a total of n/2 processors, the new method takes 18logn units which is nearly the same performance as the odd-even reduction method. Further, if p=n/2 that is, using 3n/4 processors, our method needs only 12logn+7 units of time. Further, using n/2 processors, our new method is 55% more processor efficient compared to recursive doubling and 31% more processor efficient compared to odd-even elimination.

In Section 2, we describe the mathematical framework. The algorithm itself is given in Section 3. Section 4 provides a thorough comparison of all the existing methods and suggests improvements in implementing odd-even reduction should more processors become available. Concluding remarks are given in Section 5.

2. A MATHEMATICAL FRAME-WORK

Consider a linear tridiagonal system

$$Ax = K \qquad (2.1)$$

where

$$A=\begin{bmatrix} b_1 & c_1 & 0 & 0 & 0 & \cdots & & & 0 \\ a_2 & b_2 & c_2 & 0 & 0 & \cdots & & & 0 \\ 0 & a_3 & b_3 & c_3 & 0 & \cdots & & & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & & & & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & & & & \cdot \\ 0 & 0 & 0 & 0 & 0 & 0 & a_{n-1} & b_{n-1} & c_{n-1} \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & a_n & b_n \end{bmatrix}$$

and

$$K = (k_1,k_2,k_3\ldots k_n)^T$$

where T denotes the transpose. The classical Gaussian elimination algorithm provides a framework for our analysis. We follow the notations given in [1]. Let A=LU be the factorization of A, where

$$L=\begin{bmatrix} e_1^{-1} & 0 & 0 & \cdots & 0 & 0 \\ a_2 & e_2^{-1} & 0 & \cdots & 0 & 0 \\ \cdot & a_3 & e_3^{-1} & & \cdot & \cdot \\ \cdot & \cdot & \cdot & & \cdot & \cdot \\ \cdot & \cdot & \cdot & & \cdot & \cdot \\ 0 & 0 & \cdots & & a_n & e_n^{-1} \end{bmatrix}$$

and

$$U=\begin{bmatrix} 1 & W_1 & 0 & \cdots & & 0 \\ 0 & 1 & W_2 & \cdots & & 0 \\ \cdot & \cdot & \cdot & & & \cdot \\ \cdot & \cdot & \cdot & & & \cdot \\ \cdot & \cdot & \cdot & & & \cdot \\ \cdot & \cdot & \cdot & & & W_{n-1} \\ 0 & 0 & 0 & \cdots & 0 & 1 \end{bmatrix}$$

Given the factors L and U, it is well known that solving (2.1) is equivalent to solving a system of three recurrences in the following order:

(a) $$W_i=\frac{c_i}{(b_i-a_iW_{i-1})}, \text{ for } n-1\geq i\geq 2 \qquad (2.2)$$

$W_1=\dfrac{c_1}{b_1}$. Notice that $e_i=\dfrac{W_i}{c_i}$

(b) $$g_i=\frac{(k_i-a_i\ g_{i-1})}{(b_i-a_i\ W_{i-1})}, \text{ for } n\geq i\geq 2 \qquad (2.3)$$

$g_1=\dfrac{k_1}{b_1}$

and

(c) $$x_i=g_i-W_ix_{i+1}, \quad \text{for } n-1\geq i\geq 1 \qquad (2.4)$$

$x_n=g_n$

Solving these three recurrences serially requires not more than 8n scalar operations.

Our method, like the recursive doubling, consists in first converting the first-order nonlinear recurrence (2.2) into a first-order linear recurrence in vector form. More specifically, define

$$W_i=\frac{Y_{i-1}}{Y_i}, \ 1\leq i\leq n-1,$$

$Y_0=1$ and $Y_1=b_1/c_1$

Substituting in (2.2), we obtain

$$V_i=A_iV_{i-1}, \text{ for } n-1\geq i\geq 2 \qquad (2.5)$$

where $V_i=(Y_{i-1},Y_i)^T$, $V_1=(1,b_1/c_1)^T$ and

$$A_i = \begin{bmatrix} 0 & 1 \\ -\dfrac{a_i}{c_i} & \dfrac{b_i}{c_i} \end{bmatrix} \qquad (2.6)$$

Thus, in this framework, solving (2.1) reduces to one of solving the following two sub-problems:

<u>Problem 1</u>: Solve for V_i, i=2 to n when

$$V_i = A_iV_{i-1} \qquad (2.7)$$

where V_i and A_i are 2x1 and 2x2 matrices respectively, given V_1 and A_i's.

<u>Problem 2</u>: Solve for Z_i, i=2 to n when

$$Z_i = f_iZ_{i-1}+d_i \qquad (2.8)$$

where $Z_1,(f_2,f_3,\ldots,f_n)$ and $(d_1,d_2,\ldots,d_n)$ are given.

The following section contains our main result. For other methods of solving linear recurrences refer to [2,6,7,8].

3. A NEW PARALLEL ALGORITHM

We begin by presenting a new parallel algorithm for solving Problem 1. The solution $V_i, i\geq 2$, to (2.7) in closed form is given by

$$V_i = A_iA_{i-1}\dots A_2V_1 = [\prod_{j=2}^{i} A_j]V_1 \quad (3.1)$$

As a first step in computing V_i's define for $u\geq v$

$$B[u,v] = A_uA_{u-1}\dots A_v = \prod_{j=v}^{u} A_j$$

Since the matrix product is not commutative, the order of multiplication is very important to our development. (Vacuous products are taken to be unit matrices). The following properties of the B[.,.] function are obvious:

Lemma 3.1

(a) For any r>1, B[u+r,v] = B[u+r,u+1]B[u,v]

(b) $V_1 = B[i,2]V_1$ for all $i\geq 2$.

This lemma readily suggests the following parallel algorithm. Let $p=2^k$, n=2mp, q=p/2 where $k\geq 1$ and m is a multiple of 3. The following algorithm uses 3q processors.

Algorithm V: Let Q_j, $0\leq j\leq q-1$, refer to a group of 3-processors. For consistency assume, that A_1 is a 2x2 identity matrix.

Stage 1: The processor group Q_0 computes the following:

```
FOR i = 1 to 4m
  $V_i = A_iV_{i-1}$
END
```

Each of the processor group Q_j, $1\leq j\leq q-1$ computes the following in parallel.

```
FOR i = 1 to 4m
  compute B[4mj+i, 4mj+1]
END
```

Stage 2:

```
FOR s = 1 to k-1
  base = 4m x $2^{s-1}$
  Using $2^s$ 3-processor groups, compute
  the following in parallel.
  FOR i = 1 to 4m x $2^{s-1}$
  $V_{base + i}$ = B[base + i, base + 1] $V_{base}$
  END
  FOR g = 1 to $2^{k-s-1}-1$
  using $2^s$ 3-processor groups compute the
  following in parallel.
     FOR i = 1 to 4m x $2^{s-1}$
     Compute B[m(1+2g)$2^{s+1}$+i,mg$2^{s+2}$+1]
     END
  END
END.
```

The following example illustrates the above algorithm.

Example 3.1: Let p=16, q=8 and n=32m for some $m\geq 3r, r\geq 1$. Various steps in each of the stages of the Algorithm V are given in Figure 1.

The following theorem is immediate.

Theorem 3.1: Algorithm V computes V_i's given in (3.1) for $2\leq i\leq n$ using 3q processors in

(n/p)[2+4logp]-3

units of time.

Proof: In stage 1, there are q independent segments of computations. The first segment involves a chain of 4m-1 matrix-vector products and each of the other segments involves chains of 4m-1 matrix products. Allot a 3-processor group to each of the q segments. The multiplication of two 2x2 matrices, using 3-processors can be done in 5-units of time. However, since there is a chain of products, referring to Figure 2, it is readily seen that the chain of (4m-1) matrix products can be completed in 4(4m-1)+1 = 16m-3 units of time. Likewise, the chain of (4m-1) matrix-vector products can be completed in 3(4m-1) = 12m-3 units of time. Clearly, the matrix products dominate, and stage 1 takes (16m-3) units of time.

For any s=1 to k-2 in stage 2, there are 2^{k-s-1} segments of independent computations. The first of these segments involves matrix-vector products and the rest of the segments involve matrix products. By allocating 2^s sets of 3-processor groups to each of the segments, (since the matrix products dominate) it is easily seen that each processor performs (2/3)m matrix products. (Remember that m is a multiple of 3). Thus, the computation in each step s=1 to k-2 can be completed in (2/3)mx12 = 8m units of time.

The last step (s=k-1) involves only the chain of matrix-vector products. Each of the 3-processor group performs only 2m matrix-vector products and this step takes (2m/3)x6=4m units. Thus the total time needed by the algorithm V is (16m-3)+(k-2)(8m)+4m=4m(1+2k)-3. Since

$n=2mp$, the theorem follows.

We now present a parallel algorithm for solving Problem 2 [12,13].

The solution to the linear first-order recurrence (2.8) in closed form is given by

$$Z_i = \sum_{j=0}^{i} [\prod_{s=j+1}^{i} f_s] d_j \qquad (3.2)$$

In the following we present a new parallel algorithm for computing (3.2). To this end, we introduce two functions A[u,v] and Y[s,t] of a_i's and d_i's.

Let

$$A[u,v] = \prod_{r=u+1}^{v} f_r \qquad (3.3)$$

where vacuous products are taken to be unity and let

$$Y[s,t] = \sum_{j=s}^{t} A[j,t]d_j, \text{ for } t \geq s \quad (3.4)$$

A number of useful properties of the functions A[.,.] and Y[.,.] are developed in the following lemmas.

<u>Lemma 3.2</u>: The function A[u,v] satisfies the following:

(a) $A[u,v]=1$ for all $u \geq v$

(b) $A[u,v+m]=A[u,v] \cdot A[v,v+m]$ for any integer $m>0$

The proof of this lemma is straightforward.

<u>Lemma 3.3</u>: The function $Y[s,\cdot]$ also satisfies the recurrence of the type (1.1), that is,

$$Y[s,t]=f_t Y[s,t-1]+d_t \qquad (3.5)$$

<u>Proof</u>: Rewriting (3.4) we readily obtain

$$Y[s,t] = \sum_{j=s}^{t-1} A[j,t]d_j + A[t,t]d_t$$

Since $A[t,t]=1$ and $A[j,t]=f_t A[j,t-1]$, the lemma follows.

<u>Lemma 3.4</u>: $Z_t=Y[1,t]$ for all $1 \leq t \leq n$. The proof follows from the definitions.

The following lemma which is a generalization of the Lemma 3.3 provides the basis for our algorithm.

<u>Lemma 3.5</u>: If $t \geq s$ then for $i>0$

$$Y[s,t+i]=A(t,t+i\}Y[s,t]+Y[t+1,t+i] \qquad (3.6)$$

<u>Proof</u>: From equation (3.4) it follows that

$$Y[s,t+i] = \sum_{j=s}^{t+i} A[j,t+i]d_j$$

$$= \sum_{j=s}^{t} A[j,t+i]d_j + \sum_{j=t+1}^{t+i} A[j,t+i]d_j \qquad (3.7)$$

It is readily seen from equation (3.4) that the second term is in fact Y[t+1,t+i]. From Lemma 3.2

$$A[j,t+i]=A[j,t]A[t,t+i] \qquad (3.8)$$

Substituting (3.8) in the first term of (3.7), the lemma follows.

Let $n=2mp$, $p=2^k$ $q=p/2$ where $m \geq 1$ and $k \geq 1$. In the following we use 3q processors. Let $1 \leq s \leq k$ and $0 \leq g \leq 2^{k-s}-1$. Our algorithm for solving (2.8) consists of two parts: (1) a parallel <u>Algorithm A</u> for computing A[u,v] and (2) a parallel <u>Algorithm Y</u> for computing Y[s,t]. In fact Algorithm A computes all those A[u,v] which are needed in the computation of Y[s,t]. Since these two algorithms are working in parallel, the total number of processors is equal to the sum of the processors used in both the algorithms but the time is maximum of the time needed by the two algorithms. The Algorithm Y uses p processors $P_0, P_1 \ldots P_{p-1}$ and Algorithm A uses q processors $Q_0, Q_1 \ldots Q_{q-1}$.

<u>Algorithm A</u>:

<u>Stage 1</u>: Each processor $Q_j, 0 \leq j \leq q-1$, computes the following:

```
FOR i=1 to 2m
Compute A[2m(1+2j),2m(1+2j)+i]
END
```

In this stage totally 2qm number of the A[.,.] functions are updated using q processors. Each update involves one multiplication. The stage takes n/p(=2m) units of time.

<u>Stage 2</u>: Each processor $Q_j, 0 \leq j \leq q-2$, computes the following:

```
FOR i=1 to 2m
Compute A[4m(1+j),4m(1+j)+i]
END
```

In this stage totally 2m(q-1) number of A[.,.] functions are updated using (q-1) processors. This stage also takes n/p units of time.

Stage 3:

```
FOR s=1 to k-1
  FOR j=0 to $2^{k-s}-2$
  Let $h_j=6m2^{s-1}+2^{s+1}mj$
    FOR i=1 to 2ms
    Compute A[$h_j$-2ms, $h_j$+i]
    END
  END
END
```

In any step s, there are $2^{k-s}-1$ groups of computations and within each group 2ms number of A[.,.] functions are updated. Since $2ms(2^{k-s}-1) \leq 2m(q-1)$, using not more than (q-1) processors, each of the above steps can be finished in not more than n/p units of time. Thus the entire Algorithm using q processors does not take more than (n/p[1+logp] units of time.

Algorithm Y:

Stage 1: Each processor $P_i, 0 \leq i \leq p-1$, computes the following:

```
FOR j=0 to m-1,
Y[2im+1,2im+1+j]=$a_{2im+1+j}$Y[2im+j]
+$d_{2im+1+j}$
END
```

Stage 2: Each of the processors $P_i, 0 \leq i \leq p-1$, computes the following:

```
FOR j=0 to m-1,
Y[2im+1,(2i+1)m+1+j]=
          $a_{(2i+1)m+1+j}$Y[2im+1),
          (2i+1)m+j]+$d_{(2i+1)m+1+j}$
END
```

In each of the stages 1 and 2, totally n/2 of the Y[.,.] functions are updated using p processors. Since each update requires two operations (a multiplication and an addition) each of the above stages takes n/p units of time.

Stage 3:

```
FOR s=1 to k
  FOR g=0 to $2^{k-s}-1$
    FOR i=1 to $m2^s$
    Y[$2^{s+1}$mg+1,$2^s$m(1+2g)+i] =
    A[$2^s$m(1+2g),$2^s$m(1+2g)+i]Y[$2^{s+1}$mg+1,
    $2^s$m(1+2g)]+Y[$2^s$m(1+2g)+1,$2^s$m(1+2g)+i]
    END
  END
END
```

It is readily seen that at any step s in stage 3, the algorithm identifies 2^{k-s} groups indexed by g and within each group there are 2^s processors working in parallel. Thus within each group $2^s m$ number of Y[.,.] functions are updated. It readily follows that computations in each group take the same amount of time equal to n/p units. Thus the entire stage 3 takes (n/p)logp units of time.

For the correct functioning of the Algorithm Y, the values of A[2^sm(1+2g), 2^sm(1+2g)i] for $0 \leq g \leq 2^{k-s}$ and $1 \leq i \leq k$ must be made available for each $1 \leq s \leq k$. In fact, these functions are generated in parallel by the Algorithm A. A close scrutiny reveals that all the values of the A[.,.] functions that are needed in stage 3 of Algorithm Y are in fact generated by Algorithm A at least one step ahead of time. Thus the Overall time for solving for Z_i's in (2.8) is decided by the running time of the Algorithm Y.

We now illustrate the Algorithms Y and A through an example.

Example 3.2: Let p=8, q=4, k=3, m=6, n=96. The various stages of the Algorithm Y are shown in Figure 3. In Figure 4 further details of the computations in Stage 3 of Algorithm Y are illustrated. Figure 5 illustrates various stages of Algorithm A. Comparing Figures 4 and 5, it is readily seen that the values of the A[.,.] function are made available at least one step ahead of the time they are needed in Algorithm Y.

Theorem 3.2: Using a total of 3q processors, Algorithms Y and A compute Y[1,t] for $1 \leq t \leq n$ in (n/p)[2+logp] units of time.

Proof: At the end of stage 1 of Algorithm Y, Y[1,t] for $1 \leq t \leq m$ and at the end of stage 2, Y[1,t] for $1 \leq t \leq 2^{i+1}m$ are computed. Thus the entire sequence of Y[1,t] for $1 \leq t \leq n$ is available at the end of stage 3. This proves the correctness of the Algorithm Y.

Of the (3/2)p processors, Algorithm Y uses p and Algorithm A uses p/2. Further, since Algorithms A and Y are acting in parallel and Algorithm Y takes longer time compared to Algorithm A, the total time is that of Algorithm Y. It is readily seen from the description of the algorithms, that this latter algorithm takes (n/p)[2+logp] units of time and the theorem follows.

We now state our main result.

Theorem 3.3: Let $p=2^k$, q=(p/2), n=2mp and $k \geq 1$ and m is a multiple of 3. A linear tridiagonal system of size n can be solved, using 3q processors in

(n/p)[(32/3)+6logp]-3

units of time.

Proof: Setting up each matrix A_i involves 2 divisions and 1 sign change operation. Since there are (n-1) matrices and an initial condition to be computed, this overall initialization, using 3q processors takes (2n/p) units of time. Solving for W_i, and setting up the g_i computation in the form (2.9) needs the computation of (W_i/c_i), $k_i(W_i/c_i)$ and $a_i(W_i/c_i)$. This part takes, using 3q processors (8n/3p) units. Then solving for g_i and x_i using Algorithms A and Y takes (2n/p)[2+logp] units. Adding up all these factors the theorem follows.

4. A COMPARISON OF VARIOUS ALGORITHMS

Table 1 gives the time and processor requirements for a number of known algorithms. It is readily seen from Table 1 that, with (n/2) processors, the new method has 55% more processor efficiency compared to recursive doubling and 31% more processor efficiency compared to odd-even elimination.

For the purposes of comparing the new method with the widely preferred odd-even reduction, we describe the latter as follows [1]:

Let $n' = n+1 = 2^t$ for some t>0. Define $p_i^{(u)} = (a_i^{(u)}, b_i^{(u)}, c_i^{(u)}, k_i^{(u)})$ where $p_i^{(o)} = (a_i, b_i, c_i, k_i)$.

Odd-Even Reduction:

Stage 1: This stage computes a set of vectors $p_i^{(u)}$:

```
FOR u=1 step 1 unitl t-1
  FOR i=$2^u$ step $2^u$ until n-$2^u$
      $H = 2^{u-1}$
      $\alpha i = a_i^{(u-1)}/b_{i-H}^{(u-1)}$
      $\gamma i = c_i^{(u-1)}/b_{i-H}^{(u-1)}$
    $a_i^{(u)} = -\alpha_i\ a_{i-H}^{(u-1)}$
    $c_i^{(u)} = -\gamma_i\ a_{i-H}^{(u-1)}$
    $b_i^{(u)} = b_i^{(u-1)} - \alpha_i\ c_{i-H}^{(u-1)} - \gamma_i\ a_{i-H}^{(u-1)}$
    $k_i^{(u)} = k_i^{(u-1)} - \alpha_i\ k_{i-H}^{(u-1)} - \gamma_i\ k_{i-H}^{(u-1)}$
    END
END.
```

Stage 2: This stage recovers the solution recursively. Let $X_0 = X_{n'} = 0$

```
FOR u=t step -1 until 1
  FOR i=$2^{u-1}$ step $2^u$ unitl n´-$2^{(u-1)}$
    $H=2^{u-1}$
    $x_i=[k_i^{(u-1)} - a_i^{(u-1)} x_{i-H}$
        $-c_i^{(u-1)} x_{i+H}]/b_i^{(u-1)}$
  END
END
```

This algorithm requires a total of only 19n scalar operations and thus is widely preferred when only a small number of processors are available. It is readily seen that the body of the loop in stage 1 involves a total of 14 scalar operations and that in stage 2 involves a total of 5 scalar operations. Analyzing the data dependency in the computations of the above loops, it can be seen that with 3 processors, stage 1 takes 5n units and stage 2 takes 4n units requiring a total of 9n units. However, with 3 processors the new algorithm requires only 8.33n-3 units.

Likewise, if there are 6 processors available, each iteration through the loop in stage 1 takes 4 units and that in stage 2 takes 4 units, requiring a total of 8n units. But the new method takes only 5.67n-3 units. Thus, the new method compares favorably with the odd-even reduction.

5. CONCLUSION

A new class of parallel algorithms for solving tridiagonal systems that are suitable for implementation on shared memory multi-vector architectures such as CRAY-XMP, Alliant, etc. is described. While our analysis primarily relates to the arithmetic complexity, it should be interesting to actually implement and compare its performance with other parallel algorithms for solving tridiagonal systems.

A PARALLEL COMPUTER BASED ON CUBE CONNECTED CYCLES FOR WAFER SCALE INTEGRATION

Moon Jung Chung, Edward J. Toy*, Aarti,Gupta

Rensselaer Polytechnic Institute, Troy NY 12180

ABSTRACT

The wafer scale integration (WSI) implementation of a single instruction multiple data (SIMD) computer with processing elements (PEs) grouped in a Cube Connected Cycles (CCC) network is presented. Such a network is a good candidate for WSI due to the homogeneity of the network's PEs and the localized processor connections. A RISC based instruction set and an architecture supporting such an instruction set has been developed for the processing element. The data path design for a single chip implementation of this processing element is outlined, along with initial timing and area estimates. Programming is accomplished by the specification of logical networks of processors, providing great flexibility in using the CCC network. Yield considerations for the implementation of this parallel computer with 512 PEs capable of operating on up to 128k data points for a 2μm CMOS process in WSI are given.

Keywords: Cube Connected Cycles, Parallel Processing, Wafer Scale Integration, VLSI, Computer Architecture.

Introduction

Scientists and engineers are frequently confronted by computationally intense problems. Solving these problems by traditional sequential algorithms are proving inadequate due to their lengthy processing times. In response, parallel algorithms for such problems as Fourier Transforms, convolution and matrix manipulation have been developed[1,21,26,29,36] To realize the computational power of these algorithms, massively parallel computers need to be developed. Application of this technology in such diverse fields as physics, computational geometry, signal processing and design automation and could potentially lead to the solutions of problems beond the scope of present computers.

This work describes the implementation of a parallel computer consisting of 512 processors functioning as an SIMD machine, connected with the Cube Connected Cycles (CCC) network[32], capable of operations on problem sizes of up to 128k data points. Wagner has developed a boolean vector computer based on this network[39]. While this machine is only capable of boolean operations on three 1 bit variables, it serves to demonstrate the versatility of the network. The salient features of the CCC network are: 1) interprocessor connections are strictly limited to three; 2) the network control is highly regular; 3) all processing elements are identical. A CCC network can also efficiently emulate other networks (e.g. Shuffle Exchange, Tree based, Mesh networks). It is also our intention to demonstrate that WSI is an effective means of implementation of such systems. The design will be discussed from the point of view of both hardware and software.

The paper is divided as follows. Wafer Scale Integration is introduced first, giving the rational, problems and proposed solutions of the technology. A brief review of the CCC interconnection network, followed by a novel method of supplying instruction streams to the network is then described. The envisioned programming environment is then outlined. Detailed description of the processing element, covering the instruction set, data path archictecture, timming, floor paln and initial area estimates are given. In conclusion, implemetaion of this computer in both a wafer scale integration and hybrid packaging enviornments are considered. A summary of this work was presented by Chung et. al[6,7]

Wafer Scale Integration (WSI)

Large digital circuits can be fabricated through WSI technology to yield a complete component encompassing an entire silicon wafer. The silicon wafer is then packaged intact and can be used as a component in conventional (i.e. board level) design methods, forming a complete system. In WSI, these large circuits are partitioned into modules which form the die sites on the wafer. The fabrication of these die sites is identical to that of current VLSI fabrication technology. After fabrication, the devices are tested and functioning dice are connected in place to form a working component. The main deviation from current IC technology is that the wafer is left intact. Not all the dice fabricated will be functional and hence WSI is dependent upon the wafer's yield, implying the need for redundancy and fault tolerance in design[8,24,31,33]. An effective method must exist to interconnect the functioning devices on the wafer if WSI is to be considered a viable technology[23,25,33,34] The following section gives the rationale behind WSI. An overview of the obstacles in WSI, along with some of the proposed solutions for these obstacles are outlined. Concluding our discussion of WSI will be a description of the technology selected to implement this project.

* Supported by a Digital Equipment Corporation Fellowship

Why Wafer Scale Integration?

The concept of wafer scale integration (WSI) to produce large scale integrated (LSI) circuits was first proposed by [22]. Initially, it was seen as a method for combatting poor yield in fabricating LSI circuits. As semiconductor manufacturing matured, increased die sizes permitted the required levels of integration within a single chip. At that point, the WSI concept was no longer considered a viable technology[25].

Over the past two decades, the majority of the cost in electronics systems has migrated from the raw components to packaging and assembling the components[8]. Avoidance of costly printed circuit packaging has led to interest into better utilization of silicon interconnect[8,27]. While the cost of a silicon wiring layer is approximately ten times that of a printed circuit wiring layer, three orders of magnitude increase in wire density is achieved[8]. The result is a system with near a factor of 100 increase in function/cost with silicon wiring[8]. By using WSI, an order of magnitude increase from conventional packing density can also be achieved[19,27]

Another concern in electronic systems is the communication speeds between modules. With conventional technologies, significant delays can accrue when signals travel between packages[38]. By incorporating signal paths within a single package, the inter-module delay will be reduced due to shorter wire lengths[34]. If all the critical paths reside within the wafer, significant performance gains can be achieved[38]. Further gains in signal speed can be realized by fabrication of thick wires on the wafer ($\sim 5\mu m$ thick X $10\mu m$ wide on $5\mu m$ of dielectric). Signal paths of these dimensions exhibit LC-transmission line behavior as opposed to RC charging lines, reducing the delay to that due to propagation at the speed of light (in the dieletric medium being used) over the length of the wire[2,10]. Silicon wiring also reduces the capacitive loads seen by the chip's drivers, resulting in smaller drivers and reduced power supply requirements[25,27,38]. Although the power consumption will decrease, the heat flow (watts/cm^2) will increase due to the much denser system.

With WSI the overall system reliability can be improved. The major failure sites of modern electronic systems occur at the interface of the various packaging levels used[15,25,31]. It has been noted in [16] that the chip to pin connections are the major source of device failure. Causes of such failures include weakened die to package bonds[15] and thermal stresses[16]. By incorporating a majority of the connections within a single package (i.e. a wafer), the interconnection system remains mono-metallic and will therefore be more reliable. If the number of external I/O ports on the wafer are less than the pin to chip connections in a printed circuit board, the overall system reliability will increase. The entire wafer would finally be hermetically sealed, further reducing the system's vulnerability[27].

WSI Problems & Solutions

Current problems inhibiting the development of WSI systems include developing a feasible interconnection technology, heat dissipation, package design, CAD tool development and architecture selection. The development of a method to reconfigure wafers is crucial for the successful implementation of WSI systems. Proposed methods for restructuring the wafer include laser programming [4,13,], electrically alterable signal paths[17], electron beam programming of floating gate transistors[34] and discretionary wiring[22,25]. (Discretionary wiring connects working modules with additional layers of interconnect). Some functioning wafer scale systems have been fabricated with such techniques[12,17,33,34]. If conventional geometries are used to form the interconnect, coupled with parasitics introduced in the restructuring process, the speed of the interconnect can restrict the overall system performance[10]. WSI packages employing water[31], liquid nitrogen and air[19] cooling techniques have been developed for heat flows of up to 50 W/cm^2[31]. Although extensive CAD tools have been developed for the routing of WSI circuits[9,19,31,33], simulation tools for such large systems are still unavailable.

Using WSI for logic intensive applications has been criticized in the past due to the redundancy required when using different reticles on the same wafer[5,8,17]. To avoid such problems, the architectures considered in this work have been limited to the Single Instruction Multiple Data (SIMD) type. Since the wafer will be populated with a single die type (neglecting the I/O circuitry), any defective processor can be replaced with any available spare. Another advantage with the SIMD approach is that the PEs will require a limited amount of control circuitry, reducing the overall area of the die significantly. A number of SIMD networks were considered, with the CCC being selected as the best available.

The discretionary wiring approach as outlined in [25] will provide the implementation vehicle for the CCC computer. An intermediate step towards this goal using the Wafer Transmission Module (WTM)[10,37] will also be used. Both these issues are briefly outlined below.

Discretionary Wiring With Wafer Transmission Lines

The approach to wafer customization in [25] combines discretionary wiring with a thick film liftoff process[2]. The wiring formed by this approach will be of transmission line quality. Layers are provided for the power and ground planes, two signal layers and three via layers for interconnection of signals between layers. First a $10\mu m$ dielectric (polyimide) layer is deposited on the wafer. A pattern is then defined and etched, providing stud vias from the die sites to the remaining signal layers. Another layer of polyimide is applied, patterned and etched defining the the ground plane. The process is then repeated for successive layers. Note that this process results in planar layers of metalization on the wafer.

Since each wafer will have a unique interconnection pattern, an efficent method of transferring this pattern to the wafer is required. The use of optical masks would be inefficent since such masks would be used once and then be discarded. A system to directly transfer the interconnection pattern from a computer data base to the wafer is being developed using an IBM EL-2 Direct Write Electron Beam system[9]. The discretionary wiring must have a 100% yield, or a system to repair wiring faults will have to be developed. Since no fabrication process can provide a 100% yield, a wire repairing system is being developed through the use of a scanning electron microscope to locate faults in conjunction with a focussed ion beam to repair such faults[9].

The Wafer Transmission Module (WTM)

To avoid the initial fabrication problems associated with discretionary wiring, the Wafer Transmission Module (WTM) was proposed[10,37]. The WTM is a hybrid package incorporating signal interconnect, bypass capacitors and power buses on a substrate. Differences between the WTM and current hybrid packaging include the use of thick film interconnect and a silicon wafer as a substrate. Using a silicon substrate permits batch processing of the substrate with current IC processes, while also minimizing the thermal stresses within the package. Chips are fabricated, tested and scribed as in conventional processing. Functioning chips are then affixed to the wafer by wire bonding or solder bumps. Faults in the WTM interconnect are avoided by providing redundant signal paths such as 10 bit lines for an 8 bit bus, 2 control lines where 1 is required etc. The interconnect would be tested prior to mounting the chips, which are then connected to only functioning wires. If a wafer does not have enough good wires, it will be discarded. The WTM eliminates the dependence on yield and reconfiguration in the WSI approach while achieving comparable speed, density and reliability. A similar package has been fabricated using thin film interconnect for a four chip Wallace multiplier[18].

The Cube Connected Cycles (CCC)

The CCC is derived from the binary n-cube[30] such that the network has a bounded node degree with no significant loss in processing speed. Galil and Paul[11] have used the CCC in defining a universal parallel machine, implying that the CCC can be used to simulate any special purpose parallel computer with a reasonable slow down factor ($\approx O[\log^2{}_2 n]$ time). The CCC can also do certain permutations in $O[\log_2 n]$ time[32].

The CCC network consists of $n=2^k$ processing elements, k being an integer such that $k \leq r+2^r$, r being the smallest integer that satisfies this equation. Each PE has a k bit address M, which is partitioned into two fields $[\Phi,p]$ such that $M=\Phi 2^r+p$. The PEs are grouped into $2^{(k-r)}$ cycles of 2^r nodes per cycle. The (k-r) bits of the Φ field specifies the PE's cycle, while the r bits of the p field gives the PE's position within the cycle. The inter-cycle connections form a (k-r) dimensional cube or hypercube. A 64 PE CCC network is shown in figure 1 with n=64, k=6 and r=2. Note that there are $2^{(k-r)}=16$ cycles of $2^r=4$ nodes per cycle. The connections between PEs of the same cycle are termed links, while connections between processors in different cycles are called sheaves. The PEs of the CCC network have three I/O ports denoted forward (F), backward (B) and lateral (L). The F, B, and L PE interconnections are defined by the following equations:

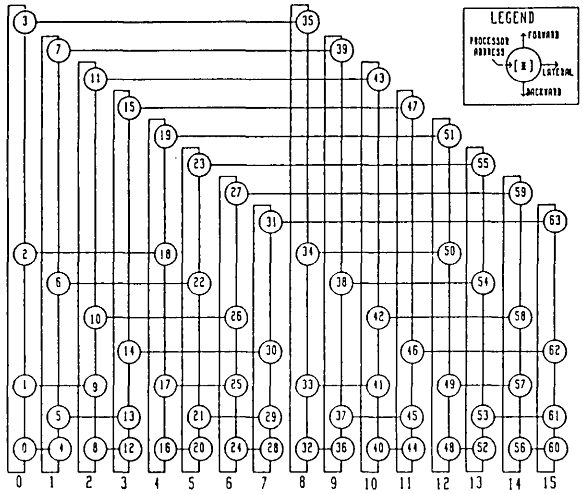

Figure 1 : 64 PE CCC Network

1) $F(\Phi,p)= B(\Phi,(p+1)\bmod 2^r)$
2) $B(\Phi,p)= F(\Phi,(p-1)\bmod 2^r)$
3) $L(\Phi,p)= L(\Phi+\epsilon .2^p,p)$;
   where $\epsilon = 1 - 2.\mathrm{bit}_p(\Phi)$

The term $\mathrm{bit}_p(\Phi)$ is the value of the p^{th} bit of the binary expansion of Φ, and can take a value of 1 or 0. Note that the F-B connections are links and the L connection is a sheaf. The CCC network of figure 1 will be controlled by a host computer. The controller will provide both instruction and data streams, along with other control signals, to the CCC network. The controller's design is the subject of future research.

Instruction Broadcasting

In a synchronous SIMD machine (as in this case), all PEs must execute the same instructions at the same time. Ideally, it would be desirable to broadcast instructions to each processor in the network concurrently. Unfortunately, in this network it is also desirable to minimize the global wiring since signal transmission via this wiring would be slow and consumes much power. An alternative to global broadcasting is necessary that minimizes the delay of instruction distribution while ensuring that all PEs execute the same instruction at the same time. The approach taken restricts communication of instructions to occur only between adjacent processors within a cycle (i.e. those whose p addresses differ by 1). Instructions are broadcast from the controller to the first node of each cycle (i.e. to node of address (*,0)). The instructions are then transferred from this node to the rest of the nodes within the cycle. The instruction transfer is pipelined so that only one instruction per execution phase need be transmitted to the cycle. This method is similar to that of filling a data path pipeline before a result can be output.

To minimize delay in instruction transfer, each PE is equipped with an instruction queue (IQ) which stores the instructions to be executed by the PE. Consider the instruction stream that is to be executed as shown in figure 2 and the CCC cycle in figure 3A. Note that the length of the

Instruction number	Instruction
0	INST A
1	INST B
2	INST C
•	•
•	•
•	•
2^r-2	INST (Q-2)
2^r-1	INST (Q-1)
2^r	INST (Q)

Figure 2- Instruction stream for input to the cycle

instruction queue is different for each node and depends on its position within the cycle. The length of the instruction queue can be determined from the cycle length and the node's p address field by the following equation:

$$\text{Queue Length (QL)}=2^r+1-p$$

Where p is the node's position within the cycle and 2^r is the number of nodes within the cycle. Before instruction execution can begin, we must distribute the first 2^r+1 instructions to each cycle within the network.

The process begins by transmitting the first instruction to the first node of the cycle (see figure 3A). This instruction is stored in the front of node(*.0)'s instruction queue. In the next phase, the second instruction is transmitted to node(*.0) of the cycle and is placed in the second position of node(*.0)'s instruction queue (see figure 3B). Concurrently, the instruction located in the front of node(*.0)'s instruction queue is transmitted to node(*.1) and is stored in the front of node(*.1)'s instruction queue (see figure 3B). This process repeats for a total of 2^r steps, at which time the first instruction to be executed is transmitted from node(*.2^r-2) to node(*.2^r-1) (see figure 3C). Recall that each cycle contains 2^r nodes labeled (*.0).(*.1).(*.2). · · · .(*.2^r-1). where * denotes the cycle number.

After the first instruction is received at node(*.2^r-1). execution can commence. At step 2^r-1. the instructions are distributed within the cy.cle as shown in figure 3C and instruction execution proceeds as follows. First. each node within the cycle executes the instruction at the front of its instruction queue. Upon completion of this instruction. node(*.p) transmits the instruction at the rear of its instruction queue to node(*.(p+1)mod 2^r) (see figure 3D). Note that node(*.0) receives an instruction from the controller and that node(*.2^r-1) does not have a node above it to transmit to The instruction queue is then shifted forward one position (see figure 3E). overwriting the front of the queue. The front of the queue now contains the next instruction to be executed. The process repeats for all subsequent instructions. requiring only one instruction transfer between adjacent nodes per execution cycle. New instructions enter the cycle during successive phases through node(*.0) of each cycle.

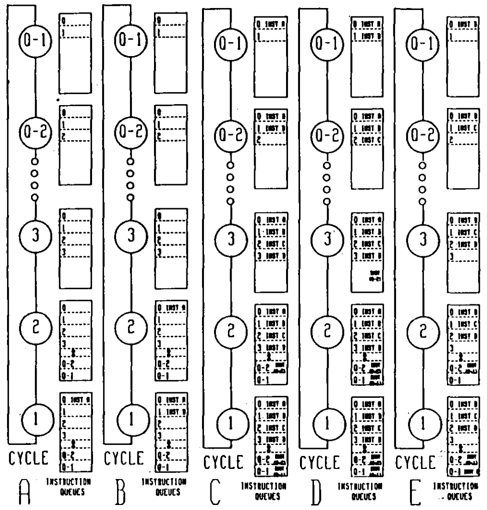

Figure 3: Instruction Broadcasting Example

Programming by Logical Networks

It is known that CCC can operate as a universal parallel machine[11]. It can simulate every reasonable parallel machine with only a small loss of time and with essentially the same number of processors[11]. For example. the CCC can emulate a hypercube with a O[$\log_2 n$] slowdown factor. In fact. it can emulate a large class of hypercube algorithms (Ascend and Descend type) within a constant slowdown factor[32]. Any fixed dimensional cube (eg. 2D mesh. 3D cube) can be emulated efficiently by a hypercube Consider. for example. the mesh network of figure 4. Each PE is identified by an ordered pair of its cartesian coordinates. Note that adjacent PEs differ by only one in any of the two coordinates. We determine the address of the node (to which each mesh PE is mapped) by applying Gray code to the mesh PE's coordinates. In this way adjacent PEs get mapped onto nodes whose addresses differ in a single bit position. These nodes therefore form a hypercube with the required adjacencies being the hypercube connections. These are easily realizable on the CCC. In this manner a mesh network can be

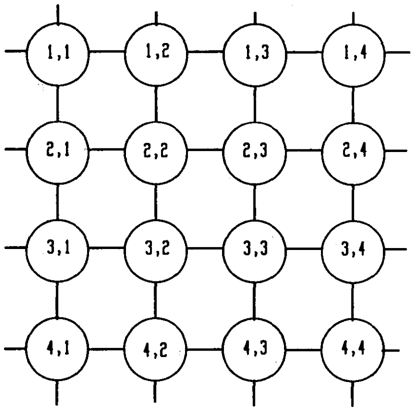

Figure 4: Logical Mesh Connected Network

efficiently realized on the CCC. Also, tree networks can be emulated by CCC within a O[$\log_2 n$] factor. Tree-like computations (such as counting) can be emulated within constant factor[3]. We therefore propose a parallel programming environment for the CCC based on the specification of logical networks of PEs.

A user may specify any logical network to execute algorithms written in a programming language similar to Concurrent Pascal. In the network specification, the user will specify a PE node type, define the interconnection pattern between nodes, describe data and control communications and finally the instruction set to be executed by the node. The instruction set will be restricted to a finite set of inter-node, as well as intra-node data movement and data path instructions. Initially, we intend to support the specification and programming of the CCC, Hypercube, Mesh, Tree, Pyramid, and Shuffle Exchange networks.

For example, consider the logical mesh connected network of figure 4. The network could be specified by defining the interconnections in terms of the cardinal directions such as North[PE(3,2)]←→South[PE(2,2)]. The program segment shown in figure 5 could then be specified for such a network. The program first specifies the network as an n by n mesh of PEs, each containing two integer type records. The next section of the program specifies the type of operations to be performed. If the four connections to a PE are denoted by the cardinal directions, this operation specifies that a PE is to sum and store the values stored in its north and west neighbors. This network specification and program is then mapped onto the CCC and its instruction set

By allowing programming via the specification of a logical network, the details of the physical CCC network remain hidden. This eliminates the need for programmers to provide information concerning the pipelining of instructions and data on the CCC. These details will be extracted from the logical network's specification and its associated instruction sequence. To further aid the user friendliness, we intend to provide a graphical interface for entering the network's connection pattern and program.

A compiler will take the network specification (and its program) and will generate a sequence of "MACRO" instructions that are supported by the underlying CCC. A MACRO instruction specifies the movement and processing of data via the CCC's sheaves, cycles, and nodes. To do such emulations, MACRO instructions such as BSHIFT, FSHIFT (forward and backward cyclic shift), LSHIFT (left lateral shift) RSHIFT (right lateral shift), and NO-OP instructions are necessary. These MACRO instructions are then mapped into sequences of CCC instructions.

```
network A: MESH n by n of

        record  X: integer;
                   Y: integer;
        end

        for i ϵ [1..n], j ϵ [1..m] do

                A[i,j]←A[i,j+1]+A[i-1,j]

end;
```

Figure 5- Sample program for a logical mesh network

If the logical network is not already specified in the compiler, the network and its program must be defined using MACRO instructions of the type listed above (e.g. BSHIFT, FSHIFT, LSHIFT and RSHIFT). This allows a user to emulate an arbitrary network. However, a programmer must fully specify the operations, in terms of the MACRO instructions, necessary to emulate the logical network.

The Processing Element (PE)

In this section, the PE instruction set and architecture are detailed. We start with a brief description of the number representation used. We then present an instruction set based on the RISC concept[14,20,28,35], and relate this instruction set to the instruction execution cycle of a conventional processor. An example of a typical execution sequence is shown. Details of implementation of conditional blocks have also been given. This is followed by a description of the hardware elements in the PE. In conclusion, we briefly give some timing estimates for performance evaluation.

Number Representation

We have adopted a very simple number representation for the processing elements. The word length is 16 bits, with negative numbers in two's complement notation. Integer data can be represented by any number of words, depending on the size of the number. For floating point data, the mantissa is 32 bits long organized as two 16-bit words. The exponent is represented by a separate 16-bit word. This representation enables floating point operations to be implemented as a series of integer operations and avoids the task of field extraction. While this system is simple, it allows much faster execution of floating point operations with our instruction set than would be possible with a standard floating point representation.

The PE Instruction Set

A normal data path cycle on a conventional processor, as shown in figure 6 consists of the following phases: 1) Operand Fetch; 2) ALU Operation; 3) Result Store. The aggregate of these phases is denoted as a major cycle. A processor implementing a major cycle must contain a certain amount of control logic to schedule these events, breaking this major cycle into a series of operations we term minor cycles (see figure 6). Note that a significant amount of information must also be provided in an instruction representing a major cycle (i.e. source operand addresses, opcode, and destination address). Providing such information to a processor efficiently will require a large number of bits even with encoding and will also require a complex control circuit. To have a processor that is as simple as possible, we provide instructions as minor cycles. Providing instructions as minor cycles allows great flexibility in controlling the PE's actions. Such flexibility will be needed if the emulation of other networks is to be done efficiently.

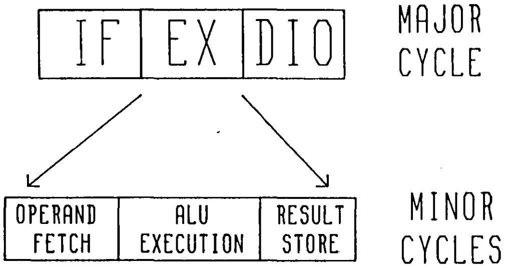

Figure 6- Conventional Processor Cycle

The decoding for each of these minor cycles is going to be simple and can be done in parallel with execution i.e. instruction i+1 is decoded while instruction i is being executed. (Note that this implies an extra queue position per processor for the IQ scheme discussed earlier). Since an SIMD machine does not allow branching within program memory, this decode/ execution pipelining does not introduce any constraints. It is completely transparent to the user in that the user is aware of one minor cycle being executed every clock cycle.

The proposed instruction set is shown in figure 7 (and the associated data path is shown in figure 14). The instruction set can be split into the following three categories: 1) Load-Store; 2) ALU; 3) Data Transfer. The complete instruction set has been encoded into a format 12 bits long. Details of the encoding scheme can be found in [7].

The Load-Store type instructions control the movement of data between the register file and the ALU. To facilitate floating point (32-bit) operations, separate load-store of the high and low words (16-bits) have been provided. An option is also provided to load an 8-bit immediate data into the ALU.inA register using the LLIT (Load LITeral) instruction.

ALU instructions are those that implement data modifications within the PE. One input to the ALU (R1) is always provided by the register ALU.inA. The other ALU input (R2) can be either ALU.inB or ALU.out. For the unary ALU operators, the input (Source) can be either R1 or R2. The result of the ALU operation (Dest) can again be either ALU.inB or ALU.out. The flexibility in choosing the sources and destination of the ALU operations helps in handling of floating point operations. For the same reason, a 16-bit as well as a 32-bit mode has been provided for the ALU. The ALU also has a set of four condition flags- C:Carry, V:Overflow, Z:Zero and S:Sign. These flags are set or reset based upon the result of the ALU operation. The status of these flags can be used to conditionally execute instructions as explained in a later section. It is to be noted that instead of providing a separate Shift instruction, an option is available to cyclically shift (left/right, with/without carry) the results of some ALU instructions (PASS,ADD,SUB). The shift is performed immediately before the results are sent to their destination eg. an add and shift can be done in one cycle.

Data transfer instructions control the PE's three connections (i.e. Forward, Backward, Lateral). These instructions simply schedule data transfers between processors.

A sample of a typical sequence of instructions implementing a data path major cycle is shown in figure 8. The normal data path cycle starts with the loading of the ALU's input buffers with two operands, followed by the execution of the operation within the ALU. The result of this operation is then stored in the register file. Note that we show the two operands being read in sequence rather than in parallel. This is because the PE's register file has only one port, as described in the next section.

The overhead associated with the transfer of instructions between nodes can be eliminated as follows. Since the operations of the instruction decoder, datapath and the I/O circuits are disjoint, the three phases of instruction decode, execution and transfer can be overlapped as shown in figure 9. This pipelining eliminates the delay in instruction distribution in all but the initial phases of the CCC's operation.

The data transfer between nodes by the FWDTR, BWDTR and LATTR instructions can also be pipelined. Note that the data transfer instructions are disjoint in operation from all but the LOAD/STORE type instructions. Provided that the effects of LOAD/STORE instructions remain orthogonal to the effects of the data transfer instructions, the data transfer instructions can be executed concurrently with the remaining instructions. The Controller can ensure that the data transfers and LOAD/STOREs are disjoint by prohibiting access of an I/O register while it is transmitting or receiving data. To implement this pipelining, two additional bits of the instruction field will be used to specify the state of the I/O operations (i.e. 00:FWDTR, 01:BWDTR, 10:LATTR, 11:no transfer). We will therefore have two instructions executing concurrently in one cycle.

Conditional Instructions

When implementing conditional blocks of code in an SIMD machine, as found within an IF-THEN-ELSE statement, the instruction streams must remain identical in all PEs. Standard implementations can not be applied because bypassing blocks of instructions via branching in the instruction memory is not allowed. The processors must be provided with each block of instructions for all possible outcomes of a conditional statement, executing only the block that corresponds to the satisfied value of the condition.

To illustrate, consider the IF-THEN-ELSE block shown in figure 10. When providing a PE in an SIMD network with instructions that implement this program, both the block of instructions for the IF segment (B1 etc) and the ELSE segment (B2) must be provided to the PE. If this is not done, the SIMD network controller will be required to monitor each processor to determine the outcome of the conditional test, and will then have to provide each individual processor with a unique instruction stream. This is not a feasible scheme, especially if there are a large number of PEs (as in our case)

In order to have the same instruction stream for all PEs, the condition codes of an earlier instruction must be able to affect the execution of future instructions. A scheme for implementing this structure is as follows (see figure 11). We have a one-bit wide and N-word deep stack called the Condition Stack (CS). Any instruction is enabled to execute if and only if all the 1-bit words of the CS are set i.e. the execution Enable signal is derived by a logical AND of all the

Figure 10- Sample Conditional Program

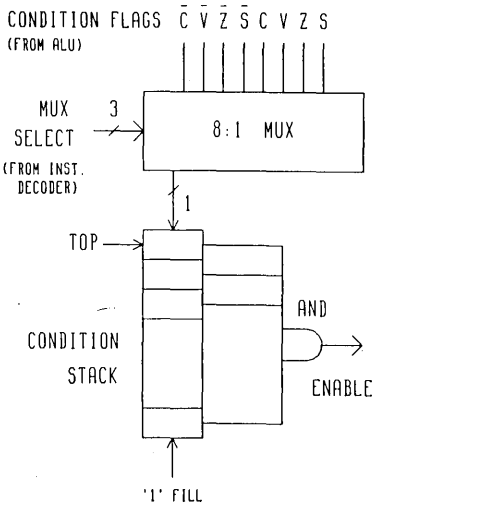

Figure 11 : Hardware for Conditional Evaluation

CS bits. As mentioned earlier, the ALU has 4 condition flags (C.V.Z.S) and their status can be used to execute an instruction conditionally. We provide an 8-to-1 multiplexer to select one of these (or their negated versions) and this selected status can then be pushed on the CS.

Consider the implementation of a simple IF-THEN-ELSE block using the above scheme. Let all CS bits be initially set. Upon encountering the if (condition) part, an ALU instruction is performed to evaluate the condition and the appropriate flag is selected and pushed on the CS. If the Enable signal (derived by ANDing all CS bits) is true, the THEN block is executed, otherwise it is skipped. When we reach the ELSE block, the top of CS is simply complemented. Note that if this bit was initially zero (i.e. the if-condition was false), it will now get set enabling the execution of the ELSE block. Conversely, if the bit was initially set (i.e. the if-condition was true), it will now get reset disabling the ELSE block. In this manner only one of the two- THEN or ELSE blocks - is executed even though both blocks are part of the instruction stream. Upon reaching the end of the conditional block, the top bit is popped off the CS and it no longer affects the instruction execution. To summarize, for every conditional block, we select and push for IF, complement for ELSE and pop for ENDif.

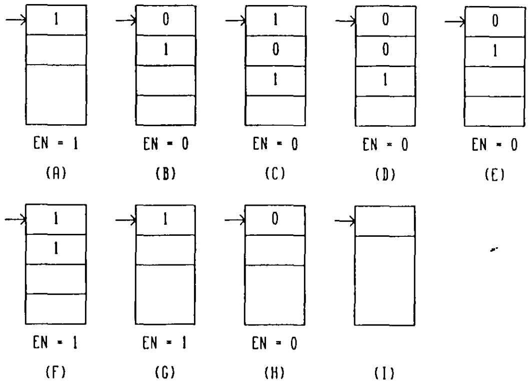

Figure 12 : Snapshots of the CS for sample program

To illustrate use of the above scheme for a Nested conditional structure consider the program given in figure 10. Snapshots of the CS at different points in the program (labelled a, b, etc.) are also given in figure 12. At (a), cond1 is selected and pushed on CS. Suppose it is true. The Enable signal is therefore true and B1 is executed. At (b) cond2 is selected and pushed. Let us assume it is false. The Enable signal is now false and execution of C1 is disabled. At (c) we select and push cond3 (true) on CS. (Note that this selection and push is done in spite of execution being disabled i.e it is not affected by the status of the Enable signal). Whatever be the status of cond3 the Enable stays false because of the false cond2. (For that reason it does not matter whether or not the test for cond3 is even valid). D1 is therefore disabled. At (d), we complement top of CS, the Enable remains false and D2 also is not executed. At (e) the ENDif for cond3 occurs and we pop CS. At (f) we again complement top of CS. This time the Enable becomes true and we execute D2- the ELSE part of cond2. At (g) the CS is popped and we then complement top of CS at (h). The Enable signal now becomes false and execution for the ELSE part of cond1 is disabled. B2 is therefore not executed. Upon reaching (i) CS is popped again and the scope of cond1 ends. Note how pushing/ complementing/ popping for corresponding IF/ELSE/ENDif maintains the correct Enable status inside a nested conditional structure. The maximum allowable nesting depth is determined by the depth of the CS.

A simple format for the conditional control field, which can implement the above operations, is given in figure 13 Note that this control field will be needed only with the ALU instructions. Rest of the instructions will simply use the Enable signal provided by the CS.

The Processor Architecture

The PE architecture is shown in figure 14. It consists of a register file (RF), a 32/16 bit arithmetic logic unit (ALU), a shifter, an exponent register, an address register, instruction queue (IQ), I/O Buffers and a simple instruction

Bit 1=0 No condition selected		Bit 1=1 Condition selected & pushed	
Bits 2.3.4		Bits 2.3.4	
100	: no operation	000 (100)	: $\overline{C}$ (C) selected
101	: complement	001 (101)	: $\overline{V}$ (V) selected
110	: pop	010 (110)	: $\overline{Z}$ (Z) selected
		011 (111)	: $\overline{S}$ (S) selected

Figure 13- Conditional Control Field

decoder. The functions of each of these blocks are summarized in Table 1.

The PE will be implemented as follows. The register file is organized as 256 16-bit words. The lowest 8 bits of the IQ are always input to the RF address decoders. Therefore address decoding for a potential memory instruction always takes place simultaneously with the instruction decoding. If the instruction is indeed decoded to be a memory operation then the appropriate word-line is asserted during the execution phase of the instruction. This is done to save address decoding delay during the actual execution of Load-Store instructions.

For the ALU, there are two 32-bit input registers (ALU.inA & ALU.inB) and one 32-bit accumulator (ALU.out). The ALU is capable of performing arithmetic operations on 16-bit as well as 32-bit data. Even though the PE's datapath is 16-bit wide, it was decided to have the 32-bit option for the ALU to speed up floating point operations. Integer operations (16-bit) are performed by using the lower half of the ALU's datapath.

The Shifter is capable of shifting a 32-bit word right or left by one bit and is used as a post-processor to the ALU. The Exponent register is used to hold the exponent during floating point operations and can be addressed as part of the RF. It is also used as an up/down counter and is automatically incremented (decremented) whenever the Shifter does a shift right (left) operation. The (Φ.p) register consists of 10 bits and contains the PE's address. This register can also be addressed as a special (read-only) RF position with the six high order bits set to zero. This way a processor can be selectively masked out based on its location within the CCC network. For the I/O buffers, two 16-bit buffers will be used for each port (i.e. one for input, one for output). These buffers are addressable as registers in the register file and the input buffers can also be loaded from a port (i.e. F.B or L). Finally, the instruction decoder will be a small finite state machine and will be implemented with a PLA and random logic. The hardware used for conditional evaluation (the Condition Stack and the Enable logic) will form part of the decoder logic.

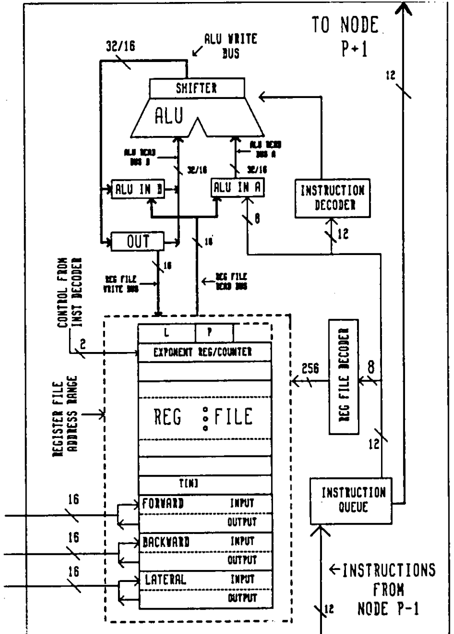

Figure 14- Processor Architecture

<u>Processor Timing</u>

The basic timing scheme for each PE consists of pipelining the three operations of instruction decode, execution and transfer per clock cycle. As discussed earlier, the instructions have been provided in the form of minor cycles leading to simple decode logic. Also, since instruction transfer takes place between adjoining processors, its timing is not critical in determining the clock rate. The determining factor for the maximum achievable clock rate is the longest delay in the datapath during instruction execution. An initial estimate of the datapath timing for the given processor architecture has led to a 50ns. clock cycle. All instructions listed in the instruction set take one cycle time to execute. This gives a performance figure of 20 Mips per processor. Note however that our instructions are minor cycles. Since three to four minor cycles are equivalent to a conventional processor cycle, one-third to a quarter of the above rate would be a reasonable figure of merit for comparison.

The PE architecture does not have any special hardware unit for performing floating point operations. However by using the Exponent register, the Shifter the 32-bit mode of the ALU and the given instruction set, we have been able to implement one floating point operation every

Table 1- PE Function Block Descriptions

Section	Function
ALU	The Arithmetic Logic Unit executes data path instructions of the type add, subtract, not etc. (16 or32 bit ALU)
Shifter	The Shifter shifts the data (16 or 32 bits) right or left by one bit This can be done with or without carry wrap-around.
Exponent Register	The Exponent Register can be accessed as a register file position or it can be used as an up/down counter. A shift right (left) operation by the shifter is accompanied by an auto-increment(decrement).
Register file	The Register File contains the local memory. This is a single port read/write RF, organized as 16 bits by 239 words. Note that its address space (0:255) includes scratch area and special registers.
I-O Buffers	There are three I-O buffers denoted FORWARD, BACKWARD and LATERAL. Each contains two registers, one for input and the other for output. Each I-O register can be accessed as a either a register position or from the port connection.
Instruction Queue	The instruction queue holds the instructions to be executed by the PE.
Instruction decoder	A simple finite state machine, implemented with a PLA.
(Φ.p) Register	This register contains the node's (Φ.p) 10 bit address. This register is set when the network is configured (i.e. it is a ROM register).

5μs i.e. each PE is capable of performing at a rate of 0.2 MFlops. This leads to a figure of 102.4 MFlops for the entire network having 512 PEs.

Implementation

In our implementation, 512 PEs will be connected in a CCC network in wafer scale integration. A floor plan of the PE die is shown in figure 15. Table 2 gives the initial area estimates for each section of the PE's circuits for a 2μm scalable CMOS ($\lambda = 1\mu$m) technology. The PE will contain 256 addressable memory locations (RF). The address space is partioned as follows: 239 data registers, 8 general purpose registers (i.e. scratch memory, constants etc.), 6 positions for the I/O registers, one for the (Φ.p) address (a read only location), one position for the exponent register and one constant register set to 0. To reduce the read/write delay caused by long word lines, the register file has been split into four equal parts of 64 register positions each. Splitting the register file also improves the aspect ratio of the die. Each of the four register file banks will be addressed by a separate decoder. Since the address field is eight bits, the two most significant bits will select one of these four banks while the remaining six bits will select a register from within it. Note that 0.25mm has been added to the perimeter of the die for the I/O pads, routing and random logic. The PE die size will be approximately 3.32mm X 2.2mm.

Following the Discretionary wiring approach [25] discussed earlier, dice will be first fabricated on a wafer and the functioning die sites will be then connected with discretionary wiring. Assuming that a 6 inch diameter ($\approx$15 cm) wafer is used, there will be only 100cm^2 of usable area equal to that of the square inscribed in the wafer. With a die size of 8.964mm^2, there will be 1114 possible die sites. With a 50% yield of dice, there will be approximately 557 functioning dice after fabrication, providing more than the minimum requirement of 512.

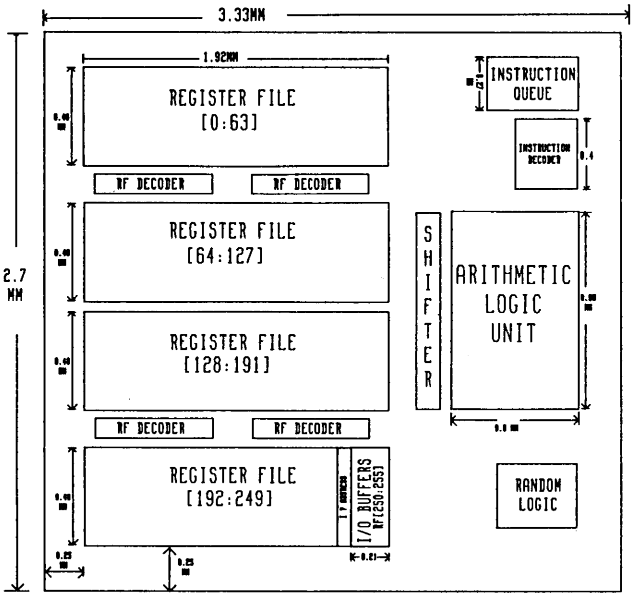

Figure 15- Processor Element Floor Plan

† This refers to the 0.25mm perimeter of the PE die

Alternatively, implementation of this network with the WTM[10,37] is as follows. A custom 6 inch interconnection wafer will be designed for maximum packing. There will be space for 512 processor chip, along with a number of specical I/O chips. The chips will be bonded to the wafer using a solder bump technology as described in [18].

Packages for both the approaches listed above are currently under development at Rensselaer Polytechnic Institute's Center for Integrated Electronics.

Conclusion

The preceeding sections have presented a feasible parallel computer with a large number of processing elements for wafer scale integration. Use of a RISC based architecture for the processing element allows great flexibility in using the computer. The architecture is both simple to construct and flexible enough to permit the emulation of logical networks in an efficient manner. The instruction set is designed for pipelined execution of instructions. Processor allocation and scheduling is done by a dedicated controller. Programming can be done by users unfamiliar with the internal architecture of the computer. Many practical problems can be solved efficiently with this computer and it effective computing power is estimated at approximatly 6MIPS per processor.

Future directions for this project include working on the design details of each PE. The PE is currently being modelled and simulated using the N.2 Simulator. Following verification of the PE architecture and instruction set, each of the modules (ALU, RF etc.) will be designed and simulated at the gate level. The transistor level design and simulations for all circuit elements will be done next. Finally, layouts for the complete processor will be made and verified.

Acknowledgments

The authors wish to thank Randy Steinvorth for the detailed explinations of the wafer transmission module technology and Austin Lobo for his sugestions during the early stages of this project. The comments and financial support

from Digital Equipment Corporation were also greatly appreciated.

GMD - Gesellschaft für Mathematik und Datenverarbeitung mbH
P.O. 1240, D-5205 St. Augustin 1

Abstract:

MUPPET is a problem solving environment for scientific computing. It consists of four areas - concurrent languages, programming environments, application environments andman-machine interfaces.
The programming paradigm of MUPPET is based on abstract machines and transformations between them. This paradigm allows the development of programs which are portable among different machines.

In this paper we discuss the programming paradigm and give a brief introduction to the language CONCURRENT MODULA-2 and the simulation system.

MUPPET is being developed as part of the German supercomputer project SUPRENUM.

1. Introduction

The new generation of scientific supercomputers depends more and more on parallel processing. Supercomputers can be divided into two groups

- multiprocessors with shared memory
- multiprocessors with local memory

The latter systems are a more radical departure from the sequential von Neumann type of machines. They can employ more than one thousand individual processors giving peak rates of more than 10 Gigaflops. Most notable is the recently announced T-series from Floating Point Systems. This incredible hardware speed has to be matched by adequate "super" software. This super software should support

- the fast development of programs
- the efficient use of the supercomputer
- the reusability of software

MUPPET (a multiprocessor programming environment) is a long term effort to address these issues in the area of scientific computing. MUPPET is designed for multiprocessors with local memory. It is part of the German supercomputer project SUPRENUM [GiMu86] , the goal forwhich is to build a supercomputer of more than one Gigoflop.

MUPPET is not simply a programming environment, but it is designed as a problem solving environment for scientific computing.

A problem solving environment can be divided into at least four areas ([FOR86])

- CONCURRENT LANGUAGES
- PROGRAMMING ENVIRONMENT
  syntax editor, program templates, library
- APPLICATION ENVIRONMENTS
  e.g. language for the solution of partial differential equations, multigrid expert systems
- MAN-MACHINE INTERFACE
  graphics, algorithm animation

Concurrent languages are necessary for driving the multiprocessors efficiently. The programming environment tries to support the programmer. Its goal is to make programming significantly easier, more reliable and cost effective by reusing previous code and programming experience to the greatest extent possible.

The application environments support the end user who does not want to do low level programming. Application environments should include knowledge about the application domains and application specific technical languages.
Most of the MUPPET tools will run on a high-performance scientific workstation with a graphic oriented man-machine interface.

The standard tools of the programming and application environment (a language-based editor supporting programming in the small, a fragment library supporting incomplete specifications and an interpreter) will be generated by the programming system generator PSG, which is described elsewhere [BSN 85]. This approach makes rapid prototyping of environments possible.

In this paper we concentrate on the specific problems encountered in parallel programming. MUPPET is being developed in close cooperation with the PIE project, whose goal is to develop a programming environment for a shared memory system [SE RU85].

The outline of the paper is as follows:
In chapter two we introduce the programming paradigm of MUPPET, in chapter three we discuss an implementation tradeoff by using the randomization method. The programming paradigm is explained in more detail in chapter four. The examples are downloading and matrix multiplication. The next two chapters describe the language CONCURRENT MODULA-2 and the MUPPET simulation system. In the last chapter we discuss some

CH2345-7/86/0000/0336$01.00 © 1986 IEEE

problems encountered an lessons learned.

2. Parallel programming paradigms and abstract machines

Programming is the conversion of an abstract (machine independent) algorithm into a program that can be run on a particular computer. A programming paradigm can be seen as a way of approaching a programming problem and thereby restricting the solution set.

Following Browne [BROW 86] we define a parallel computation as a graph where each node is the binding of an action to a data object and the edges are the dependency relationships between the computations executed at the nodes. In this paper we use a simpler model to describe a parallel program on a parallel computer ([SNY84]). The model consists of

- a graph G = (P, E) whose node set P represents processes and whose edge set E represents the communication scheme
- a similar graph H = (N, L) representing the parallel computer (nodes N and links L)
- a function π: P$\rightarrow$N mapping processes to processors
- a process set P describing the computational activity
- a communication model

MUPPET is based on this model but it is allowed that processes can be created dynamically. This model can be formulated as an abstract machine, which we call LAM-local memory abstract machine. LAM is defined as follows

(I) LAM consists of disjoint processes (no shared variables)

(II) Processes can create other processes and can terminate

(III) Communication is done by asynchronous message passing between partners (processes which know each other)

In [FIL84 p.344] this abstract machine has been advocated also as a basis for coordinated computing.

LAM can handle arbitrary communication schemes. More specific abstract machines can be defined by adding additional constraints. This will be explained by the ring local memory abstract machine-RLAM. RLAM is defined informally by

(IV) In RLAM every process has exactly two communication partners, called the neighbours. Communication is restricted to neighbours only

Similarly other abstract machines can be defined like the tree, the lattice, the hypercubes and the direct interconnected abstract machines.

Ultimately these abstract machines have to be mapped onto real machines of a given connection scheme, e.g. lattice, hypercube, butterfly. Examples are shown in Figure 1.

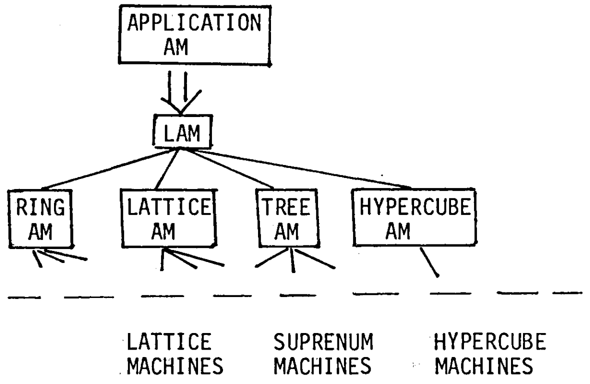

Figure 1: Abstract machines

The programming task can now be characterized as follows:The problem is formulated in an application oriented abstract machine, then it is transformed (manually and/or automatic) to a LAM implemention and may be to a more specific abstract machine implementation. This machine will then be mapped onto the topology of the real machines. We believe that this layering defines clear interfaces, which can be used to create portable and efficient programs.
The programmer has access to every layer. If the given problem has a regular communication scheme, e.g. a 2-D lattice structure, the programmer can use the 2-D lattice abstract machine directly.

The mapping of specific abstract machines to the physical machines can often be done optimally. We take as an example the mapping of a ring onto the SUPRENUM machine.
The SUPRENUM architecture can be characterized as a 2-D lattice of ring buses [GIMU86]. The straight forward mapping uses only the row or the column ring buses. The optimal mapping is the familiar Hilbert curve, which uses the communication network more equally.

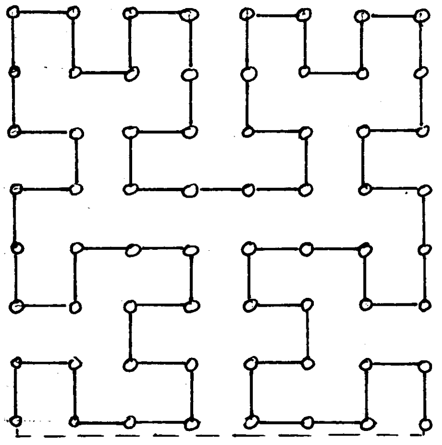

Figure 2: Mapping RLAM onto the 8 x 8 SUPRENUM machine

3. Tradeoffs for the implementation of abstract machines

Transformations of abstract machines should be guided by a goal. In order to define the goal we have to introduce a metric. In this paper we use a very simple one.
Let G1 and G2 be two graphs representing abstract machines. G1 shall be mapped onto G2. We define the Size S (G1, G2) to be

(1) S = max.distance in G2 between communicating partners of G1

The goal of the transformations is to reduce the size. Ultimately the size should be one and the resulting communication scheme should be mapped to the connection scheme of the real machine so that the size remains one in this topology.
If we end up with a size greater than one, the real system has to provide some kind of routing. Otherwise the communication scheme has to be enhanced by intermediate processes which handle the routing of messages and reduce the size to one.

This observation shows the importance of a routing service. The implementation of an efficient routing service depends on the topology of the machine and can be done by different methods.
It has been shown that random routing is a good heuristic for topologies with a rich interconnection structure (i.e. there exist many different routes between nodes). In particular, it has been proven for hypercubes and similar topologies that random routing gives a nearly optimal communication time for many interesting algorithms [ULL84 pp.232].

On these machines therefore it makes sense to provide the LAM abstract machine directly by an operating system. The operating system would use randomization and not transformations of abstract machines. It cannot be shown in general which of the two methods is more efficient. First studies on a 64-processor hypercube machine indicate that regular communication schemes with a small size should be implemented by the first method, other schemes by randomization.

4. Examples

The first example is downloading an abstract hypercube machine from a single source. The problem is to transfer M blocks from the source to all other nodes.
If we use a doubling method, downloading takes time

(2) $T_H = \log_2 N \cdot M \cdot T$

where T is the time for one communication and N is the number of nodes.
If we use the ring abstract machine we get

(3) $T_R = (N + M - 2) \cdot T$

The ring abstract machine can be mapped easily onto the hypercube so that the size is one.
We have $T_H > T_R$, if

(4) $M > \dfrac{N - 2}{\log_2 N - 1}$

This proves the rather astonishing result, that using the most primitive abstract machine gives a more efficient implementation if the problem size (M) is large enough.
The importance of the ring abstract machine has been dicovered recently by different authors (see [KRU84]). This should not really be surprising, since the ring machine is nothing else but a pipeline, a well proven paradigm for achieving high throughput.

The next example is the matrix multiplication. The multiplication of two matrices A and B is given by

(5) $c_{ij} = \sum_k a_{ik}\, b_{kj}$

We use a 2-D lattice abstract machine to implement the multiplication. In order to do this we have to make the following decisions

- how to partition the problem domain
- how to distribute the partitions

A simple distribution binds a_{ij}, b_{ij} and c_{ij} statically to process p_{ij}. The case N = 9 is shown in the next figure

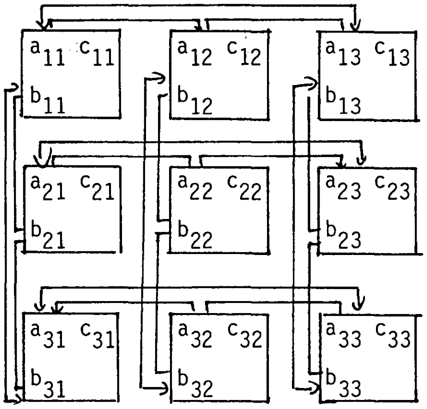

Figure 3: Matrix multiplication

This implementation gives a size of O $(\sqrt{N})$ and requires routing.
We will now try to find a communication scheme with a smaller size by applying transformations. We list only two important transformation rules

Rule 1: (How to start)
The data should be distributed in such a manner that all the processes can start with a computation.

Rule 2: (How to bind data to processes) If processes P_e and p_m request the same data d from process p_n and if the distance (p_e, p_n) = distance (p_e, p_m) + distance (p_m, p_n), we replace request (d, p_n) in p_e by a request (d, p_m) after p_m has got d from p_n.

The second rule describes a dynamic binding of the data d to the processes. These two transformation rules and a very complicated rule taking into account the data dependencies transform the first implementation to an implementation already found by Cannon.

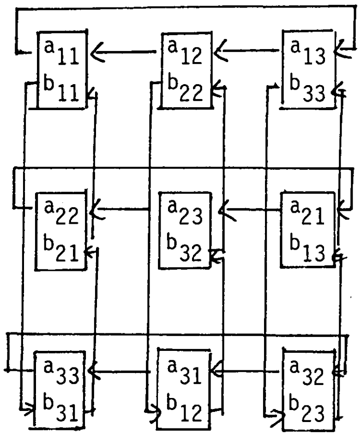

Figure 4: Matrix Multiplication by Cannon

The second implementation uses a modified 2-D lattice machine (torus), a dynamic binding of a and b to the processes and a distribution which obeys rule one. The implementation has a size of 1.

These examples demonstrate the usefulness of the proposed approach. But it should be remarked that the transformation rules are still rather informal We see the mathematics for communication schemes and their transformations slowly emerging. First steps are the metric pattern theory [GRE86] and the automatic synthesis of systolic algorithms [QUI84].

The MUPPET programming environment supports the approach outlined in chapter two and four. Generic abstract machines are provided by programm templates. The transformations will be implemented semi-automatically, this means the programmer directs MUPPET interactively.
We also want to note the similarity of this approach to the implementation assistant of the PIE programming environment [SERU85].

5. CONCURRENT MODULA-2

CONCURRENT MODULA-2 is based on the actor model of Hewitt [HEW77] and is an upward-compatible extension of Modula-2 [WIR83]. We chose Modula-2 as the base language, because it is well-structured, offers a module concept for modular programming and separate compilation of modules, and can be implemented efficiently even on micro-computers.

A CONCURRENT MODULA-2 program is based on LAM. It consists of a set of processes, communicating with acquainted processes by sending and receiving messages. In accordance with SCRIPT [FRA83] we have introduced an abstraction mechanism for communicating processes.

Several modern programming languages [COO80] [DAN81] [OCC83] have constructs to support inter-process communication; some of the constructs are slightly higher-level than others, but most can be considered low-level, because they handle some primitive communication between two partners at a time.

The following description presents the main features of CONCURRENT MODULA-2.
A parallel program in CONCURRENT MODULA-2 comprises of a set of communication patterns and process modules that 'import' some of these pattern to be used in communication steps.
A special module, marked as the initial process module is created as the first process of the parallel application and typically behaves as a supervisor of the computation.

The actions of a process in CONCURRENT MODULA-2 are specified in a program module, a syntactic entity of Modula-2, which is called process module in the following. A process is an instantiation of a process module. These process modules assure that processes operate only on local data objects, because none of the local definitions can be exported and used by other processes. Thereforeno shared data can be provided between different processes.

Processes in CONCURRENT MODULA-2 may be created dynamically during runtime with a create operation called NEWTASK. NEWTASK applied to a name of a process module creates and activates a new process and returns a reference to the active process, executing the corresponding process module.

References to processes are values of type TASK or of a special process type denoted by the name of the process module. In the same way variables can be declared of type TASK or typed with the name of a process module.

Within a process module coroutines of Modula-2 may be used to structure the internal behaviour of the process and to get smaller entities of parallelism.

Processes terminate by executing an explicit terminate statement. They cannot be killed by other processes, except by the initial supervisor process, controlling the computation.

Processes communicate by asynchronous message passing. As indicated above, a process can only communicate with acquainted processes, which means, that the process reference must be known. Each process has its own mailbox, in which the arriving messages are collected.

To participate in a communication, processes import communication patterns, which define the message types for the transaction.
Two processes can communicate successfully, if they know each other and use the same communication pattern. The use of patterns for the communication allows to check the message passing activity. Type checking can be done during compile and link time, provided typed processes are used.

A pattern definition for an ansynchronous communication consists of a pattern name and a list of types, indicating the types of the parameters of the message.

```
   PATTERN
      PatternName ( TypeList ):
```

The basic communication primitive in CONCURRENT MODULA-2 is the asynchronous send statement with no-wait semantic according to the classification of Liskov LIS79 . In a communication transaction, a sending process executes a send statement with an underlying pattern. The send statement specifies the pattern name, actual message parameters and the receiver process.

```
   SEND PatternName ( ActualMessageParms )
        TO Process:
```

A receiver process executes a receive statement, specifying the pattern and a variable list to store the incoming values of the expected message. Optionally the sending process may be denoted. During the execution of a receive statement, the mailbox of the process is checked for a matching message, i.e. a message with the respective pattern name. If no matching message is found, the process will be blocked. Otherwise the actual parameters of a message are bound to the variables of the VariableList. If a DO-END block is specified, the corresponding statements are executed with the variable bindings of the message received.
The variables in the VariableList may either be globally defined or local   to the DO-END block of the receive statement.

```
   RECEIVE PatternName ( VariableList )
       FROM Process    DO StatementSequence END
```

Higher level communication is supported by the following additional features:
A select statement allows a process to wait for the first of several acceptable messages. Every select alternative can be attached with a boolean expression and is a set of CONCURRENT MODULA-2 statements, whereby the first statement is a receive statement.
The semantic of the select statement is wellknown from the ADA DOD80 select.

One of the most important features of CONCURRENT MODULA-2 is the following:
Processes can be combined into sets. Sets can be used in send/receive statements. Therefore messages can be sent to several processes simultaneously. The usual operation on sets like union, exclusion etc. support the creation and transformation of communication schemes.
If a process set is used in a receive statement, it is possible to receive a message from one of the processes without specifying any precedence.

We illustrate the flavour of CONCURRENT MODULA-2 by means of a simple example
a parallel program with a buffer manager, a producer and a consumer process.
The parallel module BoundedBuffer, given below, includes the process descriptions for buffer, producer and consumer processes.

The supervisor module is assumed to be separately compiled and represents the actions of the process created at the beginning of the computation. The supervisor's task is to create buffer, producer and consumer processes and to install the necessary communication scheme, i.e. to send the process reference of the buffer process to both producer and consumer processes using the pattern InitProdCon.

For communication transactions with a buffer process, the pattern put is imported into the producer's module and get is imported into the consumer's module.
InitProdCon is the pattern for the necessary initializations done by the supervisor. The code segments in the producer/consumer modules are trivial: messages of the corresponding patterns are sent/received. Communication is done with the buffer process, referenced by the variable BufferProcess, declared as a Buffer-typed process. To use the name of a process module as type of a process variable the modules name must be declared in a USE-list.

A buffer process with local declarations for the control of the buffer array repeatedly waits for either a put or a get message. Put messages contain a character to be storedin the buffer array: get messages don't contain a message value.
A get transaction returns a character value to the sending consumer process, put transactions return no value.

The select statement within the buffer module has two alternatives. The first alternative handles a put message, which can be accepted whenever the buffer array is not yet filled. The second alternative accepts get messages, when data is available i.e. the buffer array is not empty.
Note that a producer process is not blocked after sending the message even if the buffer array is full. A consumer process executes a send-wait and is blocked until the reply message arrives.

```
PARALLEL MODULE BoundedBuffer;
    USE supervisor;
    PATTERN
       put( CHAR );
       get(): ( CHAR );
       InitProdCon(Buffer);

    MODULE Buffer;
    IMPORT get, put;
    CONST MaxSize=1000;
    VAR in, out, n : CARDINAL;
        buf: ARRAY [0..MaxSize-1] OF CHAR;
    BEGIN
       n:=0; in:=0; out:=0;
       LOOP
          SELECT
             WHEN n < MaxSize :
                RECEIVE put(buf[in]);
                in:=(in+1) MOD MaxSize;
                n:=n+1; |
             WHEN n > 0 :
                RECEIVE get REPLY (buf[out]);
                out:=(out+1) MOD MaxSize;
                n:=n-1;
          END (* SELECT *)
       END (* LOOP *)
    END Buffer.

    MODULE Producer;
    USE Buffer;
    IMPORT InitProdCon, put;
    VAR BufferProcess: Buffer; data: CHAR;
    BEGIN
       data:="any char";
       RECEIVE InitProdCon(BufferProcess);
       LOOP
          SEND put(data) TO BufferProcess;
       END (* LOOP *)
    END Producer.

    MODULE Consumer;
    USE Buffer;
    IMPORT InitProdCon, get;
    VAR BufferProcess: Buffer;
        data: CHAR;
    BEGIN
       RECEIVE InitProdCon(BufferProcess);
       LOOP
          SEND get TO BufferProcess WAIT (data);
       END (* LOOP *)
    END Consumer.

    INITIAL supervisor;

END BoundedBuffer.
```

Figure 5: Bounded buffer in CONCURRENT-MODULA-2

6. Tools of the MUPPET programming environment

MUPPET tries to help the programmer as much as possible before the program is run on the target machine. MUPPET relies on the synergy effect between scientific workstations and supercomputers. Some of the tools are shown in the next figure.

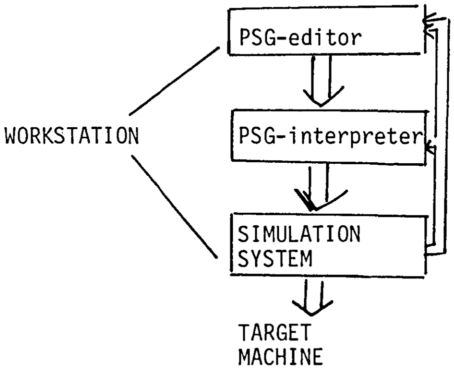

Figure 6: The MUPPET programming scenario

We will describe the simulation system in more detail. The goals of the simulation system are as follows

- the simulator should run concurrent programs unmodified
- the simulator should support different hardware topologies
- the simulator should allow interactive use

The simulator is written in MODULA-2. It is based on a discrete time, event driven and objected oriented simulation model. Some of the problems of simulators are broadly discussed in [FUJ85]. Very important is the method to determine the time which would elapse on the target machine while the program executes.
The MUPPET simulator currently supports CONCURRENT MODULA-2 and MIMD FORTRAN.

For a specific language only a preprocessor and a run-time system has to be provided. Necessary operating system services are implemented in the kernel of the simulator.
The simulator supports the MUPPET programming paradigm, Therefore it can handle different abstract machines.

The hardware machine is specified by a simple hardware description language. Predefined hardware objects like processors and buses are instantiated at runtime and connected according to the specification. In a later version the hardware specification will be assisted graphically. Each hardware object acts as a coroutine in MODULA-2. The coding of the hardware objects is hidden from the user. The programmer may also use predefined hardware machines like the 2-D lattice machine, a hypercube machine and the SUPRENUM machine. The user can specify and evaluate any process to processor mapping strategy. The runtime interface of the simulator supports interactive use. The user is able to intervene in a running experiment at any time e.g. to display some informations or to start debug actions. For that purpose a special interface language is provided.

Special emphasis has been given to the debugging features. We devide debugging into two parts

- debugging of the communication part
- debugging of sequential process

The first part will supervise and influence the flow of messages between interacting processes. The debugging features will be similar to the ones discussed in [SMI85].
Experiences with former simulation projects ([MUH81], [BMS83]) greatly influenced the design of the simulation system.

7. Experiences and Conclusions

A number of studies have been made so far, mostly with numerical applications [HOMU86]. We have found that parallel algorithms for local memory multiprocessors can be formulated either data-structure or macro data-flow oriented.

The data structure oriented approach emphasizes the global aspects of the algorithm, whereas the macro data-flow solution concentrates upon the dynamic interaction of parallel processes by the flow of data. The LAM machine can be thought of as a macro data flow machine if the processes do not have information about internals of other processes.

SIMD machines support the data structure approach. It is obvious, that a SIMD machine can easily be implemented by LAM while the reverse is not true.
The macro data flow approach leads to very simple programs for the numerical parts, but new problems arise with the control part-initialization and termination of processes and their mapping to processors.

Every "real life" algorithm seems to need at least two different communication schemes: one scheme for the numerical algorithm and one for the control part. The best way seems to implement the two communication schemes by two different process nets, one process net supervising the other net. This separation of concerns makes it possible to implement different control strategies without changing the numerical process net. We have shown that distributed process initialization and termination can be implemented efficiently with a quadtree abstract machine [HOMU86].
More research has to be done to test the reliability of the macro data flow aaproach. Of particular importance is the definition of well-structured communication schemes for a broad class of applications, the integration of these schemes into the programming languages and into the programming environment.
Another important observation is that local memory multiprocessor systems have most ot he problems of distributed systems. Fundamental problems are distributed termination, distributed snap shots and the management of time. Without solving these problems by using newest results of computer science research, the above systems have only limited applicability.

DISTRIBUTED FUNCTIONS ALLOCATION FOR RELIABILITY AND DELAY OPTIMIZATION

S. Hariri*, C. S. Raghavendra**

Department of Electrical Engineering-Systems
University of Southern California
Los Angeles, CA 90089.

ABSTRACT

In this paper, we present two optimization algorithms for allocating the functions of a given distributed task so that the reliability is maximized and the communication delay is minimized. A distributed task reliability measures the probability of executing successfully a task that is composed of a set of functions running on remote processing elements, while task delay describes the average delay incurred during the processing of a task. The allocation of resources, such as computing functions and files influences the reliability and the delay. Two different approaches are developed to allocate the resources of a given task. In the first method, the problem is reduced to a 0-1 integer linear programming problem and can be solved as two sub-problems. First, the set of allocations that maximize reliability is found using an approach based on a *branch-and bound* technique. Then, standard delay analysis is adopted to assess the average packet delay associated with each of these allocations to choose the optimal solution. In the second approach, a compound objective function is constructed to measure both reliability and delay. Then, it is used in an optimization algorithm to obtain the optimal distribution of a task's functions. A detailed example is presented to illustrate the optimization methodology.

1. INTRODUCTION

A Distributed System (*DS*) can be viewed as a collection of Processing Elements (*PE*'s) that are connected via a communications network and are controlled by a distributed operating system. A distributed task (*T*) is defined as a set of functions such as, updating a database, requesting a system service routine, and calling a remote procedure. The processing elements cooperatively execute tasks for improved performance. The number of *PE*'s involved and the degree of cooperation among them may vary considerably with the tasks. The static distribution of the resources (functions) associated with tasks influences their reliabilities, the recovery from failures, and the communication delay; the delay becomes significantly long when many intermediate computers must be visited before required resources can be accessed.

Several optimization problems have been addressed in the context of computer communication networks, for example, the capacity assignment problem, and the topology optimization problem [FRAN 72, KLEI 76, GERL 77, KLEI 80]. These problems minimize the total cost of the system to satisfy certain performance constraints such as average delay. Topology optimization with reliability constraint is a hard problem, and a heuristic solution is usually used which is to provide two or more node-disjoint paths between every pair of *PE*'s. The optimal allocations of the resources of a distributed database for minimizing storage cost and response times have been widely investigated [CHU 69, MARI 79, LANI 83, RAMA 83]. Researchers have also investigated the problem of combined allocation and network design to minimize storage and communication costs [MAHM 76, MARI 79, CHEN 80, IGNI 82, IRAN 82].

Algorithms that assist designers in determining the optimal allocations of the resources are important especially in the early stages of designing reliable distributed systems; they provide the initial estimation of the best preformance measures that can be obtained with a given set of resources. If they do not satisfy the system's requirements, alternative designs or more resources can be added. In this paper, the topology of a distributed system is assumed to be fixed, and it is required to distribute the resources of a task so that reliability is maximized and delay is minimized. In distributed systems, we are more interested in the allocation of multiple tasks than that of one task. However, our approach is still applicable to this case because these tasks can be combined together to form one task whose functions are the union of those associated with the given set of tasks. The optimization problem to be solved here is formulated as:

GIVEN	: Fixed topology. n processing elements. a task T of n_f functions.
MAXIMIZE	: Distributed task reliability (R).
MINIMIZE	: Task Packet Delay (TPD).
OVER DESIGN VARIABLES	: Allocation variables.
SUBJECT TO	: Redundancy used is less than an upper bound.

Two different approaches are used to solve this complex optimization problem. In the first method, it is decomposed into two sub-problems: 1) find the set of allocations that maximize the reliability, and 2) find the task packet delay associated with each of these allocations and choose the solution that minimizes the delay. In the second approach, a compound objective function is constructed to measure the effects of resource allocations on both reliability and delay. Then, this objective function is maximized using an algorithm similar to the one developed in the first approach. Such an optimization procedure can be used during the design phase and when there are changes in the distributed system. The optimization can be performed periodically to account for the time varying reliabilities.

The organization of this paper is as follows: in the next section, reliability analysis of distributed systems is presented. A method for estimating the average task packet delay is discussed in Section 3. Optimization algorithms, which are based on the branch-and-bound technique, to solve different variations of the problem formulated previously are developed in Sections 4 and 5. An illustrative example is presented in Section 6. Concluding remarks and summary of the paper are discussed in the final section.

2. RELIABILITY ANALYSIS

In our analysis, a distributed system is modeled as an undirected graph in which the nodes and the edges represent the processing elements and the communication links, respectively. The conventional reliability measures used in communications networks such as network connectivity and terminal reliability [WILK 72, GRNA 80, HARI 86a] are not sufficient to describe accurately the reliability in distributed systems. This has led researchers to develop new reliability measures, such as source-to-multiple-terminal reliability [SATY 81], survivability index [MERW 80], and distributed program and system reliability measures [PRAS 86, HARI 86b].

A distributed task (T) which consists of n_f functions can run successfully when all these functions are processed correctly and are accessible for information exchange. The reliability of a task can therefore be measured by the probability of processing all its functions successfully. This depends on the reliability of the processing elements and the communication channels, and the allocation of the interacting functions. The reliability p_i of a component x_i (it can be either a computer or a communication channel) represents the probability of being operating.

Redundancy in the functions (f_i's) of a distributed task is introduced to increase reliability and fault tolerance. The level of redundancy (number of redundant copies of functions or files) can be increased up to the total number of processing elements in the system. However, a large number of redundant copies of resources (such as replicated files) introduces additional traffic to maintain consistency. Typically, the number of redundant copies will be small (2 or 3 copies).

In what follows, we briefly discuss an approach for evaluating the task reliability associated with a given distribution of its functions. This is done by first determining the set of all trees that provide the required accessibility to the cooperating functions. These trees are referred to as Minimal Task Spanning Trees (*MTST*'s). An *MTST* is minimal when there is no other *MTST* of smaller size (smaller number of nodes). Then, the probability of executing a given distributed task successfully is evaluated as the probability that there exists at least one *MTST* in the operational state (all its nodes and links are fault-free) in spite of channel and node failures, i.e.,

$$R = P_r(\text{ at least one } MTST \text{ is operational}) \qquad (1)$$

Let N_t denote the total number of *MTST*'s for a given allocation of the functions. The distributed task reliability can be written as:

$$R = P_r(\bigcup_{i=1}^{N_t} MTST_i) \qquad (2)$$

The evaluation of Equation 2 can be explained through an example. Figure 1 shows an allocation of the duplicated functions (f_1, f_2) of a distributed task T.

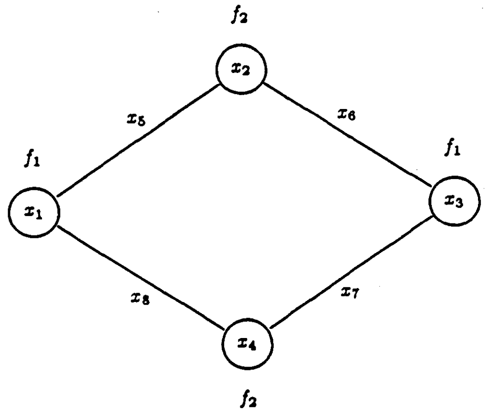

Figure 1: A maximal reliability allocation of 4 functions.

For example, in $MTST_1 = x_1x_2x_5$ of Figure 1, the functions (f_1, f_2) are processed on nodes x_1 and x_2, respectively, while channel x_5 is used for data exchange. The other trees that run the task under consideration are:

$$MTST_2 = x_1x_4x_8$$
$$MTST_3 = x_2x_3x_6$$
$$MTST_4 = x_3x_4x_7$$

Substituting these trees in Equation 2, yields the following:

$$R = P_r(\bigcup_{i=1}^{4} MTST_i)$$

The reliability expression of Equation 2 can be obtained using any terminal reliability algorithm based on path enumeration when the set of *MTST*'s are used instead of the set of the simple paths. A detailed description of algorithms to enumerate efficiently these trees and then to determine the corresponding reliability expression can be found in [PRAS 86, HARI 86b]. If we apply the SYREL algorithm in [HARI 86a] to the above example, the following reliability expression is obtained:

$$\begin{aligned} R = {} & p_1p_2p_5 + p_1p_4p_8(1-p_2p_5) \\ & + p_2p_3p_6[q_1+p_1q_5(1-p_4p_8)] \\ & +p_3p_4p_7[q_1(1-p_2p_6)+p_1q_8(q_2+p_2q_5q_6)] \end{aligned}$$

where p_i and q_i denote the reliability and the unreliability ($1-p_i$) of an element x_i, respectively.

The reliability expression can be modified by replacing the reliability of the components (p_i's) with the corresponding time-related functions to derive other reliability measures, such as availability, mean time to first failure, and mean time between failures [RAGH 83]. To measure the amount of reliability improvement achieved from adding redundant copies of the functions, we introduce a measure that relates the increase in reliability resulted from redundancy level r to the maximum obtainable improvement. This maximal reliability increase occurs when the non-redundant reliability $R(0)$ is improved up to 1 (the maximal reliability). The Reliability Improvement Factor (*RIF*) is used to measure this relative improvement, and is defined as:

$$RIF = \frac{R(r) - R(0)}{1 - R(0)} \qquad (3)$$

where $R(r)$ and $R(0)$ denote the reliability with r redundancy and with no redundancy, respectively. If we assume all the processing elements and the channels have a reliability of 0.9, the *RIF* of the functions allocation shown in Figure 1 equals 90.37%.

The evaluation of task's reliability can not be achieved in polynomial execution time [BALL 80]; therefore, it is not possible to evaluate it at each iteration of an optimization algorithm that deals with large distributed systems. Furthermore, the purpose of reliability evaluation is to direct the search of an optimization algorithm toward the allocations that maximize the reliability. Hence, the approximation of task reliability can be used effectively in this type of application. Most of the components' reliabilities are generally within a close range. Therefore, with a good approximation, we can assume that all the computers and communication links have the same reliabilities and are equal to p_c and p_l, respectively. Let n_t denote the number of nodes in an *MTST* of a task T. The reliability and unreliability of that tree are:

$$r_t = p_c^{n_t} \cdot p_l^{n_t - 1}$$
$$q_t = 1 - r_t$$

If we assume that there are only two disjoint trees (trees with no common nodes or links) for a given distribution of functions, then the reliability of executing that task is:

$$R = 2\, r_t\, q_t + r_t^2$$

If we assume that all the N_t trees of Equation 2 are all disjoint, then its evaluation can be generalized as shown in Equation 4.

$$R = \sum_{k=1}^{N_t} \binom{N_t}{k} r_t^k \cdot q_t^{N_t - k} \qquad (4)$$

However, the sets of trees are not usually disjoint and therefore there will be some common components among them. The failure of any one of them will contribute to the failure of more than one tree. As a result, the reliability given in Equation 4 can be viewed as an upper bound and can be used to approximate the reliability in the optimization algorithm presented in Section 5.

3. DELAY ANALYSIS

In addition to studying the task reliability associated with an allocation of its functions, one can also analyze the corresponding packet delay, throughput, or any other useful performance measure. In this section, we present an approach for estimating a packet delay incurred during its movement in a store-forward message switching network. It is based on queueing network models. Queues on a single communication link are characterized by the arrival rate of packets flowing through it and the distribution of transmission times. The major difficulty of the queueing network model is that the flow of traffic throughout the network is not independent. To simplify the analysis of these queueing models, the independence assumption is introduced in which the length of a message (packet) is considered as an independent random variable as it moves from one node to another. If we also assume Poisson processes for all packet arrivals, exponential distribution of packet length with $\frac{1}{\mu}$ bits per packet, fixed routing, and no nodal delay, then the average delay T_k on channel k is given by [KLEI 76] as:

$$T_k = \frac{1}{\mu C_k - \lambda_k} \qquad (5)$$

where C_k *and* λ_k denote the capacity of channel x_k and the traffic flow on it (both in bits per second), respectively, and $\frac{1}{\mu}$ represents the average packet length.

Equation 5 is an approximation of the delay associated with a channel. The consequent analysis is not restricted to that formula or to the assumptions used in its derivation. However, any other equation derived based on more realistic assumptions can be used to replace Equation 5. A Task Packet Delay (*TPD*) is defined as the average packet delay incurred during the information exchange between the cooperating computers. The links of an *MTST* can be used to dictate the routes of information exchange among the cooperating *PE*'s. One criterion for choosing an appropriate tree is identifying the one that leads to a better load balancing of the distributed system.

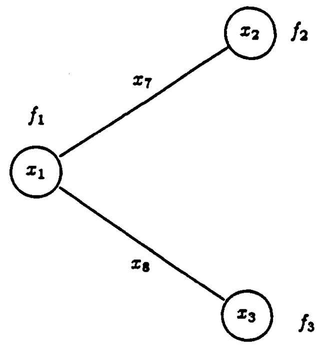

Figure 2: An *MTST* with the allocation of a T's functions.

For example, Figure 2 shows an *MTST* and the allocations of three functions (f_1, f_2, f_3) that compose a distributed task. In that tree, the following routes are used for information exchange among the functions: 1) x_7 for transferring packets between f_1 and f_2, 2) x_8 for transferring information between f_1 and f_3, and 3) $x_7 x_8$ for transferring packets between f_2 and f_3. Since there are many trees for each allocation of the functions, the TPD_p of an Allocation a_p can be computed in term of the Packet Delay (PD_i) associated with each $MTST_i$. This can be expressed as follows:

$$TPD_p = \frac{1}{N_t} \sum_{i=1}^{N_t} PD_i \tag{6}$$

where N_t denote the number of trees that can run a given task.

Let $tr(i,j)$ denote the number of packets transferred between functions (f_i, f_j) and $e_l(i,j)$ be a binary variable that takes on value 1 when x_l of an $MTST_i$ is included in the route between f_i and f_j. The total amount of traffic (γ) flowing on an $MTST_i$ is the summation of all the traffic between all the pairs of the functions, i.e.,

$$\gamma = \sum_{i=1}^{n_f} \sum_{j=1}^{n_f} tr(i,j) \tag{7}$$

The packet delay PD_i of an $MTST_i$ can be found by applying the following five steps [TANE 81]:

1. Find the traffic flow on each channel of $MTST_i$.

$$\lambda_l = \sum_{i=1}^{n_f} \sum_{j=1}^{n_f} e_l(i,j)\, tr(i,j) \quad , \forall\, x_l \in MTST_i \tag{8}$$

2. Find the total traffic on all channels.

$$\lambda = \sum_{\forall x_l \in MTST_i} \lambda_l \tag{9}$$

3. Find the mean number of hops per packet.

$$\bar{n} = \frac{\lambda}{\gamma} \tag{10}$$

4. Find the Mean Channel Delay (MCD_i).

$$MCD_i = \sum_{\forall x_l \in MTST_i} \frac{\lambda_l T_l}{\lambda} \tag{11}$$

5. Find the Packet Delay of $MTST_i$ (PD_i).

$$PD_i = \bar{n}\ MCD_i \tag{12}$$

The objective of the optimization algorithms presented here is to find the set of allocations that optimize both reliability and delay. The comparison among allocations is not straightforward because of their different effects on reliability and delay. Hence, in order to simplify the comparison, the TPD is normalized with respect to the Worst Task Delay (WTD). This delay is computed in similar steps to the one used in computing the TPD after considering the following changes:

1. The mean channel delay (MCD_i) associated with an $MTST_i$ is considered the worst possible delay. This occurs when the maximal traffic flows through the minimal capacity channel, i.e.,

$$\frac{1}{\mu C_{\min} - \gamma} \tag{13}$$

where $C_{\min}$ denotes the minimal capacity channel of $MTST_i$.

2. The mean number of hops per packet is equal to the number of links in $MTST_i$, that is:

$$\bar{n} = n_t - 1$$

where n_t denotes the number of nodes in $MTST_i$.

The ratio ($\frac{TPD}{WTD}$) is unitless and therefore can be used with the reliability function to form a compound objective function that measures both reliability and delay.

4. DECOMPOSING THE OPTIMIZATION PROBLEM

This approach is suitable for large distributed systems because it does not require the evaluation of a reliability expression to determine the allocations that maximize it. It has been shown in the literature that the time complexity of reliability algorithms is not polynomial [BALL 80]. A property of the allocation that maximizes the reliability is identified to guide the search for this type of allocation.

Let T be a distributed task of n_f functions and also require the cooperation of n_f computers. The function f_i that is assigned to run on a computer does not necessarily need to be only one function; it could be a set of small functions grouped together to form one entity in order to satisfy some other performance constraints. For a given distributed system, let $n_{\max}$ be the maximum number of trees of n_f PE's that run T and n be the total number of PE's.

Definition 1: A tree of n_f PE's is said to **cover** a distributed task T if its nodes can run all the functions such that each one runs on a distinct PE.

Theorem 1: In a distributed system with only one function allocated to each node, the reliability of a distributed task T requiring n_f functions is maximized if each of the $n_{\max}$ trees covers T.

Proof: Let us assume that there exists an allocation of the functions ($a_{\max}$) such that each tree of n_f nodes covers T. The number of trees covering T in any other allocation is either less than or equal to $n_{\max}$ because any allocation that has number of trees larger than $n_{\max}$ will have some trees with larger than n_f nodes. These trees do not contribute to the reliability of a task since they are supersets of smaller size trees of n_f nodes. If it is equal to $n_{\max}$, the reliability is the same because they both have the same set of trees that cover T. Let a_j be an allocation in which the number of trees covering T ($n_c(a_j)$) is less than that of $a_{\max}$. This set of trees is a subset of that corresponding to $a_{\max}$. Hence, the task reliability corresponding to a_j, which is the probability that there exists at least one tree in the operational state, is less than that associated with $a_{\max}$.

□

Most of the optimization algorithms of computer networks and distributed systems that address reliability as a performance requirement to be met do not use the reliability expression in their formulations. Instead, they use a simpler criterion such as the connectivity of the network or maintaining a lower bound on the number of node-disjoint paths between node-pairs. We also do not use the reliability expression to guide the search toward maximal reliability allocations, but the result of Theorem 1 is used instead to identify those solutions. That is, the number of trees executing the given task is maximized. This allows us to formulate the problem as a 0-1 integer linear programming problem.

Let $x_{i,j}$ denote a binary variable that takes on value 1 when function f_i runs on node x_j and 0 otherwise. Also, let $n_c(a_p)$ represent the number of trees of n_f *PE*'s covering a distributed task T for an allocation a_p. The allocation procedure of a task's functions can be formulated as follows:

Formulation 1

GIVEN : Fixed topology.
n processing elements.

MINIMIZE : $\sum_{i=1}^{n_f} \sum_{j=1}^{n} x_{i,j}$
; minimize the total number of allocated functions.

SUBJECT TO : $n_c(a_p) = n_{\max}$
; all trees of n_f nodes cover T.
and $\sum_{j=1}^{n} x_{i,j} \leq r_i \quad i=1, \ldots, n_f$
; r_i is an upper bound of redundancy in f_i.

In large distributed systems where the number of *PE*'s is much larger than the number of functions to be distributed, it is not practical to allocate them so that all the trees of n_f *PE*'s cover the task under consideration (T); to cover all trees, the upper bound on redundancy could be increased up to $\binom{n}{n_f}$ which is not feasible because of the difficulty in maintaining consistency and the overhead traffic. As a result, the previous formulation is modified so that the number of trees that cover a given task is maximized. We introduce a control variable c_k to refer whether or not tree t_k covers T. It is a binary variable which takes on a value of 1 only when each *PE* in that tree processes a distinct function of T and 0 otherwise.

The formulation of the problem becomes as follows:

Formulation 2

GIVEN : Fixed topology.
n processing elements.

MAXIMIZE : $n_c(a_p) = \sum_{\forall t_k} c_k$.
; where $n_c(a_p)$ denotes the number of trees covering T for allocation a_p.

SUBJECT TO : $\sum_{j=1}^{n} x_{i,j} \leq r_i \quad , i=1, \ldots, n_f$
; r_i is an upper bound of redundancy in f_i.

Formulation 2 is a standard 0-1 integer linear programming problem and therefore any efficient algorithm can be used to solve this allocation problem. An algorithm based on a branch-and-bound technique is used to solve Formulation 2 [HILL 80]. The algorithm consists of four steps: branch, bound, fathoming, and stopping. In the branch step, one set is selected according to a criterion which could be the one that gives the better bound or the most recently created set. In the bound step, the number of trees covering T $(n_c(a_p))$ is determined for a_p. In the fathoming step, the selected set is checked and then dropped if it violates the set of constraints. Once it is removed, the algorithm proceeds from the branch step. Otherwise, the following steps are performed before it proceeds to the stopping step: 1) the current lower bound (Z_l) is reset to $n_c(a_p)$ whenever it is larger than Z_l; 2) the selected allocation a_p is partitioned into two subsets about an allocation variable $x_{i,j}$. In the first subset, $x_{i,j}$ is set to 1 while in the second subset, it is set to 0. In the stopping step, the algorithm is stopped when all the allocation variables of the remaining subsets have been considered; otherwise, it proceeds from the branch step and so on. The optimal allocations are those whose $n_c(a_p)$'s are equal to Z_l.

If all the computers and the communication links have the same reliability, then any allocation a that maximizes the number of trees covering a task T will result in a maximal reliability. This is true because in this case all the trees will have the same reliability and therefore the highest value is achieved when the number of trees is maximized. However, if the elements have different reliability values, it is possible for an allocation a' to exist, for which $n_c(a') < n_c(a)$, and its reliability is larger than that of a. In general, the reliability values of computers as well as communication channels are in a close range, and therefore algorithms for solving Formulation 2 will identify optimal or near optimal solutions. Now we present the optimal file allocation procedure algorithm.

Function Allocation Procedure (FAP)

1. Initialization.
   1.1 $Z_l = 0$; the current lower bound is zero.
   1.2 $A = a_0$; list A has allocation a_0 in which no function has been assigned to any node.

2. Branch step.
   2.1 select the newest partitioned subset, say a_j,

3. Bound step.
   3.1 find $n_c(a_j)$; the number of trees covering T.
   3.2 the number of trees that can not cover T $(n_c(a_j)')$.

4. Fathoming step.
   4.1 a_j is fathomed, and is therefore removed from list A, when one or more of the following constraints are violated:
   $\sum_{j=1}^{n} x_{i,j} \leq r_i \quad , i=1 .,.,., n_f$
   $n_{\max} - n_c(a_j)' > Z_l$; the number of trees that could cover T is greater than Z_l.
   4.2 if a_j violates the constraints, go to branch step; otherwise, do

```
4.2.1 if $n_c(a_j) > Z_l$, then $Z_l = n_c(a_j)$
4.2.2 partition $a_j$ into two subsets $(a_{j_1}, a_{j_2})$ about the unconsidered variable $x_{p,k}$ such that $x_{p,k} = 1$ in $a_{j_1}$ and $x_{p,k} = 0$ in $a_{j_2}$.
5. Stopping step.
If all the allocation variables $x_{i,j}$ have been considered, the procedure stops; otherwise, go to the branch step.
```

Algorithm 1

```
1. Enumerate all the trees of $n_f$ nodes.
2. Apply FAP to obtain the set of allocations that maximize the number of trees covering $T$.
3. For each allocation obtained in 2, evaluate the task reliability using the approach discussed in Section 2. Then, discard from the set of allocations the ones that have lesser reliability than other allocations with maximal reliability.
4. Find the $TPD$ associated with each allocation obtained in 3.
5. Choose the optimal allocation such that $TPD_p$ is minimized, i.e.,
   $TPD_{opt} = \underset{\forall p}{MIN}(TPD_p)$
```

5. CONSTRUCTING A COMPOUND OBJECTIVE FUNCTION

Instead of solving the optimization problem sequentially as done in Algorithm 1, one could form a function that measures both reliability and delay and then find the allocation that maximizes that function.

$$F = \alpha R - \beta \frac{TPD}{WTD} \tag{14}$$

where α and β are weight factors assigned to reliability and delay functions, respectively.

This function (Equation 14) can further be simplified if we normalize their summation, i.e., $\alpha + \beta = 1$

Substituting β with $1 - \alpha$ in Equation 14 yields to:

$$F = \alpha\left(R + \frac{TPD}{WTD}\right) - \frac{TPD}{WTD} \tag{15}$$

The value of the parameter α can be used to reflect the relative importance of the reliability with respect to delay. For example, maximizing the function F can either lead to optimizing separately the reliability or delay or both combined. If α=0, this results in minimizing the delay function while setting α=1 leads to maximizing the reliability. However, if α=0.5, both functions will receive equal weight. The optimization problem can be solved as shown in Formulation 3.

Formulation 3

GIVEN	: Fixed topology. n processing elements. parameter α.
MAXIMIZE	: $F = \alpha\left(R + \frac{TPD}{WTD}\right) - \frac{TPD}{WTD}$
SUBJECT TO	: $\sum_{j=1}^{n} x_{i,j} \le r_i \quad , i = 1, \ldots, n_f$; r_i is an upper bound of redundancy of f_i.

In some applications, it is required to reduce the cost of running the functions of a given task on the computers and also satisfy some reliability and delay constraints. Let us assume that $C_{i,j}$ denotes the cost of running function f_i on computer x_j. If the cost is a major objective in the functions allocation problem, one could solved it as shown in Formulation 4.

Formulation 4

GIVEN	: Fixed topology. n processing elements. parameter α.
MINIMIZE	: $COST = \sum_{i=1}^{n_f} \sum_{j=1}^{n} C_{i,j}\, x_{i,j}$
SUBJECT TO	: $\sum_{j=1}^{n} x_{i,j} \le r_i \quad , i = 1, \ldots, n_f$; r_i is an upper bound of redundancy of f_i. $R \ge R_{\min}$; reliability must be larger than a lower bound. $TPD \le TPD_{\max}$; delay must be smaller than an upper bound.

The Formulations 3 and 4 can be solved using a procedure similar to the one described in FAP. Algorithm 2 describes the steps of a procedure to solve Formulation 3, and also it can be used to solve Formulation 4 with a slight modification to the objective function and the set of constraints.

Algorithm 2

```
1. Initialization.
  1.1 $F_l = 0$ , $A = a_0$
2. Branch step.
  2.1 select the newest created allocation $a_j$.
3. Bound step.
  3.1 evaluate $n_c(a_j)$ and and $n_c(a_j)'$ (the number of trees covering $T$ and those do not cover it, respectively).
  3.2 evaluate $TPD$.
```

3.3 evaluate the task reliability using either the approach discussed in Equation 2 or 4.
3.4 evaluate the objective function F .

4. Fathoming step.
4.1 a_j is fathomed when one or more of the following constraints are violated:

$$\sum_{j=1}^{n} x_{i,j} \leq r_i \quad , i=1 .,.,., n_f$$

$$n_{\max} - n_c (a_j)' > Z_l$$

4.2 if the constraints are not violated then
4.2.1 if $F > F_l$ then $F_l = F$.
4.2.2 partition a_j into two allocations about $x_{p,k}$ such that
a) in the first allocation, node x_k has function f_p .
b) in the second allocation, node x_k does not have f_p .

5. Stopping step.
If all the allocation variables have been considered, the algorithm stops; otherwise, go to the branch step.

6. AN ILLUSTRATIVE EXAMPLE

Let us assume that we have a distributed task T consisting of three functions (f_1,f_2,f_3) which are to be distributed among the PE 's of the distributed system shown in Figure 3 so that the reliability is maximized and the delay is minimized. The capacity of the communication channels, the traffic rate between functions (f_1,f_2,f_3), and the redundancy level in this example are assumed as follows:

$C_7 = C_8 = C_9 = C_{14} = 20$ Kbits/sec.
$C_{10} = C_{11} = 30$ Kbits/sec , $\frac{1}{\mu} = 1000$ bits/packet
$C_{12} = C_{13} = C_{15} = 15$ Kbits/sec.
$tr\ (1,2) = 1$ packet/sec.
$tr\ (1,3) = 3$ packets/sec.
$tr\ (2,3) = 4$ packets/sec.
$r_1 = r_2 = r_2 = 2$

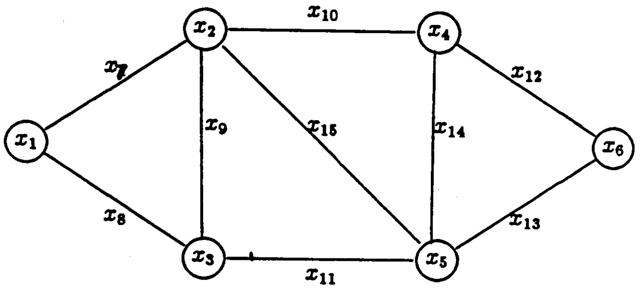

Figure 3. A six node distributed system.

In the following discussion, we use the two algorithms developed in the previous section to obtain the allocation that optimizes both reliability and delay. For simplicity, we assume that only one function could be allocated to a computer. The first step of Algorithm 1 is to find the number of trees of 3 computers that can be connected with trees of size 3. By doing so, the following 12 trees are obtained:

(x_1,x_2,x_3) , (x_1,x_2,x_4) , (x_1,x_2,x_5) , (x_1,x_3,x_5)
$(x_2,x_3,x_4,)$, (x_2,x_3,x_5) , (x_2,x_4,x_5) , (x_2,x_4,x_6)
(x_2,x_5,x_6) , (x_3,x_4,x_5) , (x_3,x_5,x_6) , (x_4,x_5,x_6)

Applying FAP leads to 18 allocations where each one of them covers only six trees of the 12 listed above. Although, these allocations cover the same number of trees, the corresponding reliability for each allocation is different because the number of $MTST$'s spanning the nodes of each tree depends on the degree of the nodes. For example, in Figure 3, there are three trees of size 3 that span nodes (x_1,x_2,x_3), while there is only one tree spanning nodes (x_1,x_2,x_4). Hence, the distributed task reliability (R) must be computed for each allocation to identify the one that maximizes it. By doing so, the number of allocations decreases to six. The distribution of the functions for each allocation of these six identified allocations is shown in Table 1.

Once the set of allocations is obtained, the next step is to use the equations in Section 3 to find the average packet delay associated with each allocation. The resulting delays and reliability of each allocation are also given in Table 1. The optimal allocation is a_2 since it has the minimal TPD_2 (107.6 msec), while allocation a_5 has the worst delay (154.6 msec) as shown in Figures 4 and 5, respectively. This can be explained as follows: in a_2, the functions that interact with each other heavily (f_2,f_3) are allocated such that they use highest capacity links (x_{10},x_{11}), while the opposite is done in a_5, in which light interacting functions (f_1,f_2) are assigned to use those links of high capacity.

If we assume all the nodes and links have the same reliability of p=0.9, the reliability of executing that task without any redundancy is

$$R\ (0) = p^5$$

and the reliability improvement factor for any one of the six allocations is

$$RIF = \frac{R\ (2) - R\ (0)}{1 - R\ (0)} = \frac{0.9597 - 0.5905}{1 - 0.5905} = 90.17\%$$

The reliability R(2) is obtained by applying the MFST algorithm given in [PRAS 86] and SYREL algorithm [HARI 86a].

Applying Algorithm 2 identifies the same optimal distribution of the functions obtained by allocation a_2.

Maximal Reliability Allocations

Maximal Task Reliability =0.9597

Allocation	x_1	x_2	x_3	x_4	x_5	x_6	TPD_i (in ms)
a_1	f_1	f_2	f_3	f_3	f_2	f_1	126.6
a_2	f_1	f_3	f_2	f_2	f_3	f_1	107.6
a_3	f_2	f_1	f_3	f_3	f_1	f_2	139.3
a_4	f_2	f_3	f_1	f_1	f_3	f_2	112.9
a_5	f_3	f_1	f_2	f_2	f_1	f_3	154.6
a_6	f_3	f_2	f_1	f_1	f_2	f_3	143.6

7. SUMMARY AND CONCLUSIONS

In this paper, we addressed the problem of resource allocation for combined reliability and delay optimization and present two algorithms. Algorithm 1 decomposes the optimization problem into two subproblems. First, the allocations of the functions that maximize the task reliability are determined using a method based on the branch-and-bound technique. Next, channel delays are analyzed using queueing network model to estimate the task packet delay for each allocation resulted with maximal reliability. The optimal allocation solution is then chosen to be the one with minimal delay. This algorithm is useful in handling large distributed systems because it does not require the evaluation of the task reliability at each iteration. It is fairly efficient due to the 0-1 integer linear programming formulation. Algorithm 2 solves the reliability and delay optimization simultaneously by maximizing a compound objective function that captures both reliability and delay using a similar technique to Algorithm 1.

The proposed algorithms can also be applied to optimize other performance measures along with the reliability of a given set of distributed tasks.

ACKNOWLEDGMENT

The authors wish to thank Dr. F. Parisi-Presicce for several useful discussions.

Abstract

An abstract model of parallel computation, specification of a base language for the abstract model, design of a high-level language and design of an architecture are steps to constructing a computing system. This paper introduces and describes the n-value logic, the NOT(OPERATION) abstract computing model based on the dataflow computing concept, functional programming and n-value logic, its effectiveness over the traditional dataflow computing models and defines DCBL, a Dataflow Computing Base Language based on NOT(OPERATION) model as a base for an efficient new class of dataflow computing languages. The major features of DCBL expressions, the expression - graph translation process, and formal and informal operational semantics are discussed in detail.

1 Introduction

Dataflow computing [1], a radical departure from von Neumann computing, supports multiple processing on a massive scale and has the potential to play a major role in next generation computing machines. In dataflow, an instruction is enabled immediately after the arrival of operands. The computations are free of side effects, and independent computations proceed naturally in parallel. The dataflow approach has the potential of exploiting large scale concurrency efficiently, maximum utilisation of VLSI in computer design, compatibility with distributed networks, and compatibility with functional high-level programming. The dataflow concept can be easily implemented in both major computing application areas: numerical computations such as scientific and technological computations and non-numerical computations such as symbolic manipulation in knowledge processing. Several dataflow computing models have been proposed for implementing dataflow computing concept in practical machines [5], [10] All these models are based on the Dennis's initiative work [1], [2]. Dynamic computing models, proposed separately by Arvind at MIT [3] and Gurd at Manchester, [4] are more efficient than the basic model.

The language is very important in representing parallel algorithms efficiently. Side-effect-free functional languages such as Pure Lisp and FP can be used effectively to execute computations in dataflow computing machines since they do not reflect the properties of von Neumann computing. Dataflow languages [1],[2],[3] should be designed with the dataflow concept in mind. Users should not consider the explicit control of memory allocations in using machines, but deal only with data values. Low-level languages for dataflow computing machines should describe dataflow computing efficiently.

In section 2, the n-value logic and NOT(OPERATION) computing model is introduced and its effectiveness over the traditional model in some important issues in dataflow computing is discussed. Section 3 introduces and defines the dataflow computing base language, DCBL (pronounced decibel) and discusses its specifications. Section 4 outlines a dataflow graph specification language since the operational semantics of DCBL expressions consist of expression translation to dataflow graphs and specifying the functionality of DCBL operators. Here, a simple specification language for parallel system specifications is introduced. Section 5 details the translation process of expressions to dataflow graphs which specify informal operational semantics. Section 6 specifies the functionality of the DCBL operators which give the formal operational semantics of DCBL expressions.

2 NOT(OPERATION) computing model

The NOT(OPERATION) model (see Fig. 1) is based on the dataflow computing concept, functional programming and n-value logic. This model provides very high performance with multi-dimensional parallelism, for parallel computing. Here, the control structures in parallel computations are composed of three primitive functions: sequential computations, parallel computations and decision making computations. Strict rules govern the way each control structure is used, guaranteeing the consistency and completeness of the specifications. Sequencing parallel computations is necessary to ensure logical correctness of the

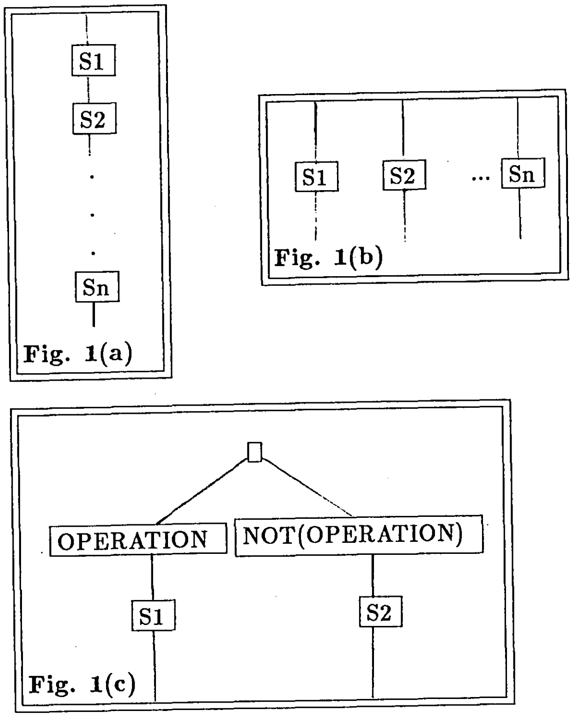

Fig. 1 NOT(OPERATION) abstract model

computations. Sequential computation control functions composed of functions that depend on the previous result of some other function. Fig. 1(a) represents the execution of ordered sequential computations S1, S2, ... Sn. Each successive computation depends on the result of its predecessor. Here, input to the S2 is the output of the predecessor S1. Parallel computations are composed of functions independent of the other for data. They are executed in parallel. Fig. 1(b) represents the execution of independent parallel computations S1, S2, ... Sn. Decision making computations use n-value logic.

- **n-value logic:** All dataflow computing languages developed so far [1] - [12] represent the class of operational semantics with two-value logic proposed by the traditional model. Executing conditional computations result in two values, TRUE (1) and FALSE (0) boolean values. These values trigger remaining computations.

  In n-value, logic the execution of a conditional computation does not give strictly TRUE or FALSE values but gives any value, including no value, instead. The translation of two-value logic conditional computations to n-value logic is performed in two steps. First, the traditional conditional computation is disintegrated into two complementary basic operations. Both operations must be executed for deadlock free computation. The next step of the translation defines the semantics of the execution. One of the two operations executed will give an output value if the operation is satisfied. 1-value logic generates TRUE boolean value and n-value logic generates any value, including no value, instead of boolean values.

Proposition 1: The traditional conditional computation can be divided into two OR parallel computations. One represents the positive state and the other represents the negative state.

The positive state of a conditional computation is denoted by OPERATION and the negative state by NOT (OPERATION). Two input tokens which will satisfy only one of the operations are required to enable the conditional computation. The parallel computing of conditional computation can be represented as **IF (OPERATION) THEN S1 OR IF (NOT(OPERATION)) THEN S2**. It is shown in Fig. 1(c).

Proposition 2: NOT(OPERATION) provides an efficient facility to implement conditional operations and hence iterative and recursive computations in parallel computing systems.

In 1-value logic the execution of both OR combined operations gives a TRUE boolean value output when the operation is TRUE. No FALSE output is given. Successive computations receiving the TRUE boolean value are executed. Boolean value generation complicates dataflow computing. n-value logic greatly simplifies the conditional computations, iterative and recursive computations in dataflow computing. Here, when the OPERATION is satisfied, input data is given as the result of execution, and the output of the NOT(OPERATION) is frozen. Otherwise, the NOT(OPERATION) gives the data value output while the OPERATION output is frozen. Boolean values can be obtained by executing CONSTANT operations when necessary.

Proposition 3: Boolean value generation in the execution of conditional computations in a dataflow computing environment is not a requirement.

There are three types of conditional computations:

- **IF A(x) THEN B(x) ELSE C(x)** Here, the value of A(x) is used in the successive B(x) and C(x) computations.

- **IF A(x) THEN B(x) ELSE C(z)** Here, the value of A(x) is used partially in the successive B(x) computation.

- **IF A(x) THEN B(y) ELSE C(z)** Here, the value of A(x) is not used in the successive B(y) or C(z) computations.

In the first and second cases, the value of conditional opertion execution is used in the following executions. Therefore, n-value logic is more efficient than 2-value logic. In the third case, B(y) and C(z) are invariants. These computations can be performed independent of A(x) whenever y and z become available and the result of A(x) can be used to trigger the final result. Fig. 2 shows the implementa-

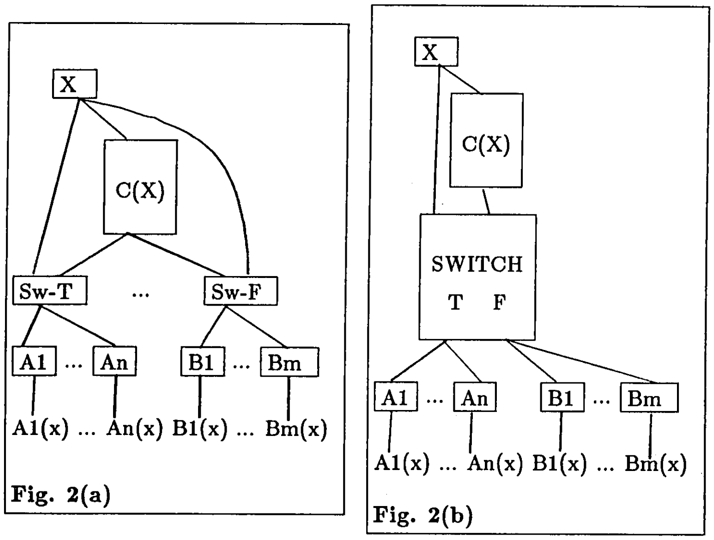

Fig. 2(a)

Fig. 2(b)

Fig. 2 Conditional computation - Traditional

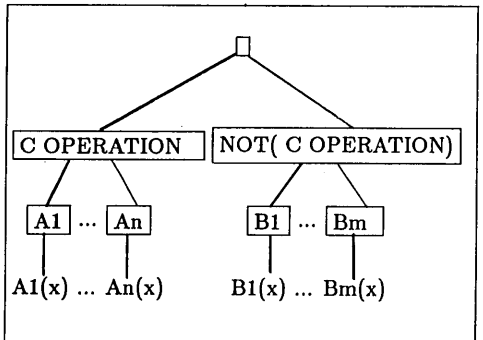

Fig. 3 Conditional computation-NOT(OPERATION)

tion of conditional computation, IF C(x) THEN A1, A2, ... An ELSE B1, B2, ... Bn, with 2-value logic. It is also possible to use a complex, macro version of switch-t and switch-f operations as shown in fig. 2(b) [3]. Fig. 2(c) shows the execution of IF C(x) THEN A1, A2, ..., An IF NOTC(x) THEN B1, B2, ... Bn. Here, the data value 'x' flows to the parallel operations, 'C OPERATION' and NOT'C OPERATION'. If it satisfies the 'C OPERATION' the same 'x' data value is given as the output value and sent to the defined destinations (thin lines in Fig. 3). The output of the NOT'C OPERATION' is frozen (dark lines in Fig. 3). If the data value 'x' satisfies the NOT'C OPERATION' the same data 'x' is given as the output and sent to the defined destinations (dark lines in Fig. 3). Here, the output of 'C OPERATION' is frozen (thin lines in Fig. 3). It is also possible to use a complex, macro version of OPERATION and NOT(OPERATION). Iterative and recursive computations are extensions of conditional computations. Hence, the representation of conditional computations has a large impact on computations. The boolean expression in the general iterative and recursive computations, can be substituted by two OR PARALLEL operations. Hence, the general while loop computation **While(boolean expression) (loop S1); S2, can be represented as (While (OPERATION) (Loop S1)) OR (NOT(OPERATION)(S2)).** and the general recursive computation **f(x) = IF c(x) then f(B(x) else x in f(z)** can be represented as **f(x) = IF c(x) then f(B(x) OR IF NOT c(x) then x in f(z).**

2.1 Effectiveness

It is easy to prove that the number of tokens necessary for the conditional computation and the time taken to enable successive computations of the conditional operation are always less in n-value logic based models than the 2-value logic based models. Several non-numerical and numerical computations were performed in the EM-3 [8],[9],[12],[13]. and the corresponding frequency of operations executed in each benchmark program was measured. These results show that SWITCH operations share a large percentage of all operations executed. The implementation of n-value logic in the EM-3 solved some problems in data-flow computing [13]. These results are summarized below.

1. **Matching bottleneck:** The basic computing cycle of double operand operations consist of: 1. matching operands 2. fetching instructions 3. executing instructions 4. dispatching results to destinations. The basic computing cycle of single operand operations consist of 2, 3, and 4 steps. A dataflow processing element basically consists of a matching unit, execution unit and a destination unit. (See Fig. 4.) The execution unit performs the execution and structure handling. The matching unit sequentially matches and synchronises the operands for execution. The larger the number of double operand operations the more matching to be performed in the matching unit. This narrows the pipeline between the matching unit and execution unit and reduces the computing speed. This is the matching bottleneck. Double operand switch operation is the major source of this. The traditional dataflow computing model reduces the computing speed described by the concept at the very first level of implementation. The implementation of n-value logic decreased significantly the number of single operand packets, double operand packets and operations executed. This results in a proportionate reduction of computing and communication cost and increase in computing speed. Fig. 5 shows machine cycles needed for single operand and double operand conditional computations with 2-value logic and n-value logic. Performance evaluation measurements in the EM-3 support these conclusions.

2. **Remaining packet garbage:** In dataflow computing, a large number of unexecuted packets wait in the matching unit until they are removed by some process. This is remaining packet garbage, RPG.

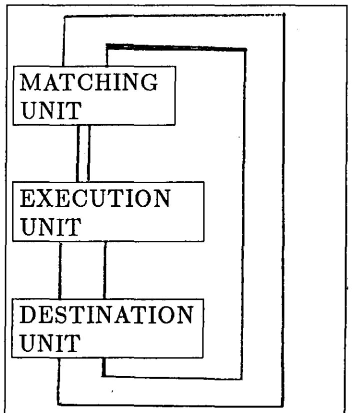

Fig. 4 Data-flow PE

Fig. 5(d) Double operand - NOT(OPERATION)

Fig. 5 Machine cycles

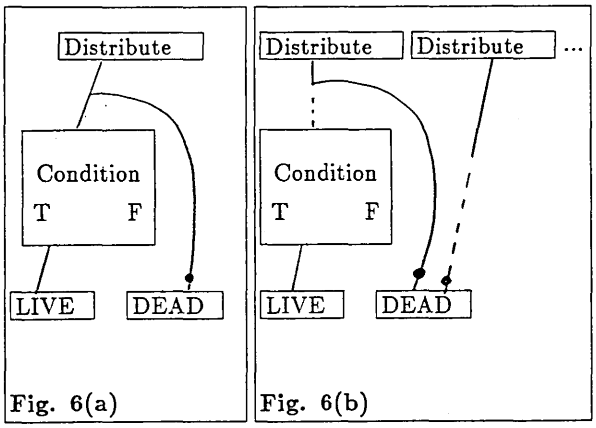

Fig. 6(a)

Fig. 6(b)

Fig. 6 Remaining packet garbage

Vertical branches created by conditional computations and multi-argument functions generate RPG. Fig. 6(a) shows RPG generation with single argument functions. A conditional computation divides the dataflow computing into two vertical branches. Execution of the conditional computation makes one branch LIVE and the other DEAD. Data flow to the operations ignores the liveness of the branch. Loading only one operand of a double operand operation in the DEAD branch results in RPG. Fig. 6(b) shows RPG generation with multi-argument functions. The multiple arguments in a function divide the dataflow computation into live vertical branches. Here, RPG is created when a DEAD branch of a conditional computation in one vertical branch receives the data values from the same vertical branch and/or from some other vertical branch. The n-value logic completely stops the flow of data from just above the conditional computation to the DEAD branch of the conditional computation. A control operation to stop the data flow into the DEAD branch, setting life time to double operand packets, dispatching a special COMMANDO packet to execute all the operations in the DEAD branch or other efficient garbage collecting mechanism must be implemented to completely remove RPG.

3. **Control of parallelism:**. Dataflow computations have huge parallelism, many times larger than the parallelism available in the hardware. Such computations tend to use excessive amounts of storage, since many partial results are created long before resources are available to process them. Therefore, it is necessary to restrict excess program parallelism to approximately match machine parallelism. A large number of unnecessary computations with pseudo parallelism in the traditional model is removed by n-value logic. Dataflow computing requires very large, complex instruction sets. n-value logic provides the facility to design an efficient, refined and reduced instruction set.

4. **Sequential computing segments:** A sequential computing segment is a program segment in which the maximum parallelism is less than the number of processors and/or pipeline stages. Such computations are involved in conditional computations, recursive procedure calls and iterative computations which uses previous computing results to continue computation. The performance of the sequential computing segments in a program is important in parallel computing. Dynamic dataflow computing models unfold loops to compute iterative computations dynamically. n-value logic eliminate sequential computing segments implemented in loop unfolding and gives high computing speeds.

3 Specification of DCBL

This section discusses the specifications of a base language for the NOT(OPERATION) model. The main objective of DCBL design is to introduce and define a new class of operational semantics with n-value logic for dataflow computing languages. The other objective is the development of high-level dataflow computing languages which are comfortable for machines and users to express many forms of concurrency. The language considered here is a preliminary version of the DCBL, therefore, it does not include features such as static arrays or dynamic arrays such as streams, records or unions. Such extensions are considered later. DCBL, a VAL like language [1], [2] allows user selected, highly concurrent algorithms to be expressed as a collection of expressions. Therefore, the execution of a DCBL program consists of a sequence of parallel executions of side effect free expressions. All individual operations in a DCBL expression are executed simultaneously. An expression execution may generate zero (no value expression), one (uni-value expression), or more than two (multi-value expression) values. Tuple expressions, multi-value function expressions, conditional expressions and parallel expressions are multi-value expressions. The specification of BNF syntax for iterative computations of DCBL is given below.

```
exp ::= function(exp)
| exp, exp, ... exp
| IF exp THEN exp IFNOT exp THEN exp
| identifiers
| constants
| LET idlist = exp IN exp
| IF exp THEN exp
| FOR idlist = exp DO iteration

iteration ::= ITER exp NOTITER exp
| LET idlist = exp IN iteration
| IF exp THEN iteration
| IF exp THEN iteration
IFNOT exp THEN iteration
idlist ::= id
| idlist id
```

The application of a function to an expression, **funct(exp)**, is used to represent sequential computations. The elementary functions are operators. The operations performed on expressions can be characterised by mathematical functions. The application of function F to the imports, x, y, and z, produces export F(x,y,z). The expression tuple |**exp, exp, ... exp** | is used to represent parallel computations. **Identifiers** and **constants** are the most elementary expressions in DCBL. Values can be bound to identifiers. Identifiers can be bound to simple types (integer and real), structured types and function calls. The **LET ... IN ...** expression provides local binding to extend the execution environment.

Decision making computations, conditional expressions and the **FOR ... DO ...** expressions in DCBL, sequence the parallel computation to ensure logical correctness and avoid initiating computations whose results can never be used. Huge collections of IF-THEN rules are used in numerical and non-numerical computations, especially in expert systems. Therefore, in the DCBL design, special attention is given to the implementation of conditional expressions. DCBL has a special conditional expression, representing the features described in the n-value logic. Therefore, DCBL has new operational semantics for conditional, iterative and recursive computations. In DCBL, the general IF THEN ELSE expressions and case expressions are represented by the **IF exp THEN exp** conditional expression. All predicates in **IF exp THEN** are supported by expressions, and depending on the imports, produce and seize exports, instead of producing boolean values. **IF exp THEN exp** provides the single branch conditional expression. **IF exp1 THEN exp2 IFNOT exp1 THEN exp3** is a two branch conditional expression with two complementary conditional computations. These expressions are executed in parallel. Combining n **IF exp THEN exp** expressions, n parallel computations with a live branch and n-1 dead branches, provides guarded command feature.

Sequential expressions of the type of iterative computations that depend on the previous iterative computation result are executed sequentially. However, the hidden parallelism of the iteration expression is exploited and the computing speed is increased by the NOT(OPERATION). The **FOR idlist = exp DO iteration** expression implements loops that cannot execute in parallel because values produced in one iteration must be used in the next. The **FOR** expression has loop initiation and a loop body. Loop initiation is performed by the **FOR idlist = exp** part and the loop body appears in **DO iteration.** Side effect free conditional expressions are included in the decision making for loop iteration. The iterative expression **FOR idlist = exp DO iteration** is evaluated by binding the iterative identifiers, the elements of **idlist**, to the values of **exp**. The evaluation of the iteration body results in a **NOTITER** expression and an **ITER** expression. Both these expressions are evaluated concurrently in each iteration. If the **NOTITER** expression satisfies the condition, this terminates the iteration and gives the computation result. Otherwise, the output is given by **ITER** expression. Here, the **ITER** expression is satisfied and continues iteration. The iteration is terminated when the evaluation of the **ITER** body results in an ordinary **NOTITER** expression. The value of this expression is the value of the

ITER expression. Parallel expressions for the computations of the type **For I := 1 to n do C[i] := A[i] * B[i]**, which represents iterations that do not depend on the previous computation result, are not discussed here. The following section describes the dataflow graph specification language.

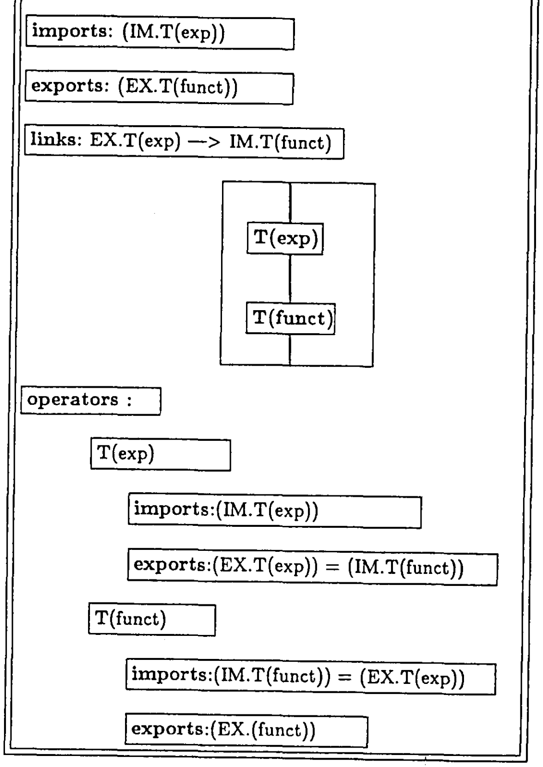
4 Dataflow graph specification language

Expressions and compiler help identify concurrency in algorithms and their program and map that concurrency into graphs. The translation of DCBL expressions gives new dataflow graphs presenting the NOT(OPERATION) abstract computing model. The graph, which connects sub-graphs composed of operators, is an explicit representation of the concurrency available in evaluating expressions. An element of a dataflow computation consists of import ports, imports, export ports, exports, import links, export links and operators. Specifications of a dataflow graph include imports, exports, data links and operators. Specification of operators is defined recursively using local imports and exports. Imports to the operator embark at import ports. Exports of the operators disembark at export ports. The number of imports or exports in a link is unlimited. This gives the dynamic computing features [3] [4]. The restriction of values to one gives the static computing feature [1] [9] [11]. The operators communicate values through their import and export ports. The graph has an import port for each free variable of the expression and an export port for each value returned by the expression. The following notations are used to specify the dataflow graphs. **IM.T(exp) and EX.T(exp)** are the set of imports to the operators of the translation of (exp) and the exports at the export ports of the operators of the translation of (exp). These imports and exports have defined import ports and export ports. Links are represented by **EX.T(expl)—>, IM.T(exp2)** which means that the exports of translated expression expl are linked to the defined import ports of the translated expression exp2 as imports. The import ports of all parallel sub-graphs are assigned the set of import values. The graph export ports are formed by concatenating the export ports of the component sub-graphs. An extension of this language will provide facilities to specify parallel systems.

5 Translation of DCBL expressions to graphs

Transfer function T maps DCBL expressions to dataflow graphs and functionality of the DCBL operator, F, map imports onto exports. The operational semantics is defined and derived by the application of F(T(exp)). This section discusses the expression specification translation to graphs and gives the informal operational semantics of the dataflow graphs.

Figure 7 **[T(funct(exp))]**



The translation of funct(exp), T(funct(exp)), is shown in Fig. 7. This shows sequentially connected dataflow sub-graphs. The translation is made by connecting the export ports of T(exp) to the import ports of T(funct). Fig. 8 shows the translation of [T(expl, exp2, ... expn)] which consists of n sub-graphs, [T(expl)], [T(exp2)], ... and [T(expn)], that can be executed in parallel. The T(let idlist = expl IN exp2) is shown in Fig. 9. Fig. 10 shows the implementation of the simplest conditional expression **IF expl THEN exp2**. Two sub-graphs are connected sequentially in this graph. Predicate expl controls the evaluation of exp2. No special gates are used in this translation. The import data value is the export of T(expl) if this data satisfies the condition expressed by **expl**; if not, the data value is simply absorbed. This expression provides the facility to evaluate n parallel conditional expressions. A simple extension of the conditional expression is the parallel execution of complementary expressions, **IF expl THEN exp2 IFNOT expl THEN exp3**. Fig. 11 shows the translation of this expression. The translation of identifier, [T(id)], gives a graph with no operators. The translation of a constant expression gives the **const** operator with import export links. A trigger-value import produces the value **const** as the export.

The iteration expression **FOR idlist = exp DO iteration** is translated as shown in Fig. 12. DCBL binds identifiers locally. In evaluating **FOR idlist = exp DO iteration,** the elements of idlist are bound to the values of exp, and iteration is terminated when the iteration results in an ordinary expression. Fig. 12.1 shows the translation of **ITERexp NOTITERexp. ITER(exp)** supports iteration if the imports satisfy the expression exp. **NOTITERexp** gives the result of the computation. The iteration body **LET idlist = exp IN iteration** is implemented in the same way as the expression **LET idlist =exp1 IN exp2** is implemented. The dataflow graph implementation of the conditional iteration body **IF exp THEN iteration** is similar to that of the conditional expression. See fig. 12.2. Both subgraphs, IF exp and IFNOTexp, provide a complete set of exports. [T(exp)] and [T(notexp)] are placed on the import paths of the iteration body sub-graphs, [T1(iteration1)] and [T1(iteration2)]. Exports of [T(exp)] or [T(notexp)] enable the evaluation of a selected iteration body.

6 Functionality

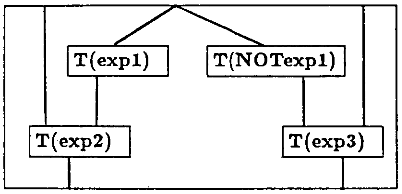
The operational semantics of DCBL expressions represent the formal simulation of dataflow graph execution. The operational semantics of the expression is the functionality of its graph. The graph is mapped onto its semantic characteristics using the functionality. The functionality of a graph is characterised by the functionality of its operators. There are two types of operators; one produces exports in the execution with the arrival of imports, and the other produces and seizes or freezes the exports, depending on the arrival of imports. In the first type, the availability of all imports enables the execution of an operator and produces exports and export via export ports to defined destinations. The destination of an export value is specified by the number of the import port of the destination operator. The export port of an operator is connected by a link to the import port of another operator; therefore, the export value of one operator is the import value to another operator. In the second type, an operator receives import values at each import port and produces or seizes export values at the export port during the execution. Producing an export value enables successive computations. These operators are used in the implementation of conditional, iterative, and recursive computations.

Figure 11 [T(IF exp1 THEN exp2 IFNOT exp1 THEN exp3)]

imports: (IM.T(exp1) + (IM.T(NOTexp1)= IM.T(exp1)) (IM.T(exp2) - (EX.T(exp1)) + (IM.T(exp3) - (EX.T(NOT(exp1))

exports: (EX.T(exp2)) = (EX.T(exp3))

links:(EX.T(exp1) —> IM.T(exp2)) + EX.T(NOTexp1) —> IM.T(exp3))



operators:

T(exp1)

imports:(IM.T(exp1) = EX.T(NOTexp1))

exports:(EX.T(exp1))

T(NOTexp1)

imports:(IM.T(NOTexp1))

exports:(EX.T(NOTexp1) = IM.T(exp1))

T(exp2)

imports:(IM.T(exp2))

exports:(EX.T(exp2)) 8

T(exp3)

imports:(IM.T(exp3))

exports:(EX.T(exp2))

The operational semantics of a dataflow operator is given by its functionality, which maps its imports onto exports. The specifications of the functionality of various dataflow operators are discussed in this section. The functionality of an operator is the usual arithmetic or boolean function associated with it. For example, F+(x,y) = x+y and Fconst(x) = const. Here, x triggers the operator, const, to give the export defined by the const operator. The functionality can be extended for an ordered set of dataflow imports. The operator, plus, can be performed to the ordered sets x.X and y.Y where x represents the first value of one ordered set, X represents the rest of that ordered set, y represents the first value of the other ordered set, and Y represents the rest of that ordered set. Hence, Fplus(x.X, y.Y) = Fplus(x,y). Fplus(X,Y)
= (x+y). Fplus(X,Y).

In executing conditional operators, the data value imported is exported when it satisfies the conditional operator; if it does not satisfy the conditional operator, no export values are produced. The pair Fcond(x) and Fnotcond(x) is the complementary set of conditional operators that can execute concurrently. Here N implies frozen or seized exports.

Fcond(x) = x if x satisfies the condition
Fcond(x) = N if x does not satisfy condition
Fnotcond(x) = x if x not satisfies the condition
Fnotcond(x) = N if x satisfies condition

Figure 12 [T(FOR id1...idn = exp DO iteration)]

imports:(IM.T(exp) + IM.T(iteration) - EX.T(exp))

exports:(EX.T(iteration))

links:(EX.T(exp) —> (IM.T(iteration))

Fgreater(y x)     = N   Fnotgreater(x y)    = N
```

7 Conclusions

Parallel processing systems give ultra-high computing speeds. The dataflow computing concept seems to be the most effective, promising computing method to implement in machine architecture for high speed computing. In this paper, n-value logic and the NOT(OPERATION) abstract computing model were introduced and their effectiveness over traditional models was discussed. In general, the NOT(OPERATION) model increases the speed of the dataflow computing by decreasing machine cycles for conditional computations, reduces the number of operations, especially double operand operations in the computation, reduces the computing and communication costs, and remove an RPG source.

All dataflow computing languages proposed so far are based on the 2-value logic. The preliminary version of the dataflow computing base language using the n-value logic based NOT(OPERATION) model, the DCBL, was introduced and defined. The BNF specifications of DCBL and a dataflow computing graph specification language were presented. The new class of operational semantics was described in detail by translating the DCBL expressions to dataflow graphs and defining the functionality of the dataflow graphs.

Evon: an Extended von Neumann Model for Parallel Processing

Wai-Mee Ching

IBM T. J. Watson Research Center
P.O. Box 218
Yorktown Heights, New York 10598

Abstract

We propose an extended von Neumann model called Evon for parallel processing. It is centrally controlled, and is capable of exploiting instruction level as well as expression level parallelism inherent in high level language programs. Its effectiveness in exploiting parallelism depends crucially on powerful primitives, and we illustrate this point by several short programming examples written in APL. We then report our work on the design of an instruction set embodying the Evon model, and a portable compiler for that instruction set aimed at extracting parallelism automatically. Finally, we compare Evon with other computational models and architectures proposed for parallel processing with pragmatic considerations and programming concerns.

1. Introduction

Different approaches to parallel processing can be discussed around several distinct axes. The first axis is whether the machine is of a special-purpose or a general purpose nature. For special-purpose parallel machines we have seen examples like the Yorktown Simulation Engine which is about 5000 times faster than what is available on sequential machines [9],[19]. For general-purpose machines, on the other hand, only moderate parallelism has been achieved in actual use such as on the Cray X-MP. In the search for general-purpose highly parallel architectures, many computational models and accompanying architectures have been proposed. This constitutes the dominant axis in the discussion of parallel processing. ' Among the contending models of computation, the following are the most actively pursued in research on parallel processing: control-driven or multiprocessing von Neumann style, data-driven or data flow, and demand- driven or reduction (see [1],[14]). Furthermore, there are also hybrid models like Rediflow [18] and Eazyflow [16]. Different computational models emphasize the exploitation of parallelism at different levels of granularity. Generally speaking, multiprocessing von Neumann architectures aim at procedure-level parallelism while data flow aims at expression-level. Among multiprocessing von Neumann models, there is the distinction of SIMD and MIMD, differences in switching network interconnection topologies and whether packet-switching or circuit switching is used.

Treleaven and Hopkins [24] pointed out that the success of the von Neumann model is related to its general-purpose nature. The flourishing of contending models for parallel processing in contrast to the limited parallelism available for general-purpose applications so far bespeaks the great difficulty in identifying a truly general-purpose model of parallel computation. We believe the success of the von Neumann model also has to do with its conceptual simplicity, and practicality in terms of hardware implementation and programmability. Thus, another important axis which is often neglected in discussing parallel processing is the set of issues involving programming and languages. Should parallelism be explicitly specified or implicitly programmed and extracted by a high-level language compiler? Should we use an established language or a brand new language for parallel processing (see [21],[20],[15]). Compilers have traditionally played second fiddle to hardware projects in parallel processing. Two exceptions are the VLIW architecture and the ELI-512 machine of Fisher [10] with a compiler doing trace scheduling, and University of Illinois's Cedar Project with Parafrase [11].

Our approach to parallel processing is also compiler-oriented. We propose an extended von Neumann model, called **Evon**, for parallel processing. Evon is centrally controlled globally but functional and data independent instructions can be executed simultaneously, similar to the ELI-512 machine of VLIW architecture which has a single instruction stream but is not a traditional SIMD machine. Like the very long instruction word in ELI-512, each instruction in Evon can potentially command a substantial amount of hardware to operate in parallel. Like in Cedar, Evon uses powerful (compound) functions to organize computations to be carried out in parallel, and also applies the principle of data flow at certain levels. As both in VLIW and Cedar, Evon is accompanied by a sophisticated compiler responsible for extracting parallelism from programs written in a high-level language, so programmers are free of the job of parallel decomposition and subtasks synchronization. Evon differs from both VLIW architecture and Cedar in the implicit assumption of the high-level language most likely, or most suitable, to be used on proposed parallel machines. Both ELI-512 and Cedar assume that programs are written in a traditional scalar von Neumann language like Fortran, while Evon assumes that programs are written in a vector von Neumann language like APL. We shall see from programming examples later that this change of language does have great significance on previous assumptions on what are the main impediments to execution in parallel of a high-level language program. Although Evon is very much like a vector

CH2345-7/86/0000/0363$01.00 © 1986 IEEE

supercomputer, it will become clear in the following sections that Evon can afford a much higher degree of parallelism than that offered by traditional vector processors.

We shall report our research work on defining an instruction-set E-code as a particular embodiment of the Evon model, and the work of a compiler (called E-compiler) which translates a substantial subset of present APL into E-code. The work on E-compiler is but a first step in our effort to achieve the goal of automatic extraction of inherent parallelism in high-level language programs. The successful completion of its first phase can provide us a valuable tool in studying inherent parallelism in various programming tasks much like Parafrase did for scientific programs written in Fortran. But we will be able to cover a wider area of applications including scientific and engineering computations, design automation algorithms and financial data processing.

2. The Evon Instructions and Instruction-level Parallelism

Like the classical von Neumann model, Evon has a central processing unit (CPU) and a linearly addressed global memory connected to the CPU by a bus of sufficient bandwidth. The memory is interleaved so as to increase its effective bandwidth. For example, if it is organized into 32 banks, then the famous von Neumann bottleneck is still there but its capacity has been increased by 32-fold. Obviously, an increase in the memory bandwidth has to be matched by an increase in the concurrency of the CPU operations to boost overall performance.

In the von Neumann model each instruction either moves one scalar datum from memory to CPU, manipulates a scalar datum in the CPU's execution unit or stores a datum in CPU to memory. In Evon each instruction can manipulate scalar as well as vector data, move a segment of vector data or a scalar datum from CPU to memory, or vice versa. Evon manipulates four primitive types of data: boolean, fixed-point number (integer), floating-point number (real) and character, both in scalar and vector. An Evon can have all the scalar instructions of some popular von Neumann machine, but most of all an Evon has vector instructions. The vector instruction-set repertoire of Evon certainly contains all those arithmetic operations found in a typical vector processor. But it must further include the following

1. calculation of all partial results of a binary arithmetic operation on a vector which corresponds to the scan operator \ in APL and includes the special case of reduction;
2. selection and expansion of vectors according to a boolean vector;
3. finding membership and indexes of a vector of elements with respect to another vector.
4. rotation and shift of vectors.
5. shuffle exchange of elements of a vector (This one has no corresponding APL primitive).

However, it shall not include functions of a special nature like matrix multiplication, inversion, or a random number generator. We also note that in the basic model the length of a vector is not restricted. But in any particular hardware realization there must be some limit mvl put on the length of a vector in cpu (we envision that 128≤mvl≤1024 for a machine not geared towards any particular scientific application). In other words, when a vector in memory is longer than the limit mvl imposed by CPU, the vector has to be wrapped around a real cpu vector register with masked tail.

In order to pursue our research in parallel processing using the Evon model and to make our case more concrete, we have designed an instruction-set, E-code, for a hypothetical simplified Evon machine. A sketch of the machine organization is given in Figure 1. The machine has four vector accumulators of a certain maximal length: BV, CV, IV, EV, one for each data type: boolean, character, integer and floating-point. The effective length of a vector residing in one of the vector accumulator is controlled by a (internal) length register BL, CL, IL, or EL according to its type. It also has several scalar registers R0-R15 and F0, F2, F4 and F6 as in System 370. E-code, like System 370, is a two-address code, i.e. one of the operands serves as the destination, which can be a scalar register, a vector accumulator, or a memory location in case of store operations. Further description of E-code is in [4]. A basic implementation of E-code on System/370 has already been accomplished. We remark that E-code is introduced here only as a convenient tool for discussing machine-code translation of some programming examples. Its underlying machine organization is not intended to represent an ideal implementation of the Evon model.

In general, an Evon CPU has three parts: (1). the I-box for instruction decoding, scheduling and issuing. (2) the M-box for memory address calculation, register file and memory accessing and data transfer. (3) the E-box for the functional execution of arithmetic and logical operations. The E-box is a collection of functional elements including operational units for +, ×, =, etc. For each arithmetic function, there are separate scalar and vector execution elements. For each vector arithmetic functional element, there are duplicate hardware execution units to carry out the actual calculation in segments of a vector. For example, there can be 32 floating-point multipliers. However, the number of duplicates can vary among functional elements. This has to do with the relative spread or the number of pipeline stages of each function's execution unit. For example, there should be more fixed-point adders than multipliers. Duplicating hardware units would overcome the limitation on effective parallelism by the pipeline stages of traditional vector processors.

It is well known that typical vector instruction can save the repeated instruction fetches and decodes in a vector loop on a conventional machine. But Evon incorporate further parallelism with the following two features which are absent in all vector machines:

First, Evon hardware supports the parallel execution of some important compound operations listed in 1) - 4) above. In particular, operand registers and the array of execution units of a functional element can be hardwired to achieve log n time for calculating all partial results of a particular binary operation on a vector. We illustrate the basic idea for a vector of 8 elements in Figure 2. Let us say the particular functional element is addition. At the first row, 8 elements v0..v7 of a vector v are sitting in 8 registers r0..r7. After first round of parallel operation by 4 adders, the even numbered registers' contents are not changed while the odd numbered registers all contain the sum of the original content and it left-neighbor. We note that a joint of two lines in Figure 2 represents the employment of an operational unit, like an adder, of a functional element. After third round of operation, the total sum is in r7. At the end of 4(=1+log8)-th round of operation, all partial sums are calculated and reside in r0-r7 (See [5] and [6] for detail). The instructions in group 4) can also be implemented by circuits doing a parallel associative search on a vector register with respect to another (However, Evon is not an associative processor because it does not employ associative memory).

Second, Evon expects each basic block of instructions (defined in the next section) to be grouped into streams by a compiler. A **v-stream** (of instructions) is an instruction sequence such that 1) all involve vectors of the same length (or all scalars) and 2) the result of one instruction is used as an operand of the next. The grouping of instructions into v-streams by a compiler represents static chaining. The chaining technique of the Cray-1 which permits successive (vector) operations to be issued as soon as the first result becomes available as an operand is well known. And we note that the chaining in Cray-1 is done at run-time while in an Evon it is going to be done at compile time. The effect of (static) chaining is that of loop fusion of the controlling micro-code. For example, the following line of code in APL

```
E←D+A←C×B
```

translated into E-code:

```
LIA Rl,100
LDI Rl,aB
MPI Rl,aC
STI Rl,aA
ADI Rl,aD
ADI Rl,aE
```

where Rl is a vector length register indicating vector length with respect to an implicit vector accumulator. The particular meaning of these instructions is not important. The point we want to make is that the last five instructions, which either move data between integer vector accumulator and memory or operate on the integer vector accumulator, can be chained together. That is, these five instructions will share the same control structure of micro-instructions. An operation on a vector element of instruction is carried out as soon as the operation of the previous instruction on that element has been completed. At the micro-code level, there is only one length checking for the five loops.

Another example for the first point above is the following: Calculate the population distribution when given B as the base population and A[0], A[1], ..., A[99] as the death rate for age 1 to 99. In PASCAL we have,

```
P[0]:= B;
FOR I=0 TO 99 DO
  P[I+1]:= P[I]*(1-A[I])
END;
```

while in APL it is

```
P←B××\1-A
```

translated to E-code:

```
LIA  Rl,100
LDE  Rl,aA
SBEM 0
ADEM 1
MPEP
MPEM aB
```

where MPEP computes all partial product of the elements in the vector and can be implemented by (n/2)-execution units with a (n/log n) speed-up. We note that this is basically the same example discussed in sec.3 of [15] in a multiprocessing von Neumann style with explicitly programmed synchronization.

Basically, there are two kind of loops (in programs written in scalar von Neumann languages): independent loops, i.e. the data of one iteration is independent of data in the previous iteration, and dependent loops, i.e. the data of one iteration is intrinsically dependent on previous iterations (this means the dependency can not be removed by renaming). The first example of chained vector instructions given above is a loop of the first kind. A vector machine can easily handle a speedup of loops of the first kind by pipelining, and machines of array architecture can also ideally handle this kind of loop. The data dependent loop presents difficulties for parallelization even if it can be recognized by a vectorizer. In general, nothing can be done to speed up such loops besides detecting certain independent portions to be executed in an overlapped fashion. The Evon approach is to use the scan operator of APL as a centerpiece to express such dependency and provide a machine primitive, i.e.instructions of class 1), which controls a large amount of hardware in parallel to carry out the execution in a theoretically optimal time. It is amazing that a large amount of seemingly intrinsically sequential code can have a speedup factor of $(n/\log n)$ where $n/2$ is the number of available execution units in the functional element. For example, the first order linear recurrence equation

```
X[0]:= X0;
FOR I=0 TO 99 DO
  X[I+1]:= X[I]*A[I]+D[I]
END;
```

can also be coded in one line of APL:

```
  Z←(RT⌽((⌽×\(0,L)↓(RT←-⍳L)⌽(SQ⍴⌽A),
(SQ←2⍴L)⍴0),(L←⍴A)⍴1))+.×X0,D
```

and benefits from the hardware supported primitives for fast execution. It is not the virtuosity of one-line coding we want to show. Rather, if a language (and machine) contains a sufficient amount of high-level primitives then we can trade storage for speed in dealing with some important classes of data dependent loops. One line APL code is functional programming, i.e. there is no change of state in the computation. The high-level primitives absorb the control structures originally in the corresponding PASCAL version, and turn the data dependent loop into an expression tree. Besides parallelism exploited in executing each node which roughly corresponds to an Evon instruction, many parts of the tree can be executed in parallel as we shall show in the next section.

From the perspective of scalar von Neumann languages, very little parallelism can be gained from instruction-level parallelism. But in the extended von Neumann model Evon where many hardware supported high-level primitives are available, the situation becomes quite different. We can profitably utilize instruction-level parallelism to speedup computation considerably.

3. Basic Block Scheduling and Local Data Flow

Compiled programs are executed on Evon one (maximal) basic block at a time. A (maximal) basic block is a (maximal) group of instructions without a branch instruction except the last one and without a branch into it except to the first one. We shall simple use 'basic block' to mean 'maximal basic block'. If we adopt an APL-like high-level language as a source language, then a basic block consists of a string of expression trees (each tree corresponds to a line of source code) produced by the parser of a compiler. Each of these expression trees can be executed in parallel within the constrains of data dependency and the availability of hardware execution units. Furthermore, the expression trees in a basic block need not be executed in the sequential order of their corresponding source code lines. In other words, Evon is globally centrally controlled in that it executes one basic block of code at a time according to a program flow graph, but locally executes its block of code according to the data flow principle.

Before we discuss the instruction scheduling scheme, let us describe Evon's instruction processing unit, the **I-box**, in general terms. The I-box has an instruction buffer which is large enough to hold all machine instructions in a basic block of average size. The front-end of the I-box is the instruction decoding unit which can decode several instructions simultaneously. For sake of concreteness, we can assume that each instruction is 32 bits wide, and 4 to 8 instructions can be decoded at the same time. This aspect of Evon is very similar to ELI-512's having very long instruction words. The instruction decoding unit has its own adders to calculate addresses. There is a functional elements' usage register, called f-register, to indicate at any machine cycle which function execution elements are idle and which are executing. The back-end of the I-box is a group of independent instruction-stacks. We can assume that there are anywhere from 3 to 8 instruction stacks in a Evon. The top of each stack holds an instruction ready to be issued for execution as soon as a hardware functional unit is available.

We have already introduced the concept of v-streams (of instructions) in the previous section. An expression tree can be decomposed into groups of v-streams of instructions. However, the compiler first calculates internal data dependency, i.e. the dependency created between instructions assigning variables in the basic block of our concern and instructions using these variables as operands. The reason we ignore data inter-block data dependency is simple: compiled programs execute one basic block at a time on Evon. When the code block of a basic block is loaded into the instruction buffer, all instances of exposed-used variables, i.e. variables assumed to be assigned outside of the basic block, should already have correct values. V-streams are then broken into pieces, called **i-sequences** (of instructions) so that only the head instruction of an i-sequence is possibly data dependent on any other instruction in the same basic block.

The basic instruction scheduling scheme for a basic block of code can now be described: Independent i-sequences of instructions in a basic block are decoded and loaded into separate instruction stacks waiting to be executed. In the beginning of the execution a group of i-sequences chosen at compile-time, whose first instructions are all independent of intra-block data and execute on disjoint functional elements, are loaded on instruction stacks and simultaneous execution of i-sequences starts. If there is competition, due to the limited number of instruction stacks and functional elements, between i-sequences of instructions to be in that first group the compiler chooses one by one according to who has the most number of i-sequences data dependent on it. Each instruction will set the occupied bit of the functional element it is going to use and each assignment instructions will set the enable bit on all instructions depending on the variable getting written into that instructions. Decoded and enabled instructions then check the f-register to see if the required functional element(s) is free. If it is, the instruction on the top of an instruction stack is issued for execution. In case of a vector i-sequence, if not all functional elements can be secured at one time, the machine breaks the stream of instructions. That is, an Evon machine would not insist on executing vector loops in a fused fashion. It can execute the loops separately to utilize available functional units. Hence it is very likely that an adder and a multiplier, or a scalar multiplier and a vector one, operate concurrently in executing a compiled program. We note that this type of functional parallelism is available on the CDC Cyber series and on the CRAY-1 where this is carried out by a scoreboard involving registers as well as functional units. Hence the run-time checking in these traditional vector machines for overlapping execution is considerably more elaborate than in Evon.

We shall briefly illustrate the scheduling and intra-block multi-functional parallelism based on compile-time dependency calculation by the following example: Find all the prime number from 2 to N. Unlike in FORTRAN or PASCAL where loops are most likely to be used, we have

```
∇Z←PRIME N;V
[1] Z←2,(~V∊(2↓~⌊N*.5)∘.×2↓⍳⌈N÷3)/
    V←1+2⍳⌊←(N-1)÷2
∇
```

and its parse tree is shown in Figure 3. Basically, it sets up a multiplication table and has the vector of odd numbers up to N be checked against that table. The ones not in the table are prime numbers. The instruction stream corresponding to the right corner subtree calculating V is mutually independent with respect to the instruction stream corresponding to the subtree (2↓..)∘.×2↓..3 rooted at the outer product node which set up a multiplication table. In short, the two subtrees delineated by the two dotted semi-circles in Figure 3 are data independent. They are the main parts of the computation and can be executed in separate hardware components if such components are available. This example shows that Evon can successfully support implicit parallelism at the expression level.

We remark that there are some broad similarities between our approach to the exploitation of expression-level parallelism and that of the expression processor [23], the block-driven data-flow processor [3] and the works on parallel execution of sequential programs [20], [21] and [24]. Our scheduling is much more specific and quite different in detail from that discussed in [3]. In [23], the execution is ultimately carried out in a tree complex of processing elements, each of which has instruction decoding capability. Our functional elements only have the capability to execute specific functions. Most works on the parallel execution of sequential programs assume that the program is already serialized which we do not assume. And we restrict our attention to a basic block. Our v-streams and i-sequences bear resemblance to the parallel execution strings of [24]. But they differ in many aspects. In particular, each instruction is not assumed to take an equal amount of time here, and we have taken the limitation of hardware execution units into consideration.

Both Evon and typical vector machines are aiming at fast execution of vector instructions. But the Evon comes with duplicate hardware execution units, not just the pipelining of one functional unit for each operation, to speedup execution on multiple data, and supports some compound operations like scan as a primitive whereas most vector machines only support reduction at most. More importantly, the Evon model relies on compile-time detection of data dependency among instructions in a basic block and appropriate hardware support to systematically achieve any possible parallelism at expression level which traditional vector machines can hardly handle.

4. Languages and Compilers

Most research in parallel processing of multiprocessing von Neumann style implicitly assumes that the source language is a scalar von Neumann language like FORTRAN or PASCAL. While data flow or reduction architectures usually explicitly require a new data flow language like VAL or Id, or a functional programming language of Backus style. We can also design a new language without blemish for parallel processing but with all desirable features. The problem with a new language is that there usually will be a scarcity of written real-life programs for experimentation (on the effectiveness of any parallel processing model). We can also use some old language like FORTRAN and then develop a sophisticated vectorizer like Parafrase to extract vector operations and piece together compound functions for Evon. This is beyond the scope of the present project. Fortunately, a well established language naturally suited for our purpose is readily available, namely APL. This will save us the demanding job of vectorization because programs in APL are not serialized as in FORTRAN. In fact, programming style in APL emphasizes the importance to turn a problem solution in a vector form whenever possible. Even though APL's usage is not as extensive as that of FORTRAN in scientific and engineering fields, it has been used for long time in wide range of applications: scientific and engineering computations, design automation algorithms and financial calculations. It is very important to have a variety of real-life programs for experimentation in research on parallel processing models for general purpose applications. The fact we choose APL as a source language for experimentation should not confuse our effort with what people usually call an APL machine. As APL's implementation at least so far is by interpreters, a so called APL-machine is mostly aimed at fast interpretation, i.e. it typically has an interpreter as its model of execution. This also includes fast recognition of syntactic units from source code which is a totally irrelevant issue and a waste of time for us. Past efforts in this direction include work on microprogramming a model of 360 to aid interpretation (see [11]).

The problem with using APL is that a compiler is not yet generally available. This hinders our research since we have no compiled code to study, to rearrange and to use for scheduling experiments. Hence our effort after designing E-code is to implement a compiler for a subset of APL to E-code. The subset excludes features which make APL not compilable. It covers about 95% of the language features of APL so most APL programs in scientific and engineering applications can be compiled without any change. In particular, it does not require declaration of variables and their types. Such an extra requirement would defeat our intention to have a ready set of programs for experimentation. The front end of the compiler is basically complete [4]. It contains a component to analyze type and shape (dimensions) of variables based on local type-shape inference and global data flow analysis. Local data dependency calculation can be easily inserted in to the part implemented. We can also add a component to group i-streams and cut them into i-sequences. A major portion of the compiler back end has also been implemented. In fact, we can already compile some simple functions and (together with the 370 E-code simulator mentioned above) run compiled code on System 370. However, due to the extremely large number of primitive functions in APL (66), not all code-generation functions (for corresponding APL primitive functions) have been implemented as of this writing.

A preliminary result of our compiler effort is the confirmation that APL programs do indeed have large basic blocks. The front end of our compiler has successfully processed three APL programs: i) a workspace called SIMPLE which is for impact printer simulation and involves finite element differential equation calculations, ii) a workspace called CUT which is for PLA minimization (in the area of design automation) and involves a large amount of boolean calculations and topological algorithms and iii) part of a workspace called GRAFSTAT which is for statistical analysis and graph drawing (the part not processed by the compiler has to do with so called auxiliary processors in the APL system controlling graphic terminals). We have the following table

Program	Fns	Lines	Blocks	Nodes	Node/Block
CUT	4	241(104-17)	57(22-2)	2014	35.33
SIMPLE	9	64(19-1)	18(5-1)	629	34.94
GRAFSTAT	22	488(71-1)	188(28-1)	6136	32.63

indicating the number of functions in the program, total number of source code lines excluding comments with the maximum and minimum number of lines of functions in brackets and similarly with blocks, the total number of parsing nodes and the average nodes per basic block. We note that the Node/Block number for a typical FORTRAN program is likely to be about 10. Also we note that in APL, operations are more likely to be coalesced, so it actually would use less nodes for the same computation than FORTRAN. Note that the average number of the large blocks, namely those likely to dominate computation time, is likely to be at least twice at large as the over all average. The large size of a basic block is important because it means rich opportunities to apply the local data flow principle to schedule instructions in parallel.

Finally, we remark that these three programs are all used without a corresponding FORTRAN or PASCAL version. That means that there must be sufficient vector operations using APL primitives to compensate for the ineffiency of an APL interpreter so that overall computation times become tolerable in comparison with possible FORTRAN versions. This indicates good opportunities for the instruction level parallelism in these programs. We hope to process and study more existing programs from more areas of applications. We also intend to write new APL programs for some computation intensive jobs for which only FORTRAN versions exist at present.

5. Comparison with Other Parallel Architectures

The multiprocessing von Neumann model and the data flow model are two of the most actively pursued directions in parallel processing research. There are critiques of each model offered by proponents of the other (see [2] and the article 'A Second Opinion on Data Flow Machines and Languages' by Gajski, Padua, Kuck and Kuhn in [1]) . We shall compare the Evon model with both the multiprocessing von Neumann model and the data flow model, and also with the VLIW architecture of Fisher. (We shall ignore the systolic array approach here because we feel that it is more towards the special purpose end of the spectrum of parallel processing.) It is not that we are necessary critical of the ambitious attempts of the two prevalent approaches or the innovation in VLIW. Rather, we simply argue that Evon is a pragmatic approach to parallel processing for general purpose applications, and a new direction worth pursuing.

Both Evon and the data flow model attempt to find parallelism at the expression level, or parallelism of fine granularity. In both cases parallelism is implicit, not explicitly programmed. The basic idea of data flow computation is to have an instruction executed as soon as its arguments are available, giving a high degree of parallelism. This does away the program counter of the von Neumann model to break the so called 'von Neumann bottleneck'. However, instructions may waste time waiting for unneeded arguments. Data values pass through data flow graph as tokens and an operation is triggered whenever all input tokens are available. Since side-effects are disallowed by using single-assignment data flow languages, any two enabled operations can be executed in either order or concurrently. For data dependent loop iteration, there is nothing to stop further iteration from proceeding, even though one is not yet completed. This causes tokens to accumulate on certain arcs of the data flow graph, hence the need to mark tokens for different rounds of computation. Complicated internal control schemes have been developed in attempts to solve this problem. The difficulty in managing input-output token queues is largely due to an abstraction at too low a level; in other words, the granularity of parallelism is too small.

In contrast, Evon explicitly employs vector operations and supports some important high-level primitives to deal with vector loops and frequently occurring data dependent loops. The overall control is centralized but computations in a basic block are distributed while the control of subtasks is diffused. In other words, by first organizing computations into some pre-specified computation chunks which absorb frequently used microprogram controls and then limiting the application of data flow principles to a basic block we greatly simplify the control structure of our computational model and make its machine realization more practical.

We can look at the multiprocessing von Neumann model as a horizontal extension of the classical von Neumann model, while Evon is a vertical extension. Strictly speaking, Evon is neither SIMD nor MIMD, but conceptually it is more like a SIMD machine. In a SIMD machine, each processing element has instruction decoding capability as instructions are broadcast to them. In Evon the functional execution elements can only execute specific operations. Centralized instruction decoding and scheduling saves hardware circuits. Even in a MIMD multiprocessing von Neumann machine, functional parallelism in terms of operating an adder and a multiplier of one processing element concurrently is almost impossible. Hence from a hardware utilization point of view, Evon is more efficient. On the other hand, the processor array configuration of multiprocessing von Neumann model has two advantages. First, as microprocessors are now widely available, aside from the complication of an interconnection network, an assemblage of processors can readily be made. Second, such a scheme is scalable, i.e. we can talk of thousands of (identical) processors connected together with potential speedup in the thousands. In Evon, if on the average we can have 1.5 of the 4 functional elements busy (for example, if floating-point adds and multiplications balance to within 50 percent), then 64 execution units in each functional elements will give us a speedup of approximately 100. Naturally, pipelining techniques can further increase the speedup rate, but this is not unique to Evon.

In a multiprocessing von Neumann model, the programmer needs to explicitly manage synchronization unless a very sophisticated compiler like Parafrase is employed to automatically transform sequential codes into parallel forms. In Evon, the programmer is freed from the concern of synchronization as this is done by the compiler during dependency calculation and partly managed by the instruction scheduling hardware.

In theory a MIMD machine like the NYU Ultracomputer, which has a very ingenious synchronization primitive, can also exploit expression level parallelism. As Gottlieb and Schwartz pointed out in 'Networks and Algorithms for Very-Large-Scale Parallel Computation' in [1 2] the Ultracomputer is fully capable of simulating a data flow machine. In reality, to explicitly program synchronization to systematically exploit parallelism at the expression level in the manner of the data flow model would be a formidable job. Also, network traffic for such fine grain parallelism on a MIMD machine is likely to be congested. Hence, a multiprocessing von Neumann MIMD machine is best suited to exploit parallelism at the procedure or task level. This requires a certain amount of job regularity, and the programmer has to decompose a programming job for parallel execution. On the other hand Evon offers ease of programming and requires less regularity within its jobs. For jobs with regularity, like physical simulation on lattice points, we can most likely turn them into vector forms to be efficiently processed by Evon. However, on those jobs an Ultracomputer-like MIMD machine can deliver much higher speedup than Evon. In a sense, Evon trades high potential parallel speedup with that of general applicability.

The VLIW architecture also requires less regularity of its jobs than do typical multiprocessing von Neumann machines. The reason the sophisticated trace-scheduling techniques has been developed for the VLIW architecture is the underlying assumption that basic blocks on a typical scientific or engineering program are quite small. We have seen that this assumption need not be true if we use a vector von Neumann language with enough high-level primitives as a source language. Indeed, many instances where the trace-scheduling techniques can successfully predict the direction of branches in the VLIW approach are the vector loops. The Evon model can apply to a much wider range of application areas for parallel processing, because when programs are written in a vector von Neumann language with sufficient high level primitives, the compiler can do a more effective job of parallelization.

6. Conclusion

We have presented the Evon model for parallel processing. It is a multifunction machine organization with global central control and local distributed computations. It executes vector instructions very efficiently and has hardware supported compound primitives to speedup some typical data dependent loops. The parallelism comes not only from parallel execution on vector instructions but also from the simultaneous execution of different hardware functional units on independent data. Parallelism is not explicitly programmed, but rather automatically extracted by a compiler from what is inherent in a high level language program. We report our research on defining an instruction set and implementation of a compiler. We believe that for many scientific, engineering as well as commercial applications, vector loop operations are most likely to dominate a large portion of computation time. If we can find an efficient and cost-effective solution to that particular form of computation, we would have made a great progress toward a practical exploitation of parallelism in computations.

We compare the Evon model with other models of parallel processing, and we see some advantages of our approach. But different models designed to exploit different levels of parallelism can be complementary to each other. We need more experimentation with existing programs as well as rewriting existing programs in languages of different style in research on parallel processing to better understand the effectiveness of various approaches.

OPTIMAL CODE GENERATION FOR EXPRESSIONS ON SUPER SCALAR MACHINES

Pradip Bose

Abstract

The problem of generating optimal code to evaluate expression trees under varied assumptions of the underlying execution model is considered. A RISC-style load/store instruction set architecture is assumed throughout. Initially, a simple non-pipelined, serial execution model, with N registers is considered. The machine model is then modified to allow pipelined execution of a single instruction stream. Finally, a decoupled access/execute (DAE) model is considered, in which each (decoupled) unit is pipelined. Concepts of optimum register allocation and code scheduling are combined into a single, efficient, tree-walk algorithm.

I. INTRODUCTION

Sethi et al [1] and Aho et al [2] consider the problem of minimizing the number of instructions and/or the number of storage references in the evaluation of an expression, given a fixed number of registers. The implicit model of the underlying execution process in such a study, is that of a strictly sequential, non-pipelined machine with infinite memory (see Figure 1). In [1], a specific architecture (instruction set) is assumed, whereas the results in [2] are applicable to a wider range of architectures; nonetheless, the underlying execution model in each case is as depicted in Figure 1. Under this assumption, code length is a valid metric for judging the optimality of a given code generation algorithm; in this sense, the algorithms presented in [1,2] do generate "optimal" code.

In this paper, we consider the task of speeding up execution of expression trees by progressively complicating the execution model without changing the basic idea of single instruction stream flow (fetch) from memory. Pipelined execution [10] is one of the principal features of modern day supercomputing. In addition, various forms of overlapped/decoupled processing combined with pipelining [3,4,6,7] have been used and/or suggested in order to enhance performance. These approaches, in effect, incorporate more and more parallel/pipelined execution modes, without diverging from the basic philosophy of "single instruction counter" processing. Our intent in this paper is to generalize the classical results of [1,2] by considering models of execution used in single instruction counter super scalar machines. In [11], we presented a brief outline of the basic structure of algorithms implemented by us, with such target machines in mind. In this paper, we present detailed algorithms, along with formal justifications of our claims and results.

Two distinct (albeit related) issues in code generation are register allocation and instruction (code) scheduling. Efficient register allocation is necessary to minimize so-called "spill-code" [12], which has the desired effect of reducing execution time, since certain unnecessary references to data memory are eliminated. Instruction scheduling as a code-generation-time optimization is also known to be beneficial [13] and has been implemented in some compilers, such as the IBM PL.8 compiler [14]. The results presented in this paper effectively illustrate that at least for straight-line tree code (i.e., no common sub-expressions, single root or result node) optimum register allocation and code scheduling can be achieved via a single tree-walk code generation algorithm.

An important parameter in generating efficient code is of course the set of commands (or instruction set) available to the compiler writer. Since our ultimate objective is to study the optimal compilation problem for decoupled access/execute (DAE) type organizations [3, 4], our assumed kernel instruction set is a basic, load/store or RISC (Reduced Instruction Set Computer) architecture, in which all arithmetic operations are performed in register-to-register (RR) style only. The only instructions which involve data transfers to and from memory, are the LOAD and STORE instructions. Thus, access/execute decoupling is reflected naturally in the instruction set architecture. Decoupling considerations aside, there are other basic justifications for RISC architectures which have been pointed out by proponents of this concept of "simple" instruction sets; -- the concept and its benefits, for both compilers and hardware implementations, are presented in [15,16].

Another important parameter in enhancement of supercomputer performance is the "instruction issue logic." By adopting more and more sophisticated issue mechanisms, out of order executions may be initiated to ease bottlenecks and hence improve performance [5,6]. Such sophistication in the instruction issue logic can be seen to ease the burden on the compiler writer, since sophisticated code scheduling algorithms are rendered almost unnecessary. Since this paper is mainly geared toward the compiler aspect of performance enhancement, sophistication in the instruction issue logic will not be considered; in other words, a simple, serial instruction fetch and issue mechansim is assumed throughout.

Note that, this paper deals only with execution of expression trees; detailed consideration of the general problem of executing loops of basic blocks (dags) is beyond the scope of this paper. Our attempt here is to describe a natural generalization of the classical results in [1], under super scalar models of execution.

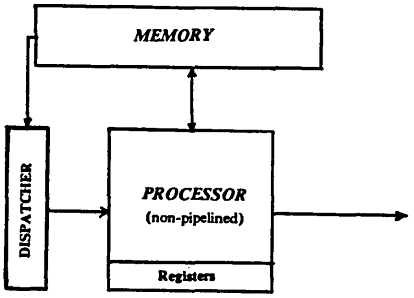

Figure 1. Machine Model A.

II. INITIAL ASSUMPTIONS

We state below, the initial set of assumptions regarding the structure of expressions, and the basic architecture and organization of our machines.

Expressions

As in [1], we assume that there are no nontrivial relations between operators and elements. For example, we assume that all data elements are distinct, and that laws such as $a*b + a*c = a*(b + c)$ are not applicable. All operations are binary; all operations are taken to be noncommutative. Thus, effectively, no restructuring of the expression tree is allowed.

Architecture

The commands permitted are of the following kinds:

1. C(mem) --> C(reg); i.e., LOAD reg, mem-addr.
2. C(reg) --> C(mem); i.e., STORE reg, mem-addr.
3. OP[C(reg1),C(reg2)] --> C(reg3); i.e., OP reg3, reg1, reg2.

Note that the exact address computation mechanism is left unspecified; it is not of concern to us in this paper. We assume a fixed number of cycles needed to decode, generate effective address and send request to memory, and receive data back from memory. Implicit in this is the possible use of a separate set of (index) registers for address computation. We are not concerned here with the number or availability of such registers: for all practical purposes we assume unlimited resources (and hence no conflicts) in that regard. We are concerned here with doing the required arithmetic computation, as fast as possible, given a fixed number of (arithmetic) registers, N.

Memory and Instruction Fetch/Dispatch

We effectively assume unlimited (infinite) storage for both instructions and data. We assume that instruction prefetch mechanisms are available, so that instruction(s) are ready for dispatch on demand. (Note, once again, that we are not dealing with branches, merely straight-line code resulting from expressions). When decoupled organizations are considered, we assume split (infinite) I-cache and D-cache, so that conflicts resulting from trying to access memory at the same time, are absent.

Hardware, Organization and Timing

With pipelined execution, a LOAD or STORE (access) instruction is assumed to take A (≥ 1) cycles (stages) to complete. Each arithmetic (execute) instruction is assumed to take E (≥ 1) cycles (stages) to complete.

The register file is assumed to have two i/o ports; a data "read" (for a computation) and a data "write" (from the putaway bus) can be initiated in the same cycle. (Where the same register is involved in the read and write, a read-before-write interlock mechanism is assumed). The register load/store mechanism uses a separate bus. Attempting to write into the same register from the two buses at the same cycle is not possible in any of our schemes; i.e., the situation does not arise.

No buffers are assumed in front of the decode unit(s); instruction dispatch is just assumed to block (to a given unit) once an instruction is blocked in the decode stage due to an interlock.

III. CODE GENERATION ALGORITHMS

In this section, we present specific algorithms to generate time-optimal code (under the assumptions made) for various models of execution. First, we state the modified tree labeling algorithm [1] needed for our load/store architecture.

The Tree Labeling Algorithm

Each node of the expression tree is labeled with a number that turns out to be the minimum number of registers needed to evaluate the node without stores. To each node n is assigned a label L(n), from the bottom up.

1. If n is a leaf then $L(n) = 1$.

2. If n has descendants with labels l_1 and l_2, then for $l_1 \neq l_2$, $L(n) = \max(l_1, l_2)$, and for $l_1 = l_2$, $L(n) = l_1 + 1$.

The first model we consider is that of a serial, non-pipelined machine: this is just for the sake of completeness and eventual comparison with the pipelined machine models.

A. Serial, Non-Pipelined, Single Dispatch Execution

Figure 1 shows the assumed model of computation, where the dispatcher (I-unit) issues a single instruction to the E-unit as soon as the E-unit finsishes a given computation fully. In this case, of course, minimizing the total number of LOADs and STOREs results in a time-optimal code sequence. It is easily seen that Algorithm 1 of [1], suitably modified by the constraint of our load/store architecture, can be used to generate the optimal code in this case. We call this Algorithm A.

ALGORITHM A

After generating the expression tree and labeling the nodes:
(1) Apply (2) to the root with registers $R_1, R_2, ..., R_N$ available. Routine (2) will evaluate the expression represented by the subtree extending from the node to which it is applied. The result will appear in the lowest numbered register available.

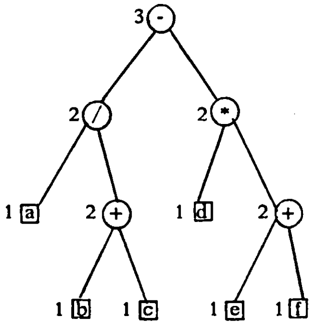
(2) Let n be a node, $L(n) = l$. Suppose, $R_m, R_{m+1}, ..., R_N$ are available, $1 \leq m \leq N$.

Case 1: $l = 1$.
(A) n must be a leaf. Enter (LOAD) the value of n, which is an input datum, into R_m.

Case 2: $l > 1$; let the descendants of n have labels l_1 and l_2.
(B) If $l_1, l_2 \geq N$, apply (2) to the right descendant with registers R_m, $R_{m+1}, ..., R_N$ available. STORE the value of the right descendant into a temporary memory location T. Apply (2) to the left descendant with registers $R_m, R_{m+1}, ..., R_N$ available, leaving the result in R_m. LOAD the value of the right descendant from T into R_{m+1}. Evaluate n using the values in R_m and R_{m+1} leaving the result in R_m.
(C) If $l_1 = l_2$, and at least one of l_1, l_2 is less than N, apply (2) to the descendant with the higher label with registers $R_m, R_{m+1}, ..., R_N$ available. Leave the result in R_m. Apply (2) to the other descendant, with registers, $R_{m+1}, R_{m+2}, ..., R_N$ available. The result will appear in R_{m+1}. Evaluate n using the values in R_m and R_{m+1} and leave the result in R_m.
(D) If $l_1 = l_2 < N$, treat the right descendant as the node with the higher label and proceed as above.

Example 1, taken from [1]:

Consider the expression a/(b+c) - d*(e+f), whose tree is:



The integers at each node are the labels assigned by the labeling algorithm. Algorithm A produces the following code for N = 2:

1. LOAD R_1, addr(f)
2. LOAD R_2, addr(e)
3. ADD R_1, R_2, R_1
4. LOAD R_2, addr(d)
5. MPY R_1, R_2, R_1
6. STORE R_1, addr(T)
7. LOAD R_1, addr(c)
8. LOAD R_2, addr(b)
9. ADD R_1, R_2, R_1
10. LOAD R_2, addr(a)
11. DVD R_1, R_2, R_1
12. LOAD R_2, addr(T)
13. SUB R_1, R_1, R_2

The proof that Algorithm A produces optimal code for the execution model under consideration and the stated assumptions, is along the lines stated in [1] and is being omitted in this paper; a couple of relevant lemmas and a theorem are stated here for completeness.

Lemma 1: Algorithm A evaluates a tree with no STORES when at least as many registers as the label of the root are available.

■

Lemma 2: The label of a node is a lower bound on the minimum number of registers required to evaluate the node without any stores. (Lemma 1 is a special case of Lemma 2, where the node being considered is the root node).

■

Theorem 1: Algorithm A produces an optimal code sequence for the stated machine model and assumptions.

■

B. Serial, Pipelined, Single Dispatch Execution

Figure 2 shows the new machine model under consideration. The dispatcher dispatches a single instruction to the decode unit on a given cycle, if it is free to do so, i.e., if the decoder is not blocked. Assumptions regarding hardware, organization and timing are as stated in section II.

Interlock Mechanism

A hardware interlock mechanism is assumed to ensure that (1) a LOAD is not decoded until the previous data in the register has been used; (2) an arithmetic instruction is not decoded until its source registers have been written with the right data and until the previous data in the target register has been used (or stored); (3) a STORE is not decoded before data in the register is ready. Essentially, we assume the existence of two 'interlock bits' or flags (READY and BUSY) associated with each register. The bits are all OFF initially. The BUSY bit of register R_i is turned ON either when a LOAD R_i or STORE R_i instruction is initiated (i.e., is dispatched to the decode unit), or when an arithmetic instruction in which R_i is an operand, is initiated. When an arithmetic instruction completes, all associated interlock bits of the source registers are turned OFF; the target register READY bit is turned ON and its BUSY bit is turned OFF. When a STORE completes, the BUSY bit of the STOREd register is turned OFF. The STORE is decoded if and only if the register to be STOREd is READY and NOT BUSY. When a LOAD completes, the BUSY bit of the LOADed register is turned OFF and its READY bit is turned ON. The LOAD is decoded if and only if the register to be LOADed is NOT BUSY. An arithmetic instruction is allowed to decode if and only if the two source registers are READY and the target register is NOT BUSY. It is not necessary to assume that the dispatcher has access to the interlock information per se; rather, it may be assumed that the dispatcher blocks only if the decode unit of the processor blocks, in a given cycle.

Under these assumptions of hardware and architectural support, the code sequence generated for Example 1 by Algorithm A (N = 2) can be shown to execute in 30 cycles on Model B (with A = 3, E = 2). By contrast, for the serial, nonpipelined case, the time to execute would have been 34 cycles, assuming the timings to be identical, i.e. a LOAD or STORE takes 3 cycles and an arithmetic instruction takes 2 cycles to execute.

If the number of registers, N is just 2 then it can be shown that we cannot decrease total execution time in this case, under the simple issue and decode mechanisms adopted. However, if N ≥ 3, (i.e. greater than or equal to the label of the root), then one can obtain optimal performance, by using the following algorithm.

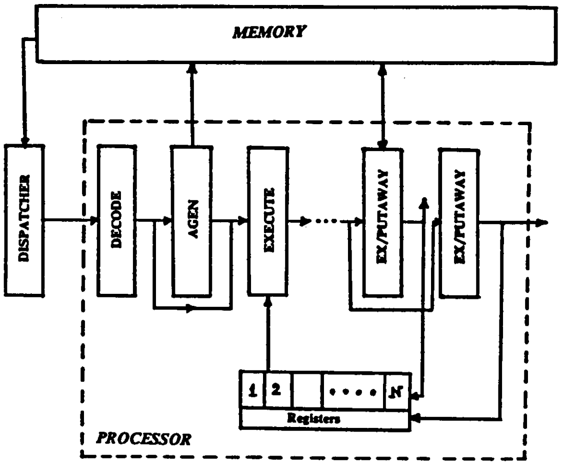


Figure 2. Machine Model B.

ALGORITHM B

Like Algorithm A, Algorithm B walks through the expression tree in emitting code; however, unlike Algorithm A, the number of visits per node is not a constant number. Also, in general, the overall tree traversal pattern can be quite complicated, depending on the tree structure and the pipeline parameters A and E. Nevertheless, the worst case complexity of the algorithm is still linear in the number of tree nodes (see section IV). For simplicity, we state this algorithm for the case: $N \geq L(\text{root})$, where N = number of registers and the labels L are generated by the basic tree labeling algorithm, as before. In other words, this algorithm generates (time) optimal code (without stores) for the machine model described (Model B, Figure 2).

Node attributes:

For a given node n of the tree, its ancestor node is denoted as father(n), its left descendant node as left-son(n) and its right descendant node as right-son(n). All non-leaf nodes of the tree are called op-nodes. Associated with each tree node is a set of attributes, which in a sense defines the "state" of the node at any given point durirg code generation. Following is the set of node attributes:
(a) n: integer; $1 \leq n \leq$ number of nodes; (* node number *)
(b) node-type: (leaf, op); (* node descriptor *)
(c) L: integer; $L \geq 1$; (* static label *)
(d) T_1, T_2: integers; $T_1 \geq 0$, $T_2 \geq 0$; (* dynamic attributes *)
(e) OP: ('ADD', 'SUB', 'MPY', 'DVD'); (* operation identifier *)
(f) ID: ('a', 'b', ..., 'z'); (* operand identifier *)
(g) l-enabled, r-enabled, ls-enabled, rs-enabled, l-visited, r-visited: boolean; (* dynamic attributes *)
(h) l-reg, r-reg: integer; (* source operand reg numbers *)
(i) t-reg: integer; (* target reg number *)

In addition, each node is understood to have upto three defined (static) pointer attributes: uptr, lptr and rptr, linking it to its ancestor, left descendant and right descendant respectively.

The static labels (L) are obtained by applying the basic tree labeling algorithm as before; in principle, these could be attached to tree nodes during actual parsing (i.e., tree-building). Similarly, the other static attributes [(a), (e), (f), along with "uptr", "lptr" and "rptr" (see above)], are all fixed during tree initialization. The attributes T_1 and T_2 may be looked upon as "time-to-fire" labels; i.e., $T_1(n)$ specifies the additional number of time units (after the last initiated instruction) one must wait before the left operand is available in a register; $T_2(n)$ specifies the same thing, but for the right operand. Thus, $T(n) = \max(T_1(n), T_2(n))$ specifies the waiting period (in machine cycles) for this op-node (instruction) to be decoded, counting from the last initiated instruction. Initially, these values are all set to ∞, for each node n.

An op-node is said to be "enabled" if LOAD/OP instructions for both its son nodes have already been generated. Initially, therefore, all the op-nodes are disabled. An op-node is said to be r- (l-) enabled if the LOAD/OP instruction for its right (left) son node has been generated. The boolean attributes l-enabled and r-enabled are used to record the above conditions. The attributes ls-enabled and rs-enabled are defined as follows: ls-enabled(n) = l-enabled (left-son(n)) and r-enabled (left-son(n)); rs-enabled (n) = l-enabled (right-son(n)) and r-enabled (right-son(n)). The attribute l-visited (r-visited) is set to "true" if the left (right) son of this node has been visited most recently. Initially, both flags are false; both these flags cannot be "true" at the same time.

Global data structures:

The registers (numbered 1 through N) are initially organized as a "free queue", called f-queue. This can be imagined to be a simple FIFO queue, for example. Each entry of this queue has two fields: (a) the actual register number, i (ϵ [1, 2, ..., N]); and, (b) a dynamic attribute t(i), associated with the register i. The t value may be looked upon as a "time-to-free" attribute, which specifies the additional number of (machine) cycles, after the last initiated instruction, one must wait before an instruction using that register as an operand can be allowed to decode. Initially, the "t field" of each entry in the free queue is set to 0. Any time a register is needed to emit a LOAD instruction, it is taken from the head of the queue; when a register is freed (after a STORE or arithmetic instruction), it is put back at the tail of the queue. The variable "f-reg" always refers to the register at the head of the free queue; f-reg = 0 signifies that the free queue is empty. Initially, f-reg = 1 and size (f-queue) = N.

Also, an "enabled queue", called e-queue, is maintained: this is a FIFO queue of pointers to enabled op-nodes at any given point of the algorithm. Initially, this queue is empty, of course. During the (algorithmic) step that a node becomes enabled, it is entered at the tail of e-queue in case it is not scheduled immediately. During the step in which an op-node (arithmetic instruction) is scheduled (emitted) by the algorithm, the corresponding entry at the head of e-queue is removed. Each valid entry of e-queue consists of two fields: (a) the (static) node number (n) of the enabled node; and (b) T(n), a dynamic attribute, signifying the "wait period", in machine cycles, (counting from the cycle of last initiation), before this node can be decoded. When a node n is first entered into e-queue, the value of T(n) is set to $\max(T_1(n), T_2(n))$. The variable "e-ptr", when defined, is the node pointer at the head of e-queue; i.e., the node pointed to by e-ptr, called "e-ptr@", is always the enabled node with the minimum T value; (e-ptr = nil <==> e-queue is empty).

In addition, a "partially enabled queue", called pe-queue is maintained. This is similar to e-queue, except that it carries information about partially enabled nodes, i.e., those which are l-enabled or r-enabled, but not enabled. Once again, nodes are entered into this queue, only if necessary, (i.e., if m becomes 0), in the order in which they become (partially) enabled. The timing field T of each entry in this case is $T_1(n)$, if the node n under consideration is l-enabled, and $T_2(n)$ if n is r-enabled. At a given step, a partially enabled node is entered into pe-queue if and only if: (a) its disabled son is a leaf node, and (b) the number of available registers at that step is 0. An entry is removed from the head of pe-queue when the next LOAD has to be scheduled. The variable "pe-ptr", when defined, is the node pointer at the head of pe-queue; i.e.,'the node pointed to by pe-ptr, called pe-ptr@, is the current candidate op-node whose disabled leaf node must be LOADed.

The queues f-queue, e-queue, pe-queue, the associated variables f-reg, e-ptr, pe-ptr and the dynamic time attributes T, T_1, T_2, and t are basically managed and manipulated (updated) by the code emission routines "gen-load" and "gen-op". These routines, it should be noted, make use of the pipeline parameters A and E (see section II) in setting and updating the above attributes (see below). The variables enabled-node-count and leaf-node-count keep track of the number of enabled nodes and the number of remaining leaf nodes of the tree respectively. The variable m records the current number of available (free) registers, where $0 \leq m \leq N$. The condition (e-ptr = nil) is identical to the condition (enabled-node-count = 0). (Note that once an op-node is enabled, its son nodes may conceptually be deleted from the tree, since they will not be visited by the algorithm again).

Informal Description of Algorithm B:

The expression tree is first initialized, with the node attributes set to proper initial values. The L labels are generated by using the basic tree labeling algorithm as in Algorithm A. The global data structures are also initialized as indicated during their definition. Tree traversal is initiated with the root node. The initial traversal pattern down the tree from the root is almost exactly along the lines of the corresponding traversal in Algorithm A; the purpose, at this stage, is essentially: selection of a start leaf node for emission of the first LOAD instruction. During subsequent traversals up and down the tree, code is generated by taking into account several factors: (a) availability of "free" registers (for LOADs); (b) state of the node visited: "enabled" or "not enabled"; (c) the scheduling strategy (based on maintained timing information) which will ensure emission of optimal code. The normal traversal pattern down the tree is: father, least recently visited son (subtree), other son (subtree), father. If neither son has been visited earlier, the one with the larger label (L) is visited first, as in Algorithm A. Similarly, the normal traversal pattern up the tree is: current son, father, other son, father.

A visit to node n may be classified as casual or busy according to the complexity of the tasks involved. A casual visit results in routine checking and book-keeping operations, without actual code emission. The book-keeping actions are mostly local node operations; for instance, the attributes l-visited, r-visited, ls-enabled or rs-enabled of the father may be set. A partially enabled or enabled node may be entered into the corresponding queue. The checking actions are local as well as global; for instance, the current state (enabled, l-enabled, r-enabled, etc.), of the node is checked; also, global values like m (number of free registers), enabled-node-count, leaf-node-count, etc., may have to be checked. A busy node visit results in some routine checking operations, as well as actual code emission by invocation of the routines "gen-load" and "gen-op". Substantial local and global attribute modification actions are associated with such invocations (as described shortly). Thus, during a given visit to a node n, the corresponding code emission task may be accomplished by invoking gen-load or gen-op (busy visit), or, if the conditions checked are not right the next node in the traversal path is visited, postponing code emission for this node to a subsequent visit. The normal traversal path is altered, at a given step of the algorithm, only if the current node visit is a casual visit, and, a specific condition is detected; for example, m = 0. In such special cases, the next node to be visited is eptr@ or pe-ptr@. (See the actual algorithm for details). A busy node visit (code emission) always results in continuation of a normal traversal pattern; i.e., the next node visited, in this case, is always the father. Invoking "gen-load" or "gen-op" requires updating of one or more of the queues f-queue, e-queue and pe-queue. "Updating", includes addition/deletion of entries as well as decrementing T and t values by proper amounts (see below).

The routines: "gen-load" and "gen-op"

These are the basic routines invoked by the algorithm for generating LOADs and OPs. By construction, the algorithm visits a leaf node if and only if the number of available registers, m, at that point is non-zero and the corresponding LOAD can be scheduled. Thus gen-load is invoked if and only if the visited node n is a leaf node. In addition to actual emission of the LOAD instruction, the following actions are associated with an invocation of gen-load from (leaf) node n:
(a) The entry at the head of f-queue is removed; the corresponding register f-reg is used for the target, t-reg, of the LOAD; f-reg is updated to indicate the new entry at the head of f-queue; the values of leaf-node-count and m are decremented by 1.
(b) The following attributes of father(n) are set/modified as applicable: l-enabled (or r-enabled), T_1 (or T_2). Thus, for example, if n is the left son of its father, then: T_1(father(n)) is set to the integral value A, where A is the pipeline parameter for LOADS (see section II); also, l-enabled (father(n)) is set to true.
(c) The t values of registers in f-queue, and the (T_1, T_2, T) values of father(n), together with those of all nodes in e-queue and pe-queue are decremented by the amount k = 1 + t(t-reg), where the necessary t value was obtained from the head entry of f-queue, during target register (t-reg) selection. (This decrementation of time attributes corresponds to advancing the pipeline execution by the minimum number (k) of cycles before the next instruction can be decoded).

The next node visited after the invocation: "gen-load(n)" is always father(n).

The routine gen-op generates the required OP with l-reg and r-reg as source registers, and either l-reg or r-reg as the target (depending on context) as far as this particular algorithm is concerned. In addition to emission of the required OP instruction (ADD, SUB, MPY or DVD), the following book-keeping operations are associated with the invocation of gen-op from node n:
(a) The freed register(s) are added to the tail of f-queue; the associated t value(s) are copied from the T value of this op-node. The value of m is incremented.
(b) Node attributes of the father are updated in the same manner as before, except that now the pipeline parameter E is used.
(c) The time attributes of the global data structures f-queue, e-queue, pe-queue, as well as those of father(n) are decremented by k = 1 + T((father(n))).

The next node visited after the invocation: gen-op(n) is always father(n).

We now present Algorithm B using a high-level (Pascal-like) notation. The detailed specification of routine book-keeping operations for casual node visits is omitted for clarity; also, the expansions of gen-load and gen-op (with their associated book-keeping actions) are not shown explicitly. (The informal description above should be referred to for completeness).

The Actual Algorithm

After the tree and the data structures are initialized as described,
(1) Apply (2) to the root with all N registers available (free).
(2) Let n be a node, with $L(n) \geq 1$ and $T(n) \geq 0$; suppose m registers are available, $0 \leq m \leq N$.

```
CASE 1. L(n) = 1, hence, m > 0 (n is a leaf node).
begin
    gen-load(n);
    apply (2) to father(n);
end; (* CASE 1 *)

CASE 2. L(n) > 1 (n is an op-node).
begin
    update-local-attributes(n);
    if enabled(n) then begin
        if (n = root) or (T(n) = 0) or (n = e-ptr@) then begin
            gen-op(n);
            if (n ≠ root) then apply (2) to father(n);
            if (n = root) then return;
        end
        else begin
            enter-into-e-queue(n);
            if (m > 0) and (pe-ptr ≠ nil) and (min (T_1(pe-ptr@),
            T_2(pe-ptr@)) ≤ T(e-ptr@)) then apply (2) to pe-ptr@
            else apply (2) to e-ptr@;
        end
    end
```

```
else if l-enabled(n) or r-enabled(n) then begin
    if (m > 0) then begin
        if r-enabled(n) and r-visited(n) and (not ls-enabled(n))
        then apply (2) to left-son(n)
        else if l-enabled(n) and l-visited(n) and (not
        rs-enabled(n)) then apply (2) to right-son(n)
        else apply (2) to father(n);
    end
    else begin
        if (l-enabled(n) and (node-type(right-son(n)) = leaf)) or
        (r-enabled(n) and (node-type(left-son(n)) = leaf)) then
        begin
            enter-into-pe-queue(n);
            apply (2) to e-ptr@;
        end
        else apply (2) to e-ptr@;
    end
end
else (* n is disabled *) begin
    if (m > 0) and (leaf-node-count > 0) and (pe-ptr = nil) then
    begin
        if rs-enabled(n) then apply (2) to left-son(n)
        else if ls-enabled(n) then apply (2) to right-son(n)
        else begin
            if (L(right-son(n)) ≥ L(left-son(n))) and (not
            r-visited(n)) then apply (2) to right-son(n)
            else if (not l-visited(n)) then apply (2) to left-son(n);
        end
    end
    else if (m > 0) and (pe-ptr ≠ nil) and (min ($T_1$(pe-ptr@),
    $T_2$(pe-ptr@)) ≤ T(e-ptr@))then apply (2) to pe-ptr@
    else apply (2) to e-ptr@;
end;
end; (* CASE 2 *)
```

The proof of the following theorem is straightforward; it follows from construction of the algorithm, as discussed earlier. The formal proof is omitted in this paper.

Theorem 2: Algorithm B produces an optimal code sequence (without stores) for the stated machine model and assumptions, with $N \geq L(\text{root})$.

■

For N = 4, the followg code generated by Algorithm B (with A = 3, E = 2), executes (on model B) in 16 cycles (optimal).

```
1. LOAD R1, addr(f)
2. LOAD R2, addr(e)
3. LOAD R3, addr(d)
4. LOAD R4, addr(c)
5. ADD  R1, R2, R1
6. LOAD R2, addr(b)
7. MPY  R1, R3, R1
8. LOAD R3, addr(a)
9. ADD  R2, R2, R4
10. DVD R2, R3, R2
11. SUB R1, R2, R1
```

Figure 3 shows the timing chart for the above example.

Note that the code generated by Algorithm A (with N = 4, A = 3, E = 2) would require 24 cycles (far from optimal) on Model B, even though the same number of instructions (11) would be emitted! Also, note that code emitted by Algorithm B is always optimal for Model A as well, in that a minimum number of instructions is generated. An additional note of interest is that for A = 1, E = 1, the code produced by Algorithm B would be identical to that generated by Algorithm A.

The generalization of Algorithm B to the case where N may be smaller than the L label of the root is easy. In this case STOREs have to be scheduled appropriately for optimal performance. Timing charactersitics of LOADs and STOREs are assumed identical in our implemented program, CODEGEN (see section IV).

Figure 3. Timing Chart (Alg. B, Model B).

C. Serial, Multi-Dispatch, Pipelined, Decoupled Execution

Figure 4 shows the excution model, under consideration, which has been formed from the notions expressed in [3,4]. While retaining the single instruction flow from memory, this organization allows upto two instructions to be dispatched every cycle to the two separate functional units: one for processing LOADs/STOREs (access processor) and the other for performing actual computation (execute processor). We assume the same hardware interlock mechanism for registers as before, to ensure correct usage and storage of data. Our optimization problem, as before, is to generate code which would produce the required results of the computation in the fastest possible time.

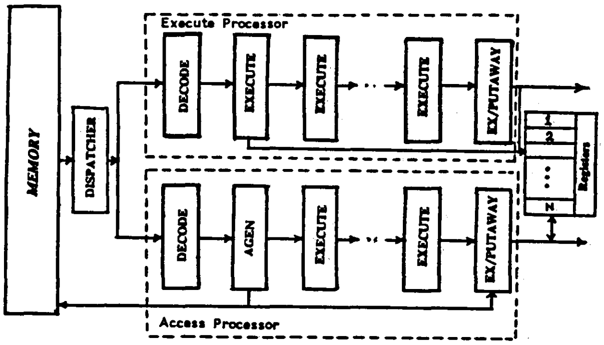

Figure 4. Machine Model C.

Algorithm C, for optimal code generation under this assumed model, is almost identical to Algorithm B. The main difference is in the management of some of the global data structures. The manner in which some of the dynamic variables are manipulated (updated) is different in this case, because of the provision of multiple instruction dispatch. The basic methodology and complexity of the algorithm remains unchanged. We omit the detailed description of Algorithm C in this paper. For N = 4, the code generated by Algorithm C (with A = 3, E= 2) executes (on model C) in 15 cycles (optimal).

In our implemented program CODEGEN (see section IV), we have coded Algorithms B and C, together with modified versions of C, in which buffers have been added before the decode units and also other organization/architecture changes have been experimented with. We leave the detailed description of these models and algorithms for presentation in a later, detailed version of this paper.

IV. ALGORITHM COMPLEXITY

In this section, we present an informal discussion of the complexity of our algorithms. We indicate, without formal proofs, that Algorithms A, B and C are all linear in the number of tree nodes, n. In each case, we shall estimate complexity of code generation after the tree has been constructed and initialized (i.e., static attributes and labels have been evaluated as applicable).

Algorithm A: In this case, as discussed in [1], the number of visits per node is constant, nan.ely 2: the first time each node is visited is when the tree is traversed from the root down to the leaves to determine the order of evaluation; the second visit occurs during traversal up the tree from the leaves producing the evaluation sequence. Hence, for this simple tree-walk algorithm, the total number of node visits is 2n; i.e., the number of steps required by the algorithm is linearly proportional to the number of tree nodes, n.

Algorithm B: In this case, the number of visits per node is not a constant number; however, there is a pre-determined upper bound on the number of visits per node (irrespective of the tree), as seen from the following lemmas.

Lemma 3: In Algorithm B, each leaf node is visited exactly once.

■

Lemma 4: In Algorithm B, the number of visits to an op-node, NV^o, is bounded as follows:

$3 \leq NV^o \leq 4$

■

The proofs of the above lemmas follow easily from the methodology expressed in the statement of our algorithm. A leaf node is visited if and only if the corresponding LOAD is to be scheduled; hence, the number of visits per leaf node is always 1. Under normal traversal pattern, each op-node is visited at least thrice. Upto 4 visits are needed in case a node is entered into e-queue or pe-queue and visited later to complete code generation.

Lemma 5: The total number of node visits (NV), i.e., the total number of invocations of part (2) of Algorithm B, is bounded as follows:

$NL + 3^*NO \leq NV \leq NL + 4^*NO$

where, NL is the number of leaf nodes and NO is the number of op-nodes. The above inequality can obviously be re-written as:

$(n + 2^*NO) \leq NV \leq (n + 3^*NO)$,

where n is the number of tree nodes (since n = NL + NO).

■

Lemma 5 clearly follows from Lemmas 3 and 4.

Thus, we see that in the worst case, the total number of node visits is linearly proportional to the number of nodes. Every visit to a node does not result in the same amount of work for the code generator (algorithm), however. Let us try to see how the total cost (TC) is split up among the tasks performed by the algorithm.

Let,

C_1 = cost per casual node visit (no code emission).

C_2 = cost per busy node visit (code emission).

Then,

$TC = (NV - n)^*C_1 + n^*C_2$.

If C_1 and C_2 are fixed (constant) costs per casual and busy node visit, respectively, then C must clearly be linear in the number of nodes, n, since NV is proportional to n. However, depending on the exact implementation of the data structures (e.g., fixed length arrays versus variable length arrays), and the manner in which they are manipulated (updated), C_2 may vary from visit to visit. For a given node, numbered i, $C_2(i) = C_{21} + C_{22}(i)$; where, C_{21} is the cost (invariant with i) for actual code emission and other routine tasks, and $C_{22}(i)$ is the cost for updating the global data structures. $C_{22}(i)$, at worst, is proportional to the lengths of f-queue, e-queue and pe-queue at the point of the algorithm where code for node i is emitted. The length of f-queue, at worst is proportional to the number of registers N, which is a constant, independent of n. The maximum length to which pe-queue can grow (for expression trees) can be shown to be 1; and, the maximum length to which e-queue can grow can be shown to be (A - E) where A and E are the pipeline parameters. It follows from the above discussion, that the total cost TC is linear in the number of tree nodes, n.

The basic methodology used in Algorithm C is the same as that in Algorithm B; it can easily be shown that in this case too, the worst case complexity is linear in the number of tree nodes, although, the number of actual node visits is slightly higher.

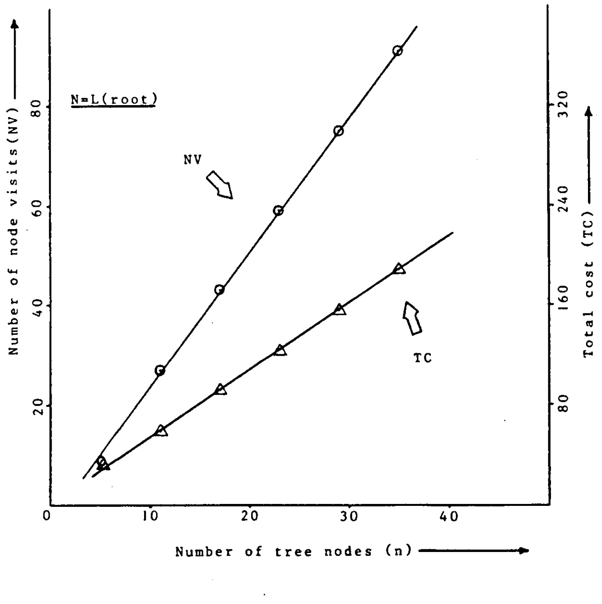

Figure 5. Performance of Algorithm B.

Family of expressions: (for Fig. 5)

n=5: a/(b+c).
n=11: a/(b+c)-(d*(e+f)).
n=17: a/(b+c)-(d*(e+f))+(g/(h-j)).
n=23: a/(b+c)-(d*(e+f))+(g/(h-j))-(k*(l+m)).
n=29: a/(b+c)-(d*(e+f))+(g/(h-j))-(k*(l+m))+(n/(p-q)).
n=35: a/(b+c)-(d*(e+f))+(g/(h-j))-(k*(l+m))+(n/(p-q))-(r*(s+t)).

Implemented Program

As mentioned previously, a program called CODEGEN has been implemented successfully, in order to experiment with tne various algorithms for code generation referred to in this paper. The fact that Algorithm B (or C) is linear can be easily proved, as discussed above. We present actual experimental results (Figure 5) for the family of arithmetic expressions shown. The total cost plotted is based on realistic (relative) cost units, and is based on actual numbers and sizes of tasks involved; thus, the TC plot is truly representative of the actual execution time characteristics of our implemented algorithm(s). Experimentation with a wide class of expression structures has exhibited the same general characteristics.

CODEGEN has been written in Pascal and runs on an IBM 370 mainframe. It includes an expression parser, tree builder and labeler, a tree printer along with the actual code generation procedures.

V. CONCLUSION

Code generation algorithms for more generalized models of execution than those considered in the classic papers of Sethi et al [1] and Aho et al [2], have been sketched. With the growing importance of high performance (super) computer architectures, such algorithms, which fully exploit the parallelism available, are deemed to be of considerable significance. We have presented outlines and performance results of basic algorithms for simplified models. Our implemented program CODEGEN is actually capable of handling more complicated models and is parametrized to handle various architecture/organization changes. In particular, methods for designing the instruction set suitably for enhanced performance, have been experimented with using techniques described in [9]; systematically derived stack [8] and other generalized instruction set architectures have been considered in conjunction with the various execution models. We are currently experimenting with an implemented program capable of handling basic blocks (expression dags), for our pipelined machine models.

A SYMMETRIC CONCURRENT B-TREE ALGORITHM

Vladimir Lanin and **Dennis Shasha**

Courant Institute of Mathematical Sciences,
New York University, New York, New York 10012
lanin@nyu-csd2.arpa, shasha@nyu.arpa

ABSTRACT: We present a method for concurrent B-tree manipulation in which insertions are performed as in an earlier paper by Lehman and Yao, and deletions are done in a symmetrical, novel fashion. The result is an algorithm in which each process holds locks on at most one node at a time, except in rare cases. To allow this low level of synchronization, the integrity constraints on the data structure are re-examined. This is useful in verifying the algorithm by a general semantic serializability proof method. Simulation shows that the algorithm is capable of achieving significantly better concurrency than other algorithms that perform insertions and deletions symmetrically.

1. INTRODUCTION

B-trees are a popular implementation of the *dictionary*, an abstract data type (ADT) that supports the actions *search*, *insert*, and *delete*. A full review of B-trees may be found in [Comer 79], but let us say here that a sequential algorithm for performing the above actions in a B+ tree usually runs in three stages: a descent through the tree to a leaf node, an operation on the leaf node that either checks for the existence of a key, adds a key, or removes a key (for search, insert, and delete, respectively), and an optional ascent during which the tree is restructured in order to rebalance it. It is also possible to restructure the tree during the descent, as described in [Guibas, Sedgewick 78]. Restructuring is done by *splitting* a single node into two neighboring ones and by *merging* neighboring nodes into one. The execution of an entire action takes time logarithmic in the number of keys stored in the structure.

It is useful to allow several different, asynchronous processes to access the B-tree concurrently. This is easy when all the processes are searches, but the goal is to also allow concurrent insertion and deletion, while ensuring correctness and allowing as much concurrency as possible.

1.1. Previous Work

The first concurrent B-tree algorithms ([Samadi 76], [Bayer, Schkolnik 77]) ensure correctness by isolating each action from the effects of all other actions active in the structure concurrently: a concurrent action never encounters a situation that it could not encounter if executing alone. Two techniques are used to achieve this isolation. We present them with their rationale:
a) An action descending from a parent node to one of its children must acquire a lock on the child before releasing the lock on the parent (lock-coupling). Without this lock on the parent, a writer action could acquire locks on both nodes, change them (e.g. split the child), and release the locks (Fig. 1). This could cause the descending action to perform incorrectly, as the search(d) in fig. 1 does.
b) A writer action (which in [Samadi 76] and [Bayer, Schkolnik 77] restructures during the ascent) must lock out other writer actions from the entire subtree dominated by the highest node it has to modify. This averts another danger: suppose writer w needs to ascend to and modify node n, and writer w' is already active below n. Since w' might also have had to modify n, either w or w' would update n first. The other would then access a different version of n than during its descent, potentially causing errors.

These techniques guarantee correctness at the expense of concurrency. Locking processes out of entire subtrees is a severe disadvantage in itself. Furthermore, the most straightforward method of achieving the subtree-locked state (which is used in the above algorithms) is for writer processes to begin placing exclusive (or at least writer-exclusion) locks from the top of the tree. This temporarily locks out new actions entirely. The simultaneous use of lock-coupling by other processes aggravates the problem by increasing the interference.

Another algorithm in [Bayer, Schkolnik 77] mitigates the above effects of subtree-locking by having writers first perform an optimistic search-like descent that uses read locks on all nodes but the final leaf, on which it uses an exclusive lock. A writer can complete after the optimistic descent if it does not have to split or merge the leaf. This has a probability of about $\frac{k-1}{k}$ if the number of keys stored in each leaf ranges from k to $2k$. Otherwise, the writer must give up and re-descend using the normal protocol.

The algorithm in [Mond, Raz 85] is a concurrent version of the [Guibas, Sedgewick 78] algorithm, and avoids subtree-locking by doing restructuring during the descent. However, it still

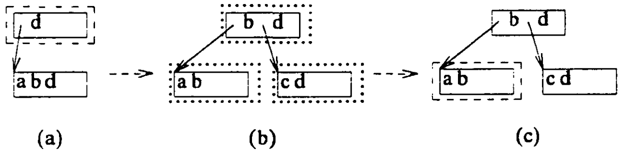

Figure 1. A sequence of events leading to error
in the absence of lock coupling

Descending action *search*(d) releases its lock (shown in dashes) on the parent node in (a) before acquiring lock on child node in (c). Meanwhile, action *insert*(c) splits the child node in (b), making the key d unavailable to the search.

This work was partially supported by the National Science Foundation under grant DCR8501611 and by the Office of Naval Research under grant N00014-85-K-0046

CH2345-7/86/0000/0380$01.00 © 1986 IEEE

employs lock-coupling and requires using exclusive locks starting at the root. We note that the [Mond, Raz 85] algorithm can also be enhanced by optimistic descents.

Simulation shows (as presented in this paper, as well as in [Ellis 80], [Shasha 84]) that in a high update environment, algorithms that use exclusive locks high up in the tree in the initial descent can not achieve significant concurrency. Although optimistic descents help considerably (especially in the [Mond, Raz 85] version), they depend on the number of keys in a leaf being large. They seem to employ more locking than absolutely necessary.

1.2. The Lehman and Yao Algorithm and Deletions

A more radical approach to achieving a minimal amount of locking is not to try to isolate actions from each other (by lock-coupling and subtree-locking), but to enable them to recover from the effects of other actions. [Ellis 80] and [Lehman, Yao 81] present such algorithms. The latter avoids both lock-coupling and subtree-locking and is simple; we base our approach on it.

The Lehman and Yao algorithm introduces the *B-link* structure, obtained from a B+ tree by connecting each level into a singly linked list. A pointer called a *rightlink* points from every node to its right neighbor, so actions can stray to the left of the direct path to a desired node, and still recover by following the rightlinks. For example, a split occurs in two stages (see Fig. 2): first, half the data is moved out of *n* into *n'*, and *n'* is inserted into the linked list; next, a pointer to *n'* is put into the parent of *n*. Between the two stages, descending processes can be allowed to make the transition from the parent of *n* to *n*, because even if they need data that was moved to *n'*, they can still reach it. Thus, lock-coupling is unnecessary. Subtree locking is unnecessary because ascending writers can follow rightlinks to the appropriate place to make their updates.

Although it is not apparent in [Lehman, Yao 81] itself, the B-link structure allows inserts and searches to lock only one node at a time. This is fully utilized in algorithms in [Sagiv 85] and [Shasha 84].

The major problem with the [Lehman, Yao 81] algorithm is that no provision is made for the merging of nodes. Thus, the structure never becomes smaller even after many deletions, although Lehman and Yao propose to rebalance it off-line. This deficiency has been addressed in the algorithms of [Salzberg 85] and [Sagiv 85], which give procedures for restructuring the entire tree that can run concurrently with the other actions. However, it is not clear how often such procedures should be run.

No algorithm has previously been given for performing a deletion analogously to an insertion, by using merges where the insertion uses splits. Independently, [Sagiv 86] has a nearly symmetric deletion algorithm similar to ours. Our merge is different and should result in fewer locks and/or accesses, but we expect the performance of our two algorithms to be close. We learned of the algorithm too late to include it in the simulation.

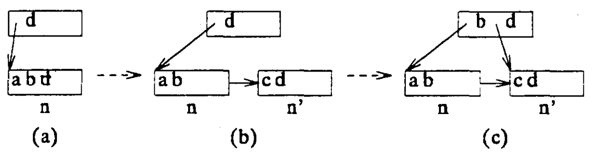

Figure 2. A split in the B-link structure.

Processes looking for *d* in *n* in (b) or (c) can proceed to *n'* and still find *d*.

1.3. Symmetric Deletion Approach

Let us consider various implementations of merging a node *n* with its right neighbor *n'* in the B-link structure. If we move the data in *n'* to *n* (Fig. 3a), there is no path that processes can follow from *n'* to the data moved out. This may, for example, lead a process to conclude that *c* is not in the structure.[1] If we move the data in *n* to *n'* (Fig. 3b), we will need to access the left neighbor of *n* to remove *n* from the linked list. Finding the left neighbor requires either much time or a doubly linked list, which increases complexity and the locking overhead (see [Shasha 84] for example).

Our novel way of doing merges solves the above problems. We move the data from *n'* to *n*, but also direct a pointer called an *outlink* from *n'* to *n* (Fig. 4). Any action needing data that was in *n'*, and still expecting to find it there, can access *n'*, see that it is empty, and follow the outlink to *n*.

The outlink is actually another application of the *link technique,* other examples of which include the original Lehman and Yao rightlinks, as well as elements in the algorithms of [Kung, Lehman 80] and [Ellis 83]. In general, the link technique calls for processes that change sections of a data structure in a way that would cause other processes to fail to provide a link to another section of the data structure where recovery is possible.

2. OUR ALGORITHM

The following section fleshes out the short description of our algorithm given above. Please refer to Fig. 5 for an example of a B-link structure and to the appendix for a pseudo-Pascal program implementing the algorithm.

2.1. Some Definitions

Each internal node consists of a rightlink, and a sequence

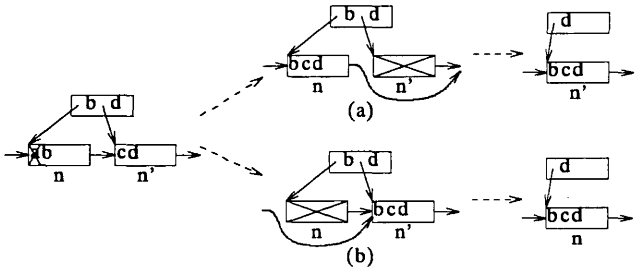

Figure 3. Two possibilities in merging *n* and *n'*.

Unfortunately, (a) is incorrect and (b) is inconvenient.

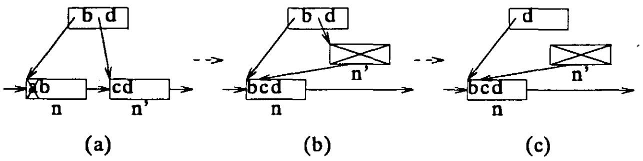

Figure 4. Merging in the B-link structure.

Processes looking for *d* in *n'* in (b) and (c) can proceed to *n* and still find *d*.

[1] This illustrates a general principle that data should only move to the right in the singly-linked B-link structure.

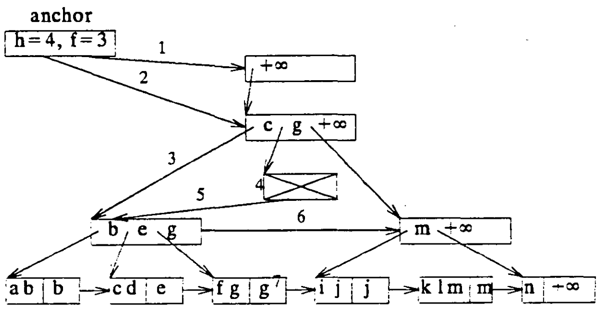

Figure 5. A possible legal state of a B-link structure.

1) The *top* pointer. 2) The *fast* pointer. 3) A downlink. 4) An empty node. 5) An outlink. 6) A rightlink. 7) A leaf's only separator.

$(p_1,s_1,p_2,s_2, \cdots ,p_q,s_q)$, where each p_i is called a *downlink* and s_i a *separator*. A downlink is a pointer to a (usually null) chain of empty nodes terminating in a non-empty node on the level below. A downlink is said to *trans-point* to this non-empty node. A separator is a value from the same domain as keys, but serves only as a navigation guide and not as a key entry. For $1 \le i < q$, $s_i < s_{i-1}$. Each leaf consists of a rightlink, a sequence of keys $(v_i, v_2, \cdots ,v_q)$, and a single separator s, where $v_i < v_{i-1} \le s$ for $1 \le i < q$.[2]

Let us define:

rightsep(d), where d is a downlink: the separator on the immediate right of d. Note that it is always in the same node as d.

rightsep(n), where n is a non-empty node: the rightmost (largest) separator in n.

leftsep(d), where d is a downlink in node n: the separator to the immediate left of d. If d is the leftmost downlink in n, $leftsep(d)$ is the rightmost separator in the left neighbor of n. If n is the leftmost node on its level, $leftsep(d)$ is considered to be $-\infty$.

leftsep(n), where n is a non-empty node and d is the leftmost downlink in it: $leftsep(n) = leftsep(d)$. If n is an empty node whose outlink points to n', let us define $leftsep(n) = leftsep(n')$.
coverset(n), where n is a non-empty node: $\{x \mid leftsep(n) < x \le rightsep(n)\}$.

2.2. Locks

The locking model used in [Lehman, Yao 81] assumed that an entire node could be read or written in one indivisible operation. This assumption enabled that algorithm to let reader processes access nodes without first locking them in any way. Since it is not always reasonable to assume the availability of atomic node reads or writes (such as when the structure is in primary memory), and in order to make comparisons to other algorithms easier, we use a more general locking scheme similar to the one in [Bayer, Schkolnik 77]. It is a simple matter to convert our algorithm to fit the [Lehman, Yao 81] model, as should be done when atomic node accesses are provided by the hardware.

Two kinds of locks are used: a read lock and a write lock. Many processes may hold read locks on a node at the same time, but a write lock demands exclusive access to a node, allowing no other locks. A process must hold at least a read lock to perform a non-modifying operation on a node; a process must hold a write lock to modify a node. Deadlock is not possible in our algorithm, so lock managers of different nodes may be co-independent.

Each action holds no more than one read lock at a time during its descent, an insertion holds no more than one write lock at a time during its ascent, and a deletion needs no more than two write locks at a time during its ascent.

2.3. The Locate Phase and the Decisive Operation

The first phase of all three actions (search(v), insert(v), and delete(v)) is called the *locate phase*, as its function is to locate and place a lock on a leaf n such that $v \in coverset(n)$. That is, n should be the node where v should be if it is anywhere in the structure. The locate phases of all three actions are identical, except that the last two must leave a write lock on n, not a read lock.

The locate phase does not use lock-coupling. On the path to the appropriate leaf, the locate phase locks each node, determines which link to follow out, and unlocks the node. It does not, however, unlock the final leaf. Each node-to-node transition usually follows a downlink, but follows a rightlink or outlink if necessary. Write locks are used on the leaf level if the calling action is insert or delete, and read locks elsewhere.

Once the locate phase completes, an action performs its *decisive operation*, which consists of checking for v (for search), adding v (for insert), or removing v (for delete) in the locked leaf.

2.4. Restructuring

Adding or removing information in a node may leave it too crowded or too sparse. As in sequential B-tree algorithms, this is rectified by *normalizing* the node: i.e. splitting it into two nodes or merging it with its neighbor.[3] Since a split or a merge involves inserting or removing the pointer from the parent node to the node being created or vacated, the normalization of a node may make further splits and merges higher in the structure necessary. Thus the tree is restructured by an ascent from the leaf accessed by the decisive operation.

2.4.1. Two-Phase Splits and Merges. In order to avoid having to lock the parent (and possibly more distant ancestors) of a node while normalizing it, our algorithm performs splits and merges in two stages, as shown in figures 2 and 4. The first stage (fig. 2b and 4b), which does not involve the parent of the node being split or merged, is called the *half-split* or the *half-merge*, respectively. After a half-split, n and n' may still be regarded as one logical node. The half-merge may be regarded as logically merging n and n', and re-directing to n the downlink to n'. After the completion of a half-split or a half-merge, all locks are released.

The second stage (Fig. 2c and 4c) is called the *add-link* or *remove-link*. This operation takes place on an "appropriate" node on the level above the node n which has just been half-split or half-merged. In a sequential computation the appropriate node is always the (unique) parent of the node involved. This can not work in our algorithm because a node may (rarely) have several or no parents. The purpose of a downlink — to channel to its target the locates of keys in the target's *coverset* — suggests a better criterion. Let s be the rightmost separator in the left node after a half-split, or the rightmost separator in the left node before a half-merge. The (unique) appropriate "parent" node p is the one for which $s \in coverset(p)$.

An add-link consists of inserting s and the downlink to the

[2] For the sake of simplicity, we have restricted the structure to holding only unique keys.

[3] Merging two nodes into one may result in a node that is too crowded. Thus a merge may be followed by a split; this is our version of rotation.

new node into the sequence in p, with s on the immediate left of the downlink. A remove-link consists of removing s and the downlink to the empty node from p, with s on the immediate left of the downlink[4].

Normally, finding the node with the right *coverset* for the add-link or remove-link is done as in [Lehman, Yao 81], by reaccessing the last node visited during the locate phase on the level above the current node. Sometimes (e.g. when the locate phase had started at or below the current level) this is not possible, and the node must be found by a new descent from the top.

2.4.2. Changing the Height of the Structure. If an ascent can not proceed because the current level is the top level, a new top level is created (by the *grow* operation). Safely removing unneeded top levels turns out to be too difficult. However, descending through them for every action is unacceptable. Thus, instead of actually removing them, we simply avoid searching through them. A continuously running process called the *critic* keeps track of (a good guess at) the highest level containing more than one downlink, called the *fast* level. The critic uses only read locks in getting this information. Pointers to the leftmost nodes of both the fast level and the top level are kept in the *anchor*, whose address is known to all processes. If need be, the critic modifies the fast pointer. The locate phase of all actions begins at the leftmost node on the fast level. (The locate phase will complete at the correct leaf regardless of the precise height of the fast level because it is in fact safe to start a locate at any level.) The levels above the fast level remain unused until they are needed again when the fast level contains too many (e.g. more than 2) non-empty nodes. Since these levels normally consist of only one node and number no more than the maximum height of the structure over time, they take up little space.

2.5. Freeing Empty Nodes

Once all pointers to an empty node are removed, the node becomes a candidate for re-use[5]. However, it can not then be freed immediately since processes may exist that obtained some pointer to it before the pointer was removed. If such a process were to access the node once it was re-inserted into the structure, the process might be misdirected or damage the node.

Two approaches are possible. One, introduced in [Kung, Lehman 80] and called the *drain technique*, is to delay freeing the empty node until the termination of all processes whose locate phase began when pointers to the node still existed. The other approach is to store information in every node (its height and *leftsep*) such that a process can recognize that it has become lost and recover by going back to the previous node it accessed or to the anchor. The appendix does not contain code for either approach, but freeing empty nodes by the drain technique is transparent to the rest of the algorithm and can be added on as a separate module.

3. CORRECTNESS

We verify the algorithm by applying the ideas of semantically-based concurrency control to the dictionary abstract data type ([Ford, Calhoun 84], [Goodman, Shasha 85]). [Kung, Papadimitriou 79] established the theory of a semantic approach to concurrency control by showing the relationship between the information available to a concurrency control algorithm and the achievable concurrency. Our algorithm, like Lehman and Yao's, is not serializable in the usual syntactic sense (i.e. in the unrestricted reads and writes model), thus the more general semantic approach is necessary.

The *state* of the dictionary abstract data type (ADT) is a set of keys. The set of all potential keys is called *KeySpace* and we assume it contains the values $+\infty$ and $-\infty$ which are, respectively, larger and smaller than all others. The dictionary ADT supports the dictionary actions *search*(x), *insert*(x), and *delete*(x), which map a dictionary state s to a dictionary state s' and return value v. For search(x), $s'=s$ and $v=(x \in s)$; for insert(x), $s'=s \cup \{x\}$ and $v=(x \notin s)$; for delete(x), $s'=s-\{x\}$ and $v=(x \in s)$.[6] A sequence of dictionary actions $a_1,a_2 \cdots ,a_k$ maps an initial dictionary state s_0 to a final state s_k and a sequence of return values $v_1,v_2, \cdots ,v_k$, where each a_i maps s_{i-1} to s_i and returns v_i. It is the job of our algorithm to implement dictionary actions correctly when they execute concurrently.

A search structure state (a set of nodes and edges with associated information) implements a dictionary state. For each node n in the search structure, *contents*(n) is the set of keys in the node. The dictionary state implemented by a set of nodes N is $\bigcup_{n \in N} contents(n)$. Operations on the search structure state are called *search structure operations*. For our algorithm, these are operations like half-split, add-link, and check-key. Search structure operations map a search structure state to another search structure state and a return value. Each dictionary action is implemented as a program of search structure operations.

Let a set of dictionary actions A be run concurrently.[7] The resulting computation C consists of an initial search structure state s, a final search structure state s', the set of dictionary actions A, the set of executed search structure operations O, a function *parent* from the members of O to A, a function r from the members of $A \cup O$ to their return values, and a partial order $<$ on the members of $A \cup O$ (where $o<o'$ means o completes before o' begins, and $\neg(o<o' \vee o'<o)$ means o and o' were at least partially concurrent). We assume that for dictionary actions a and a', $a<a'$ only if for every operation o of a and operation o' of a' $o<o'$, i.e. a terminated before a' began.

Definition: A computation C with s, s', A, r and $<$ defined as above is *serializable* if the members of A can be arranged in a sequence A' such that A' maps the dictionary state represented by s to the dictionary state represented by s', produces the same return vales for the members of A as does r, and extends the partial ordering imposed on A by $<$ (i.e. if $a<a'$, then a precedes a' in A'). An algorithm is serializable if all computations it produces are serializable.

In our algorithm, locking ensures that only non-modifying operations are allowed to access the same node concurrently. This implies that the final state and return values of every computation are as if the operations occurred in an interleaved sequence that extends the partial ordering $<$ ([Goodman, Shasha 85]). This makes it possible to think of each operation as occurring alone and starting and finishing in a well-defined search structure state, which facilitates reasoning about computations.

We now develop several results needed to show that our algorithm is serializable.

[4] There are special cases in performing the remove-link. If s is the rightmost separator in p, then the downlink is leftmost in the right neighbor of p. The simplest solution is to merge p and its neighbor prior to the remove-link and to normalize afterwards. In rare circumstances, s and the downlink will not be in p at all, in which case we reissue the remove-link later. We know that it will eventually succeed because the empty node was originally created by a half-split, and all half-splits are eventually followed by the appropriate add-links. The remove-link is this add-link's counterpart and was delayed because the add-link was slow in completing. Similarly, an add-link has to be tried again if s is already present in p; this happens only when this older s's remove-link has been slow.

[5] A counter of the number of outlinks pointing to the empty node must be used. Furthermore, just the absence of a downlink to the node is insufficient, as the add-link may simply be very slow and still active. The correct condition is the completion of the remove-link.

Definition: A B-link structure state is *legal* if

LS1) There exist values h and f, $1 \leq f \leq h$, such that the non-empty nodes form h linked lists through the rightlinks, where all leaf nodes are on list 1, all downlinks from list i trans-point to nodes on list $i-1$, and the anchor contains pointers to the source nodes of lists h and f, as well as the values h and f.

LS2) The separators on each list form a strictly ascending sequence terminating in $+\infty$. The keys in each leaf are in the leaf's *coverset*.

LS3) If a downlink d points to node n, $\mathit{leftsep}(d) \geq \mathit{leftsep}(n)$. (This is the minimal condition sufficient for safe descents. If $\mathit{leftsep}(n)$ were greater than $\mathit{leftsep}(d)$, actions could follow d to n while the data they seek lies to the left of n.)

B-link Proposition: For all operations mapping legal search structure state s to state s', for all nodes n present in s, if $\mathit{leftsep}(n)=l$ in s and $\mathit{leftsep}(n)=l'$ in s', then $l' \leq l$.

Proof: This follows directly from the definitions of the operations, as the reader can easily verify. For example, an add-link can not violate the proposition because it never adds the largest separator to a node, thus not changing any *leftsep*s. As another example, a half-merge decreases the *leftsep* of the node it empties (by the definition of *leftsep* for empty nodes). This proposition is a formal re-statement of the rule that information never moves to the left in the B-link structure. □

Lemma 1: If d is one of the operations check-key(x,n), add-key(x,n), or remove-key(x,n) in computation C of our algorithm (i.e. d is a decisive operation), and C starts in a legal state and all operations up to d finish in a legal state, then n is a leaf and $x \in \mathit{coverset}(n)$ in the search structure state preceding d.

Proof: It is the locate phase that finds and locks the node on which the decisive operation acts. We note that the height of a node is never changed by any operation that maintains a legal state. The locate phase starts out at the leftmost node n at some height f. Since f is read from the anchor and the heights of all nodes remain the same, the locate phase can correctly calculate the height of any node it accesses. Furthermore, since it starts at the leftmost node, $\mathit{leftsep}(n) = -\infty < x$. The next node to be visited, m, is chosen such that $\mathit{leftsep}(m)$ is as large as possible without violating $x > \mathit{leftsep}(m)$. (LS1, LS2 and LS3 guarantee that this decision can be safely based on the values of the separators in n.) By the B-link Proposition, $\mathit{leftsep}(m)$ can only get smaller with time. Thus, when a lock is placed on m, $x > \mathit{leftsep}(m)$ still. Since m now becomes the new value of n, $x > \mathit{leftsep}(n)$ remains invariant throughout the locate phase. The locate phase terminates only when the leaf level is reached and $x \leq \mathit{rightsep}(n)$, which, together with the invariant, implies $x \in \mathit{coverset}(n)$[8]. □

Lemma 2: If o is one of the operations add-link(s,c,p) or remove-link(s,c,p) in a computation C of our algorithm, and C starts in a legal state and all operations up to o finish in a legal state, then a pointer to c trans-points to a node on the level below p and $s \in \mathit{coverset}(p)$ in the search structure state preceding o.

Proof: The argument that this condition is met (by the locate-internal subroutine) is similar to the proof of Lemma 1. The condition that c is at height one below p is met because node height does not change and is calculated correctly. As for the *coverset* condition, it is satisfied as it was for the decisive operations, except that locate-internal does not always start at a leftmost node. However, when it doesn't, the *leftsep* of the starting node is known to have been smaller than s at some previous time. By the B-link Proposition, the *leftsep* can only have gotten smaller since that time and the invariant condition is met. □

Lemma 3: If o is an operation in a computation C of our algorithm, and C starts in a legal state and all operations prior to o finish in a legal state, then o will finish in a legal state.

Proof: Clearly, no operations other than those in Lemmas 1 and 2 are capable of mapping a legal state to an illegal one. By the lemmas, these remaining operations must satisfy their respective height and *coverset* conditions, which implies that they too can not violate LS1 or LS2.

It remains to consider LS3. The only operations that could conceivably change the *leftsep* of any existing downlink are add-link and remove-link, which add and remove separators as well as downlinks. However, since the separator added or removed is the one on the left of the downlink added or removed, these operations do not change the *leftsep* of any existing downlink. By the B-link Proposition, the *leftsep* of any existing node can only get smaller. Thus, LS3 can only conceivably be violated in the introduction of a new node or downlink. Newly created nodes do not have downlinks pointing to them, so LS3 is not violated. Thus, a problem can only arise if for some add-link(s,c,p), $s < \mathit{leftsep}(c)$. However, we note that an add-link(s,c,p) is done only after a half-split(c',c) which results in $s = \mathit{rightsep}(c') = \mathit{leftsep}(c)$. By the B-link Proposition, $\mathit{leftsep}(c)$ can only get smaller between the half-split and the add-link, thus LS3 is never violated. □

Theorem: All computations produced by our algorithm that begin in a legal state are serializable.

Proof: All keys reside in non-empty leaves. By LS1 and LS2, the *coverset*s of the non-empty leaves in a legal B-link structure partition *KeySpace*. By LS2, the keys in each leaf are in that leaf's *coverset*. Thus, for every key and every legal B-link structure there is exactly one node (i.e. the leaf into whose *coverset* the key falls) that could possibly contain the key.

By induction on Lemma 3 we have that the algorithm maintains a legal state throughout a computation if it begins in one. Then Lemma 1 shows that for every decisive operation on key x in node n, $x \in \mathit{coverset}(n)$ and n is a leaf, which implies that $x \notin \bigcup_{m \in N-\{n\}} \mathit{contents}(m)$ in the state preceding the operation.

By inspection of each action, only the decisive operation is capable of changing the set of keys in the structure and only the decisive operation affects the return value of the action. Furthermore, the definition of each decisive operation is identical to the definition of its parent action, except that it acts on a single node instead of the entire structure. Since we know that this node is the only one that contains any information pertinent to the action by Lemma 1, each decisive operation correctly performs all of the work of its parent action. Thus the sequence of actions given by the sequence of their decisive operations would produce the same final set of keys and the same return values as the actual computation. □

It should be pointed out that although the algorithm is susceptible to livelock, it is free from deadlock on lock resources because of a well-ordering on the acquisition of locks. Whenever a process holds two locks simultaneously, the two nodes are always adjacent at the same height, and the lock on the node on the left is always obtained first.

[6] For simplicity, we omit a formal description of the handling of records usually associated with keys.

[7] The following definitions are actually applicable to two-level computations on any abstract data type. Simply replace the words "dictionary" with "top level", and "search structure" with "bottom level".

[8] Note that there is no guarantee that the locate phase will terminate. For example, a slow search could be indefinitely delayed by continuous half-splits on a node it needs to access. Thus, the algorithm is susceptible to livelock.

4. PERFORMANCE SIMULATION

In order to compare the actual performance of the B-link algorithm to that of previous algorithms supporting insertion and deletion, we have run the algorithms under various conditions in a simulated concurrent environment provided by the language Concurrent Euclid [Holt 83].

4.1. Model of Concurrency

We compare speedup, i.e. the ratio of the time it takes one processor to do a given amount of work to the time it takes *n* processors to do that same amount of work. Ideally, the speedup achieved by *n* processors is *n*, but actual concurrent algorithms achieve lower speedups due to interference through waiting for locks.

In our simulation, the processors receive a common list of actions constituting the work to be done. Each processor removes an action from the list, executes it, gets another, etc. When the last action completes, the simulated time is noted.

The only activity which takes time in the simulation is reading and writing nodes. (An action reads a node after obtaining a lock on it, and possibly writes it out before releasing the lock.) However, a process may be delayed while waiting for a lock held by another process which itself is reading or writing a node.

A node access (a read or a write) always takes exactly one time unit. If *n* processors issue *n* node accesses at the same time, all *n* accesses complete at the same time, after one time unit. Thus, node accesses are simulated to occur completely in parallel. Studies ([Schultz, Mukkamala 85], [Ford et al 85]) have shown that when several physical processors contend for a single relatively slow storage device capable of handling only one request at a time, the storage device can become a bottleneck and prevent the realization of most of the potential concurrency. Thus, our model of complete non-interference at the physical storage access level is most applicable to systems where data is distributed over many storage modules (such as disk drives) :capable of operating in parallel. Our results are actually quite close to those obtained in [Schultz, Mukkamala 85] for the Lehman and Yao algorithm in a simulated system containing as many storage devices as processors.

4.2. Parameters of the Simulation

For each simulation run, the values of the keys in the initial B-tree and of the arguments of the job actions were randomly and uniformly distributed over *KeySpace*. The values picked for insertions and deletions were guaranteed not to be redundant.

The parameters that could be varied in comparing the algorithms were the number of keys in the initial B-tree, the order of the tree (i.e. the out-degree of nodes), and the proportion of searches, insertions, and deletions in the actions. Since searches never interfere with each other and in the absence of updates achieve perfect speedup, including them in the simulation only masks the amount of interference produced by updates, the source of the problem. Thus, we excluded searches from the actions performed and simulated a "mix" where half the actions were insertions and half deletions.

Besides the symmetric B-link algorithm, we simulated four other algorithms. Two of these, algorithm 1 of [Bayer, Schkolnik 77] and the [Mond, Raz 85] algorithm, use lock-coupling (and, for the former, subtree-locking) with exclusive locks from the top of the tree. Algorithm 2 of [Bayer, Schkolnik 77] strives to reduce subtree-locking and exclusive locking high up in the tree by having updates first perform an optimistic search-like descent using read-lock lock-coupling. We also simulated our own version of the [Mond, Raz 85] algorithm which uses an optimistic descent like algorithm 2 of [Bayer, Schkolnik 77] and re-descends by the [Mond, Raz 85] method.

We did not simulate algorithm 3 of [Bayer, Schkolnik 77] (as well as an analogous version of the [Mond, Raz 85] algorithm) because it differs from algorithm 1 only in the partial substitution of exclusive locks by writer-exclusion (or alpha) locks. Although this substitution can improve performance by allowing read-locks to be held on alpha-locked nodes, only searches use read-locks in this algorithm (alpha-locking and optimistic descents can not co-exist because of the possibility of deadlock). Since our simulation excludes searches, its results would not be changed by the substitution.

4.3. Results of the Simulation

Figure 6 shows the speedups achieved by the various algorithms in an initial B-tree containing 800 keys with each node having between 7 and 13 children or keys. Under these conditions (and all other update-intensive conditions we have tried), the algorithms that place exclusive locks from the root during the initial descent achieve a maximal speedup of only about two. Optimistic descents improve this result significantly, with our version of [Mond, Raz 85] achieving a maximal speedup of around 10 before ceasing to get better performance with larger

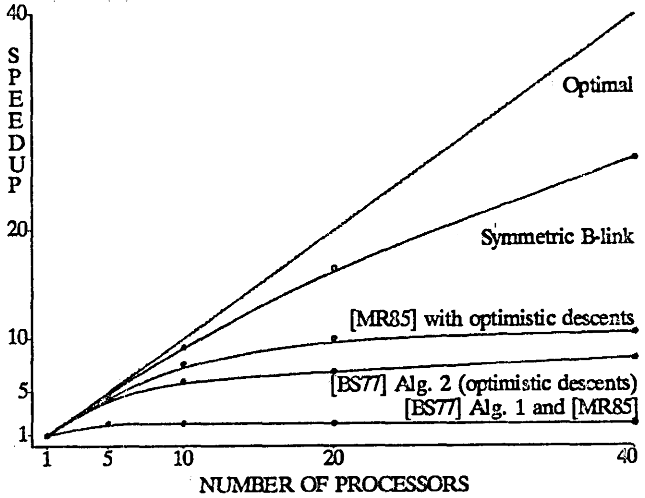

Figure 6.
Simulation of insertions and deletions in a 7-13 B-tree containing 800 keys.

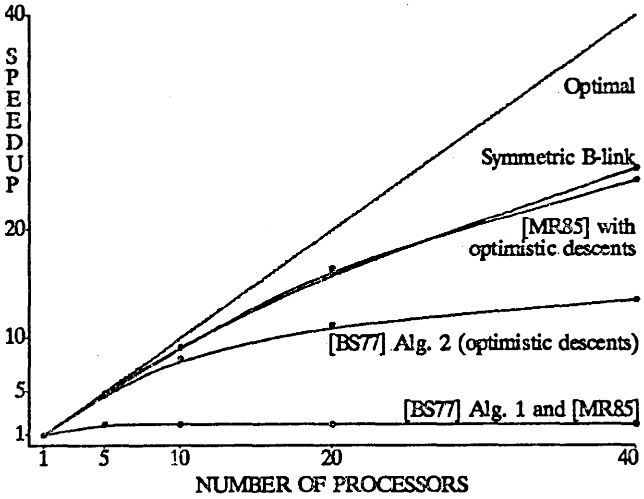

Figure 7.
Simulation of insertions and deletions in a 20-39 B-tree containing 10,000 keys.

numbers of processors. The somewhat worse performance of the second [Bayer, Schkolnik 77] algorithm must be attributed to the use of subtree-locking by the latter. The B-link algorithm, however, gets a speedup of 26.5 with 40 processors and would probably get a better speedup with a larger number of processors (compiler constraints prevented simulation of more than 40).

Varying the parameters to the simulation brings some significant changes to the results. When the algorithms were run on a 7-13 tree with 100 keys, the small size of the tree (only two levels) increased the interference and thus decreased the performance of all algorithms. The B-link algorithm was still best, but achieved a maximal speedup of only 7. This figure increased to 14 with an initial tree size of 200 keys.

More significantly, increasing the size of leaves greatly improves the performance of the algorithms employing optimistic descent. This is because splits and merges become less frequent, increasing the probability that the optimistic descent will succeed. In a 20-39 tree with 10000 keys (roughly three levels), our version of the [Mond, Raz 85] algorithm achieves only slightly lower speedups than the B-link algorithm, as shown in Fig. 7. The second [Bayer, Schkolnik 77] algorithm lags somewhat behind these two, probably because of its subtree-locking.

5. CONCLUSION

We have presented a deadlock-free concurrent B-tree algorithm supporting search, insert, and delete which employs less locking than any other algorithm that treats deletions symmetrically with insertions. To verify the algorithm, we use a correctness criterion based on the semantics of the dictionary ADT. This criterion permits executions that would not be considered correct in the model of uninterpreted reads and writes. Simulation has shown that the algorithm is capable of achieving much better concurrency than the earliest (and still most widely used) concurrent B-tree algorithms that employ much exclusive locking high in the tree. It performs at least as well as other algorithms which also try to avoid using exclusive locks, and performs significantly better than these in trees containing a small number of keys (e.g. under 20) in each leaf.

APPENDIX

The following implementation of our algorithm is written mostly in Pascal. Two non-Pascal constructs are used: the use of records as return values of functions, and the use of *spawn* as a way of invoking processes. A value of a record type is represented as $(f_1, \cdots, f_n)$. The semantics of *spawn*(procedure call) are to create a process to perform the procedure call. No further communication takes place between the spawner and the process spawned, and the two execute at the same time and terminate independently. The parameters to this procedure must be entirely call-by-value; in particular, the descent stacks must actually be copied[1]. No requirement is placed on the length of time that may pass before the spawned process becomes active. If the drain technique is used, the starting time of each spawned process must be recorded as the starting time of the parent process.

[1] This restriction may be lifted for those parameters that will not be accessed again by the spawner (or passed to another spawned process).

The ascent is performed by creating a new process for each add-link or remove-link to be done. We choose this method for simplicity of presentation, although it is more efficient to spawn fewer processes. For example, the add-link and remove-link necessitated by a rotate are usually both done in the same node and should thus be done by a single process. However, this can not always be done and makes the code more complex, although this heuristic was implemented for the simulation. Whatever method is used, it can not make one add or remove wait for the completion of another if the other is redundant and must wait, since this can cause deadlock.

ABSTRACT

This paper describes a fiber optics based distributed information network named FORTIS. FORTIS is an integrated (voice, data, video, and sensor), end-to-end digital packet switching system. FORTIS is implemented as a multilevel, multiprocessor distributed network system using MPUs, I/O processors and the latest VLSI components. The system can modularly expand from a one device-one node system, to a subnet, net and supernet. The system can be connected to existing networks and various data LANs, as well as serve as a data extension to existing PBXs. Currently FORTIS can support the RS232C asynchronous protocol for data, and RJ11 physical connection for phones. It will support other higher level protocols in the near future.

INTRODUCTION

There are three major areas of computer applications growing in importance during the next decade. One, as is traditional, will be the use of computers for the purpose of numerical analysis [1]. This computer application will require computers with greater throughput than presently available, especially for applications in meteorology, nuclear physics and modeling large scale systems.

The second major area of computer applications concerns the massive quantity of data in large databases used for decision support systems [2]. This application area will continue to play a growing role in banking, insurance, record processing, information retrieval, etc. In these applications, the number-crunching capabilities of traditional computers are not as important as the capability to store and retrieve large amounts of data rapidly and at reasonably low cost. Computer networking will play an expanding role in these applications, for they will have to access not just a single database but a collection of interconnected databases. In response to this need, many advances in computer networking are required [3].

The third major area for computer applications is what has become to be known as "Knowledge Engineering". Knowledge engineering is one of the major areas of Artificial Intelligence [4]. Within knowledge engineering, a field of primary importance is the expert system. The required computers for this application are different than those needed in the other two areas.

All of these computer application areas are growing in importance, some more rapidly than others. This paper primarily addresses the second area: the accessing of interconnected databases. It also addresses the interconnection of all types of communication devices such as telephones, data terminals, workstations, disks, printers, plotters and sensors, as well as computers.

Technology in areas of voice communications, data communication, distributed computing, and fiber optics have evolved in parallel but through fairly independent approaches. The creation of functionally and physically independent networks to share resources for voice communication and data communication is inefficient and provides for a costly solution to the user's management of information. Presently, users are increasingly demanding a convergence of these technological approaches as a result of their need to share voice and data information by more convenient and less costly methods.

A traditional approach to handling intrapremise communication consists of a centrally located circuit switch such as a PBX which connects pairs of intercommunicating devices for the duration of a session. This approach is adequate for voice applications since voice traffic is continuous but is inefficient for interactive data terminal usage. The capacity of the PBX circuit switch is inefficiently used in the case of the in-

CH2345-7/86/0000/0390$01.00 © 1986 IEEE

teractive data terminal usage since most data sessions consist of short bursts with long idle periods. A local area network which uses packet switching for interconnection is superior to circuit switching because the network connection is not used during idle periods and is available for use by others.

The Fiber Optics based Distributed Information Network (FORTIS) is a state of the art, end-to-end digital packet switching system which is capable of fully integrating voice, data, video communication and other types of information, such as sensor data, into an intelligent distributed system. FORTIS utilizes a packet switching technique to permit devices connected to the network to transmit in bursts, thereby allowing the bandwidth of the network to be used more efficiently. At the same time, it preserves the real time nature of voice communication by prioritizing it.

The system provides to the user the properties of economy (cost per connection), integrity (robust and fault tolerant design), performance (parallel processing through local and network distribution) and modularity (expandable and simple to maintain). It uses multiple dsitributed microprocessors and the latest in VLSI components to provide maximum programmability, reliability and flexibility at minimum cost.
The system can also be configured with existing networks and various data LANs [5-10] as well as a data extension to an existing PBX. The FORTIS system is described in detail in the rest of the paper.

FORTIS SYSTEM DESCRIPTION

By design, the FORTIS system is modular. The system can be visualized in three ways: (1) as a standalone node, (2) as a subnet with two or more nodes linked together and (3) as a network with two or more subnets connected together. Each of these structures is explained in detail in this section.

The node design is a unique three level distributed processor architecture as shown in figure 1. A design requirement for the standalone node was to provide the capability of allowing 256 devices (telephones and/or terminals) to communicate with each other in a non-blocking environment. The design was also predicated upon being event-driven, rather than polled. It was evident that a single or multiple processor (68000 class) connected in a traditional bus structure would not be able to handle that many devices in real time. An architecture was needed which exhibited the characteristics of pipelining and parallel processing, as well as asynchronous processing. It was also determined that a bus structure which permitted parallel transfers was necessary. The rationale for this unique architecture was driven by the tradeoff of speed versus intelligence. The more intelligence demanded of a processor, the more time it takes to achieve it. Level 1 is the intelligence level. Level 2 peforms the task of I/O and is the device handler level. Level 3 is the communication level whose task is to communicate to devices in a network that are external to the node.

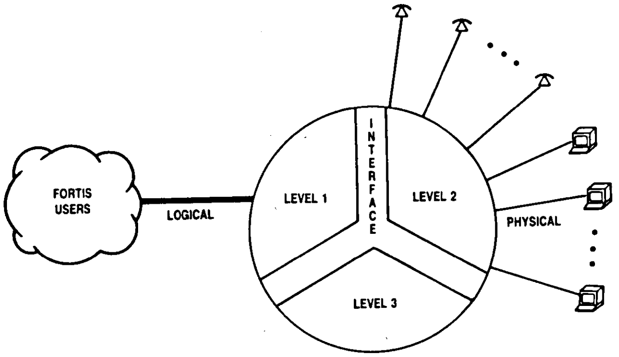

Figure 1. FORTIS: NODE ARCHITECTURE

As depicted in figure 1, a user is logically connected with level 1. Level 1 contains the node specific information such as the types of devices connected to the node, the list of valid node users, etc., as well as subnet and network specific information. Level 1 also has the necessary system software for supporting user interface, establishing connectivity between various resources in the system, and for system monitoring. A more detailed configuration of Level 1 is shown in figure 2a. As shown, it is a traditional architecture using a 68000 MPU interconnected with a VME bus structure and a disk subsystem.

User resources such as terminals, phones, (micro, mini, and mainframe) processors, etc., are physically connected at level 2. The devices in this level are configured into clusters. Each cluster can have up to eight devices of the same

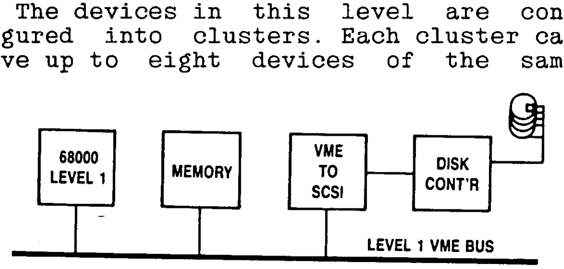

Figure 2A. LEVEL 1 ARCHITECTURE

type, as shown in figure 2b for the phone cluster and figue 2c for the terminal cluster. The minimum configuration is one cluster with up to 8 devices.The system can expand by modules of eight devices, up to 256 devices (or 32 clusters of 8 devices per cluster). Clustering increases the modularity and reduces the cost of the system.

Each of the clusters of level 2 has a processor, memory and enough intelligence to handle packet creation and transfers. As shown in figure 2, a cluster is composed of three logical elements: (1) the cluster control unit (CCU) (2) a device line interface card (telephone or data terminal - TLIC or DLIC) and (3) a physical card to hold the connectors (PIC or DIC). The CCU is a high speed I/O processor (5 mips). Level 2 handles intracluster and intercluster information exchange within a node. It has the ability to do self-diagnosis and to report any abnormality or error conditions to the network/node manager resident in level 1.

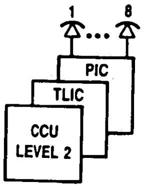

Figure 2B. LEVEL 2 PHONE CLUSTER (PC)

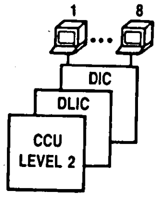

Figure 2C. LEVEL 2 TERMINAL CLUSTER (TC)

The physical connectivity of level 1 and level 2 with the parallel bus structure is shown in figure 2d. Level 1 communicates to level 2 clusters via the I/O bus controller. This path is selected when level 1 intelligence sets up the path between devices (for example, source device 1 in cluster 4 is to be virtually connected to destination device 1 in cluster 7 for packet transfers). The actual packet transfer is accomplished in a burst mode on the level 3 burst bus. The burst bus controller performs a hardware poll of all clusters requesting the use of the burst bus. The arbitration is accomplished by ring priority; the last to use the bus has the lowest priority. The actual transfer between clusters is achieved at a 10 megabyte rate (a 64 byte transfer is achieved in 6.4 microseconds).

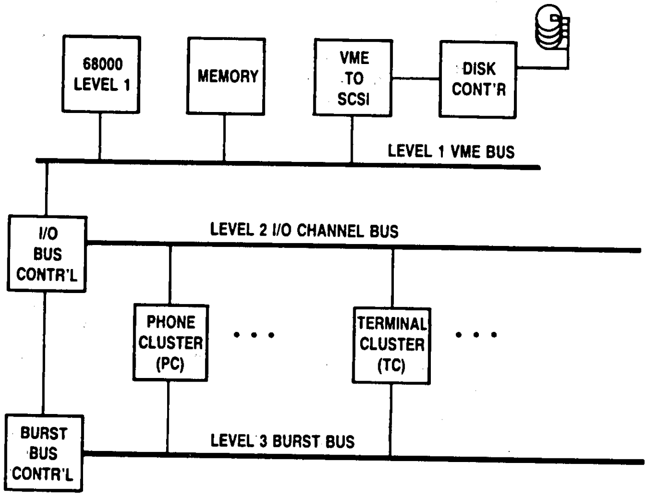

Figure 2D. FORTIS: NODE ARCHITECTURE

The FORTIS architecture design is aimed at providing a maximum of asynchronous parallel operation at all levels by design of multiple parallel processors and multiple parallel bus structures within each node. Each level has at least one processor, and memory. Level 2 could have as many as 32 processor with 32 programming streams executing in parallel.

Subnet Architecture

The architecture of the FORTIS system allows networked expansion of the self-standing nodes. Two or more nodes could be interconnected through passive fiber optic star couplers to form a subnet as shown in figure 3a. The connectivity using a passive star coupler between nodes operates in a broadcast fashion and therefore is a fully interconnected topology.

After level 1 has determined the connectivity, level 2 performs the packet transfers. A packet transfer is achieved by a handshake and a burst transfer to another level 2 cluster or to level 3. Level 3 is the off-node communication handler. As depicted in figure 3b, level 3 consists of a cluster control unit (CCU) identical to the level 2 CCU's (and a programming stream), a link line interface card (LLIC) whose function is to provide the interface between the CCU and the optics interface card (OIC). The OIC contains the following modules: (1) byte to bit serial and bit serial to byte convertors, (2) modulator and demodulator to

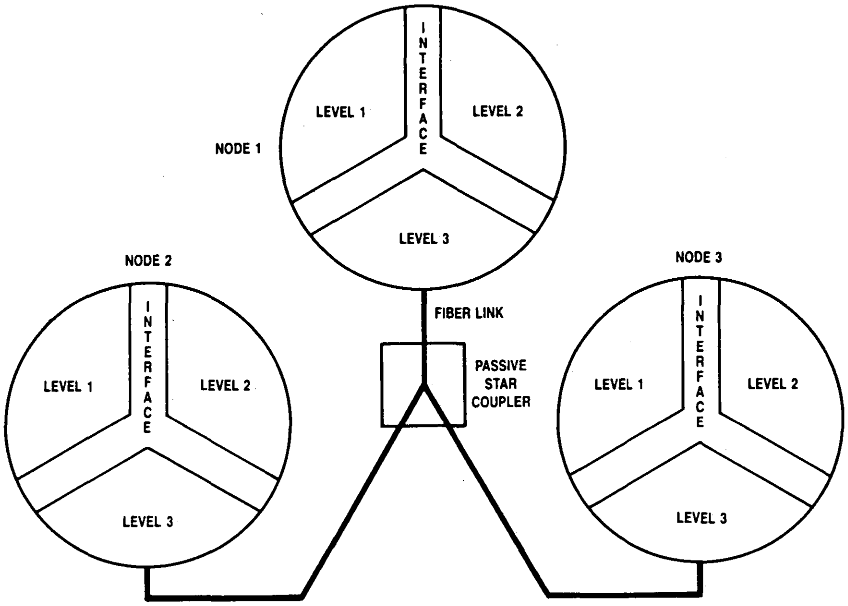

Figure 3A. FORTIS: SUBNET ARCHITECTURE

drive the fiber optic transmitter, (3) LED or laser transmitter to launch the energy onto the fiber, (4) receiver module designed to settle in 4 bit times, and (5) high speed state machine to provide real time state information to the level 3 CCU.

The link arbitration protocol is a priorty round-robin technique. This technique combines priority with a virtual token passing scheme. With the combination of packet switching and the priority round robin link protocol, a real time response of 8 milliseconds is guaranteed for resources such as phones. The same modular design philosophy is followed in deployment of the fiber communications link. A minimum of two links is provided, each operating at a 20Mhz rate. More than one link supports a more robust system operation, and eliminates any single point failure mechanism [11]. However, the system is capable of operating on a single link. If more throughput on the communication between nodes is desired, the system is designed to stack multiple links. As technology advances, the link rate could be increased to the 40-100Mhz range. Also, the modular design of FORTIS enables the use of advanced technology such as Wave Division Multiplexing (WDM) [12].

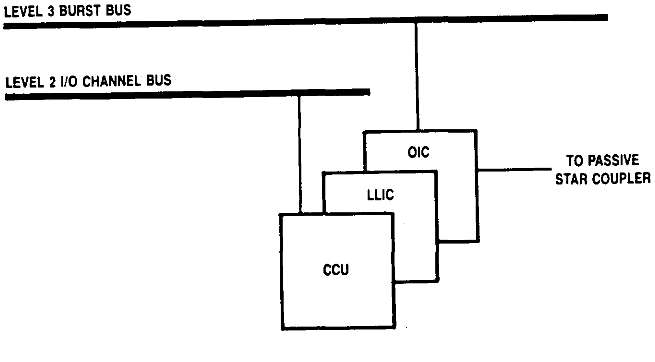

Figure 3B. FORTIS: FIBER LINK ARCHITECTURE

The minimum number of nodes in a subnet is two; the maximum number in a single subnet is 20. The maximum is governed by present fiber component technology and optical power budget calculations. As fiber technology advances, this number can increase to the logical FORTIS addressing limit of 256 nodes per subnet. The framework of each of the nodes in a subnet is identical and represents an independently operating part of the system. The intelligent nodes therefore operate in a distributed fashion which is inherently fault tolerant.

Network Architecture

Subnets can be interconnected via bridges to form a FORTIS net as shown in figure 4a. The subnets and/or nets can also be connected to other networks such as Ethernet [10], through gateways as in figure 4b. FORTIS allows 256 subnets per net. Two hundred and fifty six such nets can be interconnected to form a supernet as in figure 4c. (Practical problems in designing nets and supernets are currently under study.) FORTIS has a total address space of 256x256x256x256 = 4,294,967,296 devices. At the same time

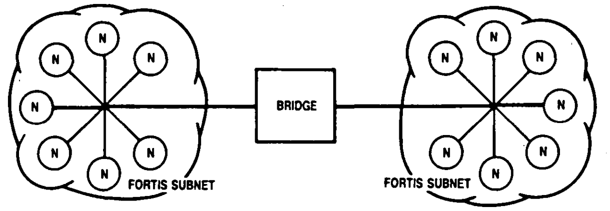

Figure 4A. FORTIS NET USING SUBNETS

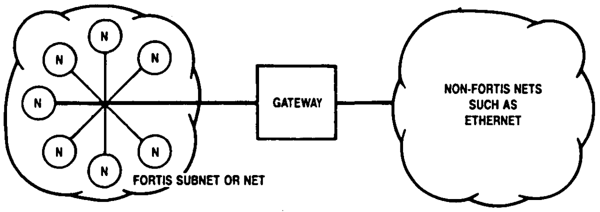

Figure 4B. FORTIS NET WITH OTHER NETWORKS

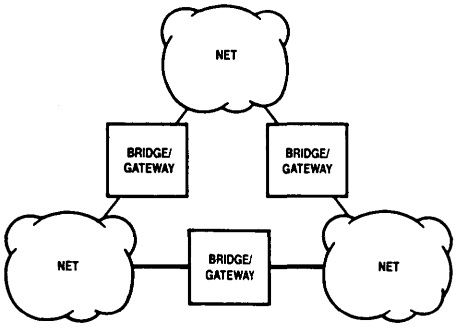

Figure 4C. FORTIS SUPERNET

it is modular enough to grow in small steps of one cluster to satisfy the future requirements of customers. Modular expansion alleviates large capital expense problems associated with capacity planning.

Software Structure

The FORTIS system was designed to allow software visibility to all levels of the hardware. This allows greater programmability and more extensive diagnostics. Resident in each of the nodes is a real-time networking operating system. The software is structured in a layered fashion as shown in figure 5. Also, 99% of the code is written in C language. Hence, it is easy to debug, integrate, maintain and transport the software.

The FORTIS software can be divided into three major categories: (1) system software, (2) application software and (3) diagnostic software. The system software performs major networking functions. It can be further classified into: distributed real-time operating system, networking, user interface and system microcode. The distributed real-time opeating system performs functions such as multitasking, memory management, interrupt handling, real time clock, error processing, performance monitoring, etc. The networking software has many modules to perform network related functions such as node supervisory, phone supervisory, data supervisory, global and nodal systems management and monitoring. The system microcode resides in level 2 and level 3 of the node. It performs tasks such as packet transfer between different devices anywhere in the FORTIS system.

The user interface is the logical connection between the FORTIS users and level 1 mentioned earlier. This portion of software provides user friendly interfaces to phone and data including help provision. It also has a command processor to process all the user commands. An example of commands provided for the data users include connectivity, programmability, and positive flow control which allows speed matching. With a standard 2500 telephone set, the phone commands include standard PBX features such as hold, transfer, forward, pickup, etc.

The FORTIS application software consists of voice mail and electronic mail. In the future, it will be possible to provide many more application software packages such as word processors, distributed file servers, database management, language processors and even computing power.

The final piece of system software is the diagnostic software. Diagnostic software exist at all levels to test various parts of FORTIS system. Provisions exist to diagnose individual boards, each node, and the link in the network.

FORTIS also provides many value-added features to the end-users as well as to the network. Some of the value-added network features are: accounting, load balancing, security by password and encryption, on-line help, system manager, system monitor.

It is important to note that each node has information about its own devices/resources only. Information about devices/reources existing in other nodes in the system are obtained 'on demand' basis in real time. This allows dynamic changes to resources in a node without any need to update or inform other nodes in the system. The totality of information is distributed across the network.

Network Protocols

Currently FORTIS system supports RS232 asynchronous protocol. Data terminals and

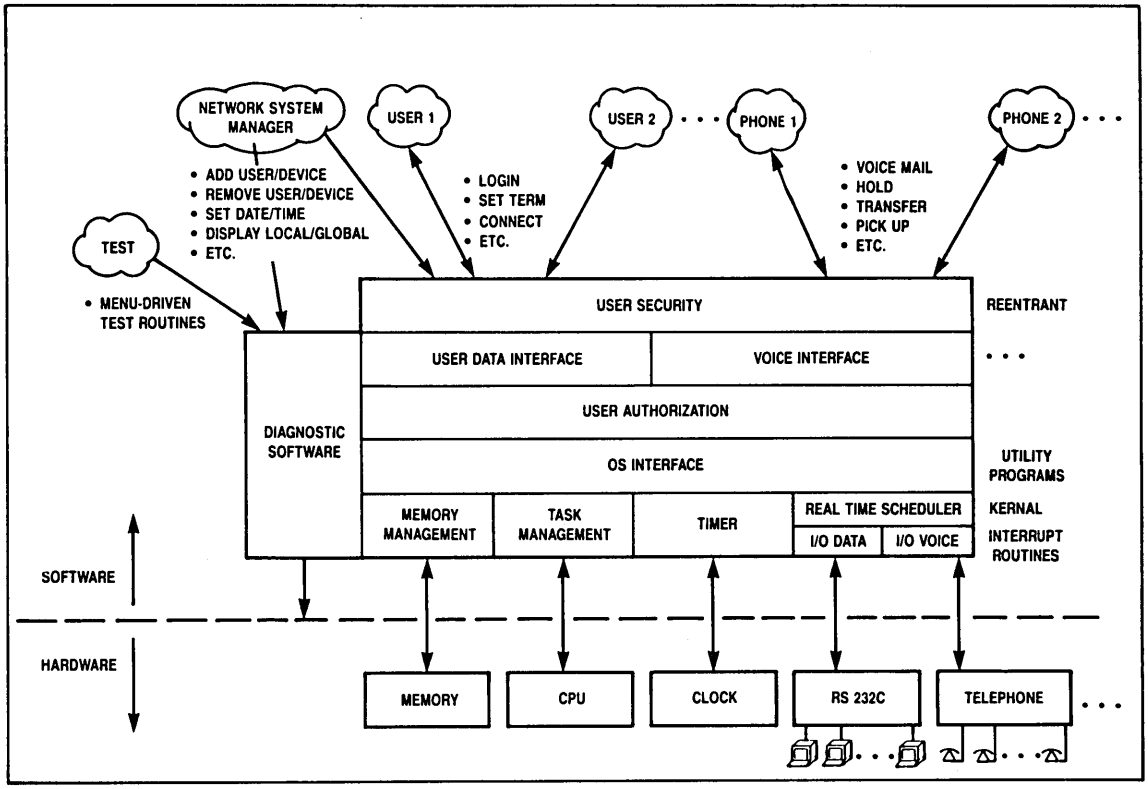

Figure 5. FORTIS SOFTWAY STRUCTURE

CPUs are connected to the system through RS232 lines. Phones are connected to the system using standard RJ11 connectors. However, in the future, FORTIS can easily support other higher level protocols such as HDLC, X.25, ISO-OSI, SNA, etc. [3,13].

FORTIS APPLICATIONS

The typical environments where FORTIS is applicable today and in the near future include: offices, companies and universities, factories, laboratories, hospitals, distribution and sales, banking, easily maintainable and cost saving building wiring distribution, and so on. FORTIS supports office automation functions such as electronic mail, text/word processing, document distribution, and voice mail. It provides communication, links for accessing centralized or distributed databases and mainframes using terminals or teller machines. It also provides a medium for factory automation, including automated manufacturing techniques such as CAD/CAM, robotics, and numerically controlled manufacturing processes requiring real-time response. It can provide the communication links which are needed for order entry and inventory control systems, patient diagnostics, file retrieval and status monitoring. Other user needs [14] are extensive network management services for system administration and maintenance. FORTIS allows the users to efficiently accomplish these required tasks and increase individuals' productivity. To further emphasize possible applications, two are explained in detail in the following paragraphs.

Multistory Building or Industrial Park

A typical application for the FORTIS is a multiple story building or an industrial park with multiple tenants. For the purpose of this example, a floor in a multistory building can be configured identically to a building in an industrial park. The pictorial view of this application is depicted in figure 6. As shown, it represents an eight story building or eight separate buildings in an industrial park. Each floor is divided into multiple tenants.

To distinguish business types of tenants, four classes are defined below: (a) class 1 busines - 64 phones, 32 terminals, (b) class 2 business - 64 phones, 8 terminals, (c) class 3 business - 16 phones, 4 terminals and (d) class 4 business - 8 phones, 0 terminals. The dis-

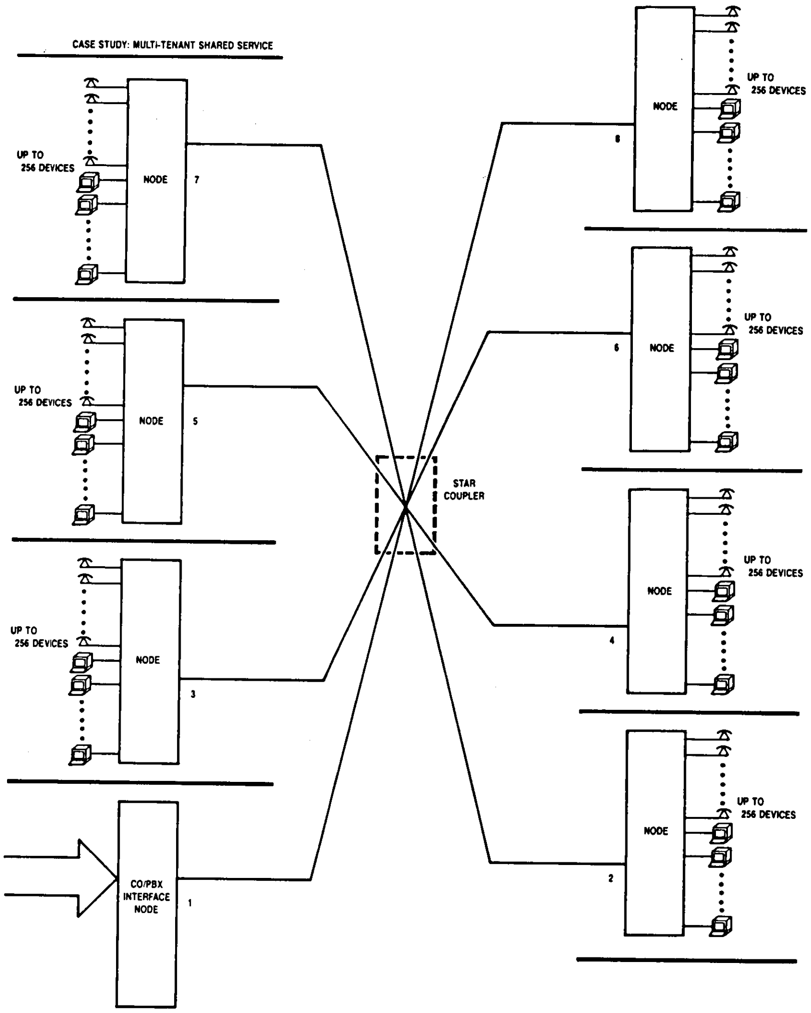

FIGURE 6 MULTIPLE STORY BUILDING OR INDUSTRIAL PARK

tribution of the multiple tenants and their respective business types for each of the floors is provided in Table 1.

Floor 1 will be reserved for the interface to the local central telephone office. The interface could be multiple wire-pairs as used in analog voice connections and/or T1 carrier and SLC 96 as used for digital connections. The cabling media to interface could be wire or fiber. All of the tenants share the trunk lines and the inherent lower costs of connection to the outside business world. This is true because the subnet pools the outside lines and requires fewer trunks to provide the same grade of service. In this application, the subnet connects 520

Table 1. Distribution of Multiple Tenants

floor/building	tenants	phones	terminals
8	one class 1	64	32
7	one class 1	64	32
6	one class 2	64	8
6	four class 3	16	4
5	one class 2	64	16
4	two class 3	64	8
4	one class 4	32	8
4	one class 1	8	0
3	one class 1	64	32
2	eight class 4	64	0
2	one class 3	16	4
totals	22	520	144

telephones for a grade of service of B.05 (4 ccs) and requires only 58 trunks or 3 T1 lines into the network. For the 22 tenants this reflects a savings of greater than 40 percent over that of each tenant bringing in individual trunk lines, as well as simpler cable installation. Further, each tenant has the potential to share a mainframe, word processing services, energy management and security to the building. The building management offers additional value to the user of the space which reflects a competitive edge over other building space of comparable value.

Data Networking Architecture

Examining the requirements of the data market in a little more detail could provide some further networking insight. There exist today two architectures for networking computer systems. These are the "Computer Network Architecture" and the "Terminal Access Network Architecture". The "Computer Network Architecture" is suited for CPU to CPU communication and sharing of peripherals (SNA of IBM Corp., DNA of Digital Equipment Corp., DEC Clustering Architecture, etc. [3].) and is an adjunct to "back-end processing". "Terminal Access Network Architecture" is, as the name implies, an interconnection of a terminal to a computer port and is an adjunct to "front-end processing". The relationship of both of these networks is shown in figure 7a. At present, both networks coexist in many computer systems. FORTIS can combine both of these networks into one for greater economy and ease of maintenance as shown in figure 7b.

SUMMARY AND CONCLUSION

This document describes the FORTIS network and provides the rationale for its development. FORTIS provides the user with real-time response which is a requirement for voice communication, and other applications such as process control. The network differs from many systems by providing a packetized virtual circuit between devices such as digitized voice, data, video, sensor interfaces and the central telephone office. Ease of use was an important consideration in the design of the node, subnet, net, operating system and other support software.

FORTIS provides a cost effective solution for interconnection requirements by providing an integrated information network with productivity enhancements provided by software value-added features. The truly integrated approach and the value-added capability provided by the software of the FORTIS system creates the foundation and framework for new solutions for a variety of application areas. The programmable FORTIS hardware framework allows quick development of specific interfaces as dictated by a rapidly changing market place.

Presently, three nodes interconnected as a subnet are operational in our Westboro facility. They are connected with two passive star couplers at a distance of 1 kilometer from each other with a link rate of 20 Mbps. Multiple telephones, terminals and CPUs are connected in the subnet. Aetna Telecom. Labs has many patents on various technical aspects of the FORTIS network.

The system described in this paper was conveived in the last quarter of 1982, designed and successfully implemented by the spring of 1985 as a fully populated three node system. An equal number of standard telephone sets and VT100 like terminals were connected to these nodes. Now that we have demonstrated the system, the team can reflect back and provide others with observations which we feel are meaningful.

In this age of openness, standards, and multi-vendor environments, propriety communication systems have a short future. The impetus for the work of the IEEE 802 LAN committee was that standardized LAN's are a requirement. The team extends this requirement further suggesting that there should be one LAN network which not only handles interconnection between mainframes, and mainframe peripheral equipment but also handles voice communication. Further we feel that not only physical integration between the telephone sets and terminals should be a requirement but logical integration as well.

It would be a serious omission on our part when a paper on high-speed fiber-based networks does not mension (the stanard currently being developed by the IEEE and ANSI) the Fiber Distributed Data Interface (FDDI), which is a 100 Megabit Token-ring communication system, using fiber. (FDDI-2 is an alternative specification using slots for synchronous (voice) data. A reference [15] is provided for additional information.

ACKNOWLEDGEMENT

The FORTIS net is the accomplishment of a highly talented team whose efforts sometimes knew no bounds. The authors express their sincere appreciation to all the members of Aetna Telecom. Labs for their cooperative efforts.

ON THE DESIGN OF FAULT-TOLERANT SYSTOLIC ARRAYS WITH LINEAR CELLS

ABSTRACT

In many numerical systolic systolic arrays, each processing element in the regular part of the array is itself a linear system (we call this a linear cell). A systematic approach to the design of fault-tolerant systems for such systolic arrays is developed in this paper. Most of the proposed systolic arrays for matrix operations, polynomial operations, and digital signal processing can be made fault-tolerant using our procedure. The design procedure preserves the structure of the original (non-fault-tolerant) systolic array making it easy to incorporate fault tolerance; the faulty units can be identified, which permits reconfiguration if necessary.

The design methodology encodes the inputs data at a high level and ensures that the algorithm generates encoded output data; the encoding is tailored to the structure of the systolic array. The encoded input data are passed through the systolic array in ways which will avoid problems with error masking due to failures. This approach, therefore, results in extremely low overhead for fault tolerance.

I. INTRODUCTION

Conventional general purpose machines are unable to support, without high cost, the increasing demands for large amounts of computation in many real-time scientific and signal processing applications. Fortunately, the tremendous progress of VLSI technology has made feasible cost-effective parallel computation. Among these parallel schemes, systolic arrays have earned a great deal of research attention since they are amenable to special-purpose VLSI design. Many algorithms, well suited for VLSI implementation, have been developed for matrix multiplication, QR decomposition, LU decomposition, Discrete Fourier Transform (DFT), solution of Toeplitz linear systems, eigenvalue problems, etc [1]. However, along with the tremendous increase in the performance, reliability has become a serious consideration: all cells or Processing Elements (*PE*s) in the array need to be fault free for correct operation, and the overall system reliability decreases rapidly as the number of *PE*s increases.

Fault tolerance can be obtained either by masking the error caused by physical failures or by detecting them, isolating the faulty unit, and reconfiguring the system around the faulty unit. Fault masking is usually done by replicating the hardware and voting on the outputs of the replicated modules, but this is extremely costly in terms of hardware redundancy. An alternative is to detect errors by periodic testing. Unfortunately, the increase in transient errors caused by decreasing geometries means that off-line testing alone cannot be used to detect erroneous modules. Techniques for *Concurrent Error Detection (CED)* are therefore needed to detect errors concurrently with normal operation.

Fault-tolerant structures for systolic arrays have been proposed by many authors [2-7]. However, in all these papers, discussions are limited to the problem of *reconfiguration*, and the difficult problems of CED and *fault location* have not been discussed. Other papers [8-12] did discuss the problem of concurrent error detection. However, as far as systolic arrays are concerned, [8] and [9] can only be applied to matrix multiplication. In [10], each *PE* has to be implemented with PLAs, and this is impractical for VLSI implementation of the multipliers and adders. Techniques proposed in [11] and [12] require double or triple calculations to compare or vote, resulting in time penalties. It has been shown in [13-15] and [8] that we can always fully utilize the systolic arrays, i.e., with no idle *PE*s during the operation of the systolic array, even for the case of bidirectional systolic arrays. Therefore, duplicated or triplicated operations will certainly mean a large overhead.

In this paper, efficient fault-tolerant schemes for systolic arrays are developed through the analysis of some common features of most existing numerical systolic arrays. These require low hardware overhead and low time redundancy, and can be applied to most existing numerical systolic arrays, including those for matrix multiplication, Finite Impulse Response (FIR) filters, Infinite Impulse Response (IIR) filters, LU decomposition, matrix triangularization, least square minimization, convolution, polynomial multiplication, polynomial division, etc. It is well known that there is no clear definition of a systolic array. Generally speaking, according to [15], a systolic array is a computing network possessing the following features: (1) synchrony, (2) regularity, (3) temporal locality, and (4) pipelinability. From this definition, it is clear that systolic arrays will differ significantly in their specific structures. Moreover, even with the same structure, the systolic arrays may still differ a lot from each other due to the different functions of each individual *PE* and the irregular *PE*s at the boundaries. Thus, since systolic arrays are not clearly defined, it is likely that a universal approach toward the design of fault-tolerant schemes for diverse systolic arrays is extremely difficult, or even impossible. Therefore, in this paper, instead of trying to derive a scheme which can be applied to all systolic arrays, we set our goal to develop a scheme to successfully handle most of the existing systolic arrays for numerical computations.

In this paper, the general fault model is defined in Section II, and the linear cells and the linear property are defined in Section III. Section IV develops the CED design for one-dimensional systolic arrays using the linear property encoding, while Section V develops the CED design for two-dimensional systolic arrays. The fault location and reconfiguration problems are discussed in Section VI. finally, Section VII presents the conclusion of this paper.

This research was supported by the Semiconductor Research Corporation (SRC) under Contract SRC-RSCH 84-06-049-4.

II. FAULT MODEL

As the geometric features of integrated circuits become smaller, any physical defect which affects a given area on a chip will affect a greater amount of the circuitry and will cause a larger logic block to become faulty. Thus, the traditional gate level fault models are not satisfactory. In this paper, we allow a computation unit (such as multiplier or adder) to produce any arbitrary logical errors under failures. Furthermore, a single computation unit fault model is used, where we assume that at most one computation unit could be faulty within a given period of time which will be reasonably short compared with the mean time between failures.

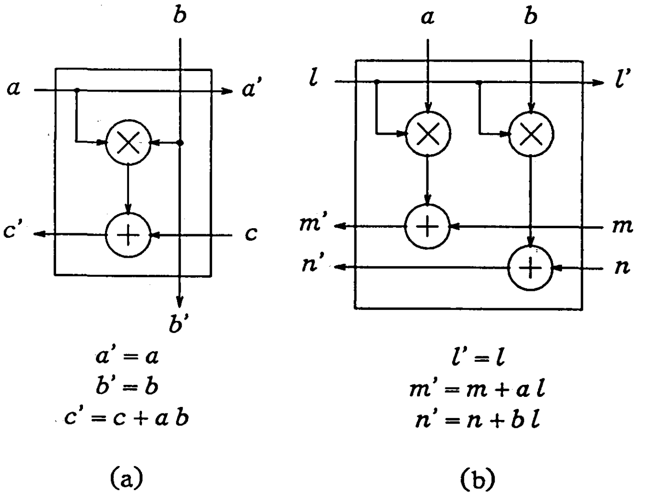
Since effective error detecting (or detecting and correcting) schemes, such as parity, Hamming codes [16] and alternate data retry [17], exist for communication lines and memories, failures in the communication lines and memories can be readily detected (or detected and corrected) by those methods. We therefore concentrate on detecting and correcting errors due to the failure of each computation unit, e.g., an adder or a multiplier. However, faults in the communication lines will also be specifically discussed (to allow the fault model to cover faulty lines and registers) in this paper.

III. LINEAR CELLS AND THE LINEAR PROPERTY

Through an extensive study of systolic schemes, we found an interesting feature which is common to most existing numerical systolic arrays proposed for Digital Signal Processing (DSP), matrix-related operations, polynomial operations, etc. That is, each Processing Element (*PE*) in the repetitive part of the systolic array is itself a linear system (we call it a *linear cell* in the following discussion). As an example, the inner product cell used in matrix multiplication is a linear system. Figure 1(a) shows the function of the inner product cell. Note that, to simplify the discussion, input and output buffers are not shown in this diagram. If we use L to denote this linear system, then the input vector and coefficient of this linear system L can be identified as follows: (b, c) is the input vector of L, and a is the coefficient of L (will be explained later). In the following discussion, L_a is used to represent a linear system L with coefficient (or coefficient vector) a. When we say that a is the coefficient (or coefficient vector, when a contains more than one value) of the linear system L, we mean that if a is kept fixed, and X_1 and X_2 are two input vectors (we use the term vector to specify that it may contain more than one value) to L, then

$$L_a(m_1X_1+m_2X_2)=m_1L_a(X_1)+m_2L_a(X_2),$$

where, m_1 and m_2 are any real numbers. (Notice that, in this paper, when we use the term *PE* we normally mean the *PE* in the repetitive part of the systolic array (instead of the irregular boundary *PE*).) By using this terminology, Figure 1(a) is shown to be a linear cell as follows:



$a' = a$
$b' = b$
$c' = c + a\,b$

$l' = l$
$m' = m + a\,l$
$n' = n + b\,l$

(a) (b)

Figure 1. Example of Linear cells.

For any real numbers m_1 and m_2, and input vectors (b_1, c_1) and (b_2, c_2):

$$\begin{aligned} &L_a(m_1(b_1, c_1)+m_2(b_2, c_2)) \\ &=L_a(m_1b_1+m_2b_2, m_1c_1+m_2c_2) \\ &=m_1c_1+m_2c_2+a(m_1b_1+m_2b_2) \\ &=m_1(c_1+ab_1)+m_2(c_2+ab_2) \\ &=m_1L_a(b_1, c_1)+m_2L_a(b_2, c_2). \end{aligned}$$

This shows that L_a is a linear system. Note that, given the functional description of a linear cell, there may be different ways to identify the input vector and the coefficient vector. For example, in Figure 1(a), we can either say that a is the coefficient and (b, c) is the input vector, or we can also say that b is the coefficient and (a, c) is the input vector. In other words, we can also show that L_b is a linear system with input vector (a, c). Another example of a linear cell is the *PE* used in the design of Infinite Impulse Response (IIR) filters (shown in Figure 1(b)) [15], where l is the coefficient of the linear cell, and (m, n, a, b) is the input vector. Although each linear system L can be of any form of a linear function, say, a differentiator, an analog linear system, etc., in this paper, we will focus on the situation where each L consists of only multipliers and adders, because this is the case with most existing numerical systolic arrays.

A property exists for linear systems (we call it the linear property):

Linear Property :

$$L_a(m_1X_1)+L_a(m_2X_2)+\cdots+L_a(m_nX_n)=L_a(\sum_{i=1}^{n}m_iX_i),$$

where, each X_i is an input vector of L_a (i.e., a linear system L with coefficient (or coefficient vector) a), and each m_i is a real number. Based on this linear property, a word level encoding scheme (we call it the *linear property encoding*) is proposed as follows:

Linear Property Encoding :

In this encoding scheme, each $L_a(m_iX_i)$ is calculated by a distinct *PE* and is accumulated to get $\sum_{i=1}^{n}L_a(m_iX_i)$ (i.e., by adding extra variables to pass through the systolic array to get this value). A different *PE* is used to compute $L_a(\sum_{i=1}^{n}m_iX_i)$. Finally, $\sum_{i=1}^{n}L_a(m_iX_i)$ is compared with $L_a(\sum_{i=1}^{n}m_iX_i)$. Any inconsistency will reveal that there exists a faulty *PE*. Since roundoff errors may occur during the computation, a relative small difference must be allowed in checking for equality, even though we will imply mathematical equality in equations and lemmas by using the equal sign. Notice that if each $L_a(m_iX_i)$ is not calculated by a distinct *PE*, it is possible that an error may be masked. For convenience of description, we call the requirement that each $L_a(m_iX_i)$ be calculated by a distinct *PE*, the *independence goal*. Note that during the normal operation, we set the value of each m_i to be 1. Different values of m_i will be used in the fault location phase discussed in Section VI.

In order to obtain fault tolerance, we are trying to encode data into the form of a linear property encoding, and trying to

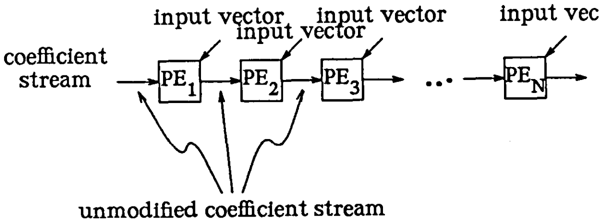


Figure 2. Diagram to show the coefficient stream passing through the array.

achieve the independence goal at the same time.

IV. CED TECHNIQUES FOR ONE-DIMENSIONAL SYSTOLIC ARRAYS

Another feature common to most existing numerical systolic arrays is that the coefficient stream for each *PE* (which is a linear cell) passes through the whole array without being modified. For example, in Figure 1(b), $l' = l$. This situation is shown in Figure 2, where the coefficient stream passes from the left end to the right end of the array without being modified. At each PE, there will be an input vector. Note that each value of the input vector can come from an adjacent *PE*, external input, or an accumulator inside the *PE*. For example, if each *PE* is the same as in Figure 1(b), then the l stream is the coefficient stream which passes through the array without being modified, and the input vector is (m, n, a, b). A CED scheme can be designed for those systolic arrays which satisfy the following two conditions (these are the two features common to most numerical systolic arrays):

Condition 1:

Each *PE* in the repetitive part of the systolic array is a linear cell.

Condition 2:

The coefficient stream passes through the array without being modified.

As was discussed in the previous section, there may be different ways to identify the input vector and coefficient vector. For example, if each *PE* in Figure 2 is like that of Figure 1(a), then we will choose the a (instead of b) to be the coefficient because it passes through the array without being modified.

The CED scheme using the linear property encoding is described as follows:

If v is a coefficient vector (we use the term *vector* to specify that it may contain more than one value) of the coefficient stream, then, when v reaches PE_i, PE_i becomes L_v (i.e., a linear system L with coefficient v). Suppose that v meets input vector X_1 at PE_1 to generate $L_v(X_1)$, meets input vector X_2 at PE_2 to generate $L_v(X_2)$, ..., meets input vector X_N at PE_N to generate $L_v(X_N)$. During the operation, each $L_v(X_i)$ is accumulated to generate $\sum_{i=1}^{N} L_v(X_i)$. By using a distinct (extra) PE_i to calculate $L_v(\sum_{i=1}^{N} X_i)$ and compare it with $\sum_{i=1}^{N} L_v(X_i)$, we can achieve CED through the linear property encoding (with each $m_i = 1$). Note that the independence goal is also achieved by using a distinct *PE* to calculate each $L_a(X_i)$.

Therefore, it is clear that we need an extra *PE* to calculate $L_v(\sum_{i=1}^{N} X_i)$, and, thus, we also need to pass the vector $\sum_{i=1}^{N} X_i$ to this extra *PE* for the calculation of $L_v(\sum_{i=1}^{N} X_i)$. Finally, we will also have to pass the vector $\sum_{i=1}^{N} L_v(X_i)$ to this extra *PE*, and compare it with $L_v(\sum_{i=1}^{N} X_i)$ to achieve the CED through the linear property encoding. All of these extra operations are performed by adding extra variables to pass along with the coefficient stream. In most cases, the number of extra variables can be reduced. by using the specific structure of a systolic algorithm.

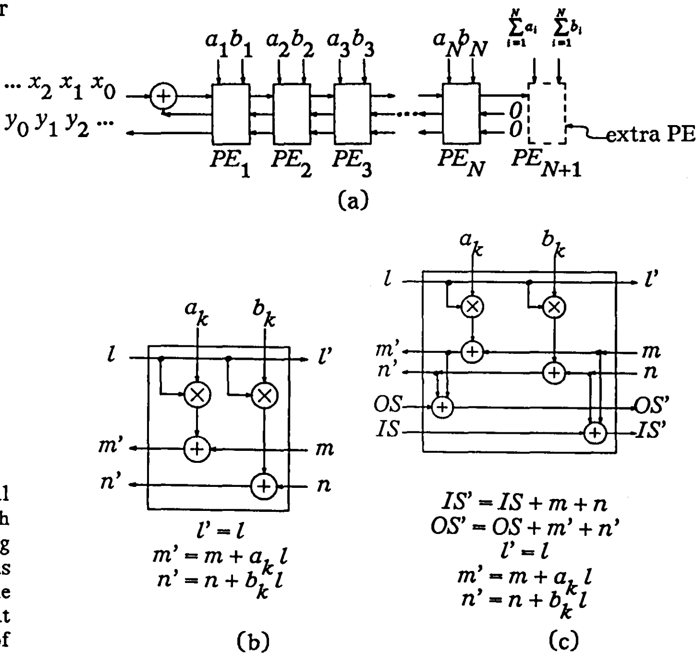

Figure 3(a). A systolic array for the IIR filter, (b). PE used in the original (non-CED) design, (c). PE used in the CED design.

Details are shown in the following examples:

EXAMPLE 1: Infinite Impulse Response (IIR) filter.

A systolic array for an Infinite Impulse Response (IIR) filter defined by the difference equation

$$y(k) = \sum_{m=1}^{N} x(k-m)b(m) + \sum_{m=1}^{N} y(k-m)a(m)$$

is shown in Figure 3(a), and the function of each *PE* is shown in Figure 3(b). This design is by S.Y. Kung in [15], which is derived from the signal flow graph in [18]. Note that in this design $b(0)$ is assumed to bo zero. However, if $b(0)$ is not zero, we can slightly modify the left boundary part (simply add a multiplier and an adder), and the *PE*s at the regular part of the array remain the same. Detailed procedures for transforming a signal flow graph into a systolic array are discussed in [15]. We add an extra *PE* (shown by the dashed box PE_{N+1}) at the right end of the array for the CED design. The procedure to incorporate CED into this IIR filter is described in the following three steps:

Step 1: Check the function of each *PE* to make sure that it is a linear cell. In this example, it is easy to show that this condition is true.

Step 2: Identify which variables form the coefficient vector or the input vector of each *PE*, and see if the coefficient stream passes through the array without being modified. In this example of the IIR filter, the coefficient for each *PE* is l, and the input vector is (m, n, a_k, b_k). Moreover, the coefficient stream (i.e., l stream) flows through the array from left to right without being modified.

Step 3: Add extra variables and the extra PE to the systolic array.

The extra variables and the extra PE are added as follows. Consider l_p which is a coefficient of the l coefficient stream. It is clear to see that l_p passes through the array without being modified. When l_p reaches PE_k, PE_k becomes L_{l_p} (a linear system L with coefficient l_p), and the input vector is (m_k, n_k, a_k, b_k), such that

$$(m_k', n_k') = L_{l_p}(m_k, n_k, a_k, b_k).$$

Here, m_k and n_k are used to represent the m-value and n-value which l_p meets at PE_k, and m_k' and n_k' are used to represent the m'-value and n'-value generated at PE_k (when l_p is at PE_k). Now, since that l_p meets (m_1, n_1, a_1, b_1) at PE_1 to generate (m_1', n_1'), meets (m_2, n_2, a_2, b_2) at PE_2 to generate (m_2', n_2'), ..., meets (m_N, n_N, a_N, b_N) at PE_N to generate (m_N', n_N'), the independence goal has been achieved. Then according to the linear property encoding discussed in Section III, we have to compare

$$L_{l_p}(m_1, n_1, a_1, b_1) + L_{l_p}(m_2, n_2, a_2, b_2) + \ldots + L_{l_p}(m_N, n_N, a_N, b_N)$$

with

$$L_p(\sum_{i=1}^{N}(m_i, n_i, a_i, b_i)).$$

Here,

$$L_{l_p}(m_1, n_1, a_1, b_1) + L_{l_p}(m_2, n_2, a_2, b_2) + \ldots + L_{l_p}(m_N, n_N, a_N, b_N)$$

$$= \sum_{i=1}^{N}(m_i', n_i')$$

$$= (\sum_{i=1}^{N} m_i', \sum_{i=1}^{N} n_i'). \qquad (1)$$

On the other hand, $L_{l_p}(\sum_{i=1}^{N}(m_i, n_i, a_i, b_i))$ is equal to

$$(\sum_{i=1}^{N} m_i + (\sum_{i=1}^{N} a_i) l_p, \sum_{i=1}^{N} n_i + (\sum_{i=1}^{N} b_i) l_p). \qquad (2)$$

Thus, if the linear property is satisfied, vector (1) will have to be equal to vector (2). However, it will be shown in this example that it is easy to implement the PE such that any faulty adder or multiplier will cause at most one component of vector (1) or vector (2) to become erroneous. Therefore, instead of comparing vector (1) with vector (2), we can simply compare

$$(\sum_{i=1}^{N} m_i' + \sum_{i=1}^{N} n_i') \qquad (3)$$

with

$$(\sum_{i=1}^{N} m_i + (\sum_{i=1}^{N} a_i) l_p + \sum_{i=1}^{N} n_i + (\sum_{i=1}^{N} b_i) l_p). \qquad (4)$$

That is, we can simply compare the sum of the two components of vector (1) (i.e., term (3)) with the sum of the two components of vector (2) (i.e., term (4)). Therefore, it is clear that we need an extra PE to calculate term (4), and, thus, we also need to pass $\sum_{i=1}^{N} m_i + \sum_{i=1}^{N} n_i$, $\sum_{i=1}^{N} a_i$, and $\sum_{i=1}^{N} b_i$ to this extra PE for the calculation of term (4). Since each a_i and each b_i are system parameters, which are precalculated and used for a long time without being modified, we can precalculate both $\sum_{i=1}^{N} a_i$ and $\sum_{i=1}^{N} b_i$, and directly apply them to the extra PE (as shown in Figure 3(a)). Thus, we only have to pass $\sum_{i=1}^{N} m_i + \sum_{i=1}^{N} n_i$ to the extra PE for the calculation of term (4). Finally, we will also have to pass term (3) to this extra PE and compare it with term (4).

Based on the above analysis, a CED scheme for the IIR filter can be designed. Along with the clocking of each coefficient of the l coefficient stream, two new variables are added :

$$IS' = IS + m + n \ ,$$

$$OS' = OS + m' + n' \ ,$$

where IS' and OS' are the updated values of IS and OS at each PE, and the IS and OS which enter PE_1 are both 0 (see Figure 3(c)). Finally, at the right end of the array, we use an extra PE (i.e., PE_{N+1} in Figure 3(a)) to compute

$$val\,1 = IS + l(\sum_{i=1}^{N} a_i + \sum_{i=1}^{N} b_i),$$

and compare $val\,1$ with OS. Any inconsistency will reveal that there exists a faulty PE (will be shown in Lemma 1). According to the implementation of IS and OS, it is easy to show that, under the fault free situation, at PE_{N+1} (the extra PE),

$$IS = \sum_{i=1}^{N}(m_i + n_i),$$

and

$$OS = \sum_{i=1}^{N}(m_i' + n_i').$$

Note that

$$OS = \sum_{i=1}^{N} m_i' + \sum_{i=1}^{N} n_i'.$$

This is the sum of the two components of vector (1) (i.e., term (3)).

Notice that, under the fault free situation,

$$val\,1 = IS + (\sum_{i=1}^{N} a_i + \sum_{i=1}^{N} b_i) l_p$$

$$= \sum_{i=1}^{N} m_i + (\sum_{i=1}^{N} a_i) l_p + \sum_{i=1}^{N} n_i + (\sum_{i=1}^{N} b_i) l_p .$$

This is the sum of the two components of vector (2) (i.e., term (4)).

Notice that since the linear property encoding is mainly used to detect the faults in the regular part of the array, the adder at the left end of the array (see Figure 3(a)) has to be duplicated or specially designed with some other technique to make sure that it functions correctly.

LEMMA 1: In the above design, by using different adders to compute IS' and OS', if there exists a faulty multiplier or adder in the array, then we have $val\,1 \neq OS$ at PE_{N+1}.

PROOF: To satisfy the linear property, vector (1) will have to be equal to vector (2). Thus, the sum of the two components of vector (1) will have to be equal to the sum of the two components of vector (2), i.e., at PE_{N+1}, OS will have to be equal to $val\,1$. If there is a faulty multiplier or adder in PE_i (where $1 \leqslant i \leqslant N$), then either the correct value of $L_{l_p}(m_i, n_i, a_i, b_i)$ will not equal (m_i', n_i') (i.e., OS' will be erroneous), or IS' will be erroneous. Thus, either IS' or OS' (but not both) at PE_i will become erroneous. If IS' at PE_i becomes erroneous, then $val\,1$ at PE_{N+1} (the extra PE) will become erroneous. If OS' at PE_i becomes erroneous, then OS at PE_{N+1} will be erroneous. If there is a faulty multiplier or adder in PE_{N+1}, then $val\,1$ will become erroneous. Therefore, under the assumption of single computation unit fault (described in Section II), any faulty adder or multiplier will change the value of either OS or $val\,1$ (but not both) at PE_{N+1}, and results in $OS \neq val\,1$. □

Notice that the same adder should not be used to calculate IS' and OS'; otherwise, it is possible that a faulty adder will cause both IS and OS to become erroneous. Since we assume that any faulty module may result in a random output, it is possible that the error will be masked (i.e., it is possible to cause both $val\,1$ and OS at PE_{N+1} to become erroneous). However, the probability of a fault being masked due to this reason is very small (will be discussed later).

In the above discussion, we only consider the faults coming from an adder or multiplier. However, it is very easy to extend the discussion to cover the faults from the busses or interconnection lines between two computation units. Consider the PE in Figures 3(c) and 4, which is redrawn in Figure 4 with each line being labeled with a number. Notice that in Figure 4, two extra adders are shown to calculate IS' and OS' (see Figure 3(c)). Actually, there are several ways to avoid the increase of the number of extra adders. For example, the extra adders can be shared between two adjacent PEs to cut the number of extra adders to half (by using some tricky interconnections). The other way is to use the original adders to calculate IS' and OS'. For the latter case, if a transient fault occurs during the operation of an addition, then only IS' or OS' (but not both) will be faulty, thus it will be detected at PE_{N+1}. If it is a permanent fault, and if the probability of a fault being masked at a faulty PE during a single linear property checking is p, then the probability of having an undetectable fault is p^t, where t is the total number of inputs (x's). The reason that we have this value is explained as follows. Since there are t inputs (x's), there will be t linear property encoding groups. Thus the fault will have to be masked for t times. An experiment has shown that p is about 0.02. This means that, for the case where $t = 50$, the probability of having an undetectable fault is about $p^t = 0.02^{50}$, which is almost equal to zero. This shows that even if we use the original adders to calculate IS' and OS', although it is theoretically possible to have an undetectable fault, the probability of having such an undetectable fault is almost equal to zero. Moreover, it will be shown later that we can timeshare the same bus to pass l, IS, and OS. However, to simplify the discussion, we simply assume that the two extra adders and two extra busses are used as shown in Figure 4. The results are applicable to other cases (i.e., the case with no extra busses, or the case with fewer extra adders).

It is easy to prove that any single fault in lines 1, 4, 6, 9, and 10 will make m' become erroneous, which in turn causes OS' to become erroneous. Any single fault in lines 2, 5, 7, 13, and 14 will make n' become erroneous, which in turn causes OS' to become erroneous. Any single fault in lines 16, 17, 20, and 21 will also cause OS' to become erroneous. Any single fault in lines 18, 19, 22, and 23 will cause IS' to become erroneous. Since all the above line faults will cause either IS' or OS' to become erroneous (but not both), they will be detected at PE_{N+1}. Now consider the case where line 11 becomes faulty. Assume that the value at line 11 is different from the correct value by d, i.e., its value is equal to (correct value + d). Then IS' will be increased by d, and OS' will be increased by d, and this fault will not be detected. Similarly, the fault at line 15 will not be detected, either (note that line 8 and line 12 are treated similarly at the next PE). Finally, if line 3 becomes faulty in PE_k, and its value is different from the correct value by d, i.e., its value is (correct value + d), then, at PE_{N+1}, $val\,1$ will be equal to

$$(\textit{correct value} + d\,(\sum_{i=1}^{N} a_i + \sum_{i=1}^{N} b_i)),$$

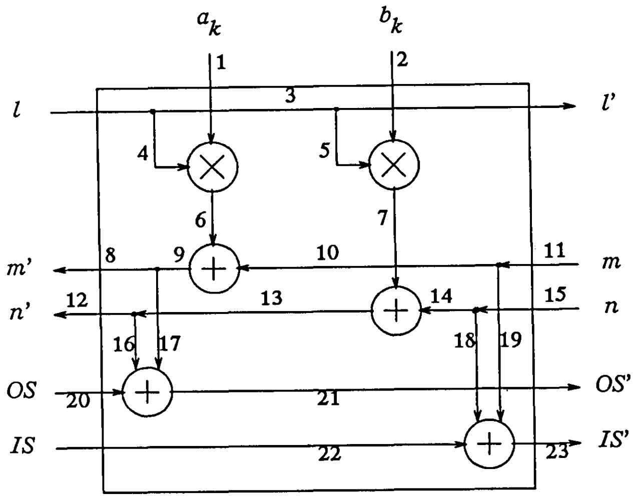

Figure 4. Circuit diagram to show the possible line faults of Figure 3(c).

while OS will be equal to

$$(\textit{correct value} + d\,(\sum_{i=k}^{N} a_i + \sum_{i=k}^{N} b_i)).$$

Therefore, it is clear to see that, normally, only when $k=1$ will a fault possibly cause an undetectable error. Thus, by specially designing the line 3 in PE_1 (such as adding a parity bit), we do not have to consider the line 3 fault in all other PEs. From this discussion, it can be seen that the only lines to which we have to apply some encoding scheme (e.g., parity bit) are lines 8, 11, 12, and 15. Faults in all other lines will be detected by the linear property encoding.

Notice that the faults in the input or output buffers (to simplify the discussion of linear property encoding, they are not shown in the figures) can be considered similarly as line faults, and are covered by the above discussion.

Since each coefficient l is multiplied by a_k and b_k and then m and n are added at each PE_k, while each IS and OS is only added once, and since l, IS, and OS are going in the same direction, we can use the same bus for the l stream to pass IS and OS by time-sharing the bus. In other words, the processing time for the value l at each PE is much longer than that for IS or OS, thus we can pass the value l and let it be processed first, and pass IS and OS subsequently by using the same bus as for the value l. Since the bus transmission time is usually very small compared with the processing time, the clock period will be almost the same. Therefore, the system throughput will also be the same. The two extra busses shown in Figure 4 can thus be avoided, that is, no extra busses are needed between two adjacent PEs. However, the adder at the left end of the systolic array has to be duplicated or specially designed with some other techniques to make sure that it functions correctly. Consider the case where each bus contains 24 bits, and a fixed point number system is used (where the layout area of an array multiplier is much larger than that of an adder), then the estimated hardware redundancy in terms of CMOS layout area for each PE is less than 5% and can be assumed to be negligible. In the case of floating point number systems, where the complexity of an adder is similar to that of an array multiplier, the redundancy ratio at each PE is about 15%. However, as is discussed previously, even if we use the original adders to calculate the IS' and OS', the probability of having an undetectable fault is almost equal to zero. Thus, we can avoid the redundancy at each PE if we use this approach. Moreover, the extra PE at the right end of the array is about half the complexity of the regular PE. Thus, the total hardware redundancy is about $\frac{1}{2N}$. Since the whole computation, including the extra PE, is pipelined, there is no time redundancy in terms of performance (i.e., the throughput is the same as before). However, if we consider the total job latency (between the time a job enters the IIR filter and the time this job leaves the IIR filter), the redundancy is less than $\frac{1}{N}$.

Another way to implement the IIR filter can be found in [19], where again each PE is a linear cell, and the coefficient stream (x, y) passes through the array without being modified. Thus a similar CED design approach can be applied.

In Figure 3(a), there are N PEs used in the IIR filter. However, in actual implementation, only $\frac{N}{2}$ PEs are needed. The reason is as follows. It is clear that for a bidirectional linear systolic array such as in Figure 3(a), there will be a zero value between any two consecutive input x's (for the sake of simplicity, we did not show it in Figure 3(a)), thus only one of two consecutive PEs will be active at any instant. Therefore a group of two PEs can share a common arithmetic unit (including multipliers and adders) without any penalty in the throughput rate. Another way to keep the processor utilization ratio equal to 1 (i.e., no idle processors during the operation) is to interleave two jobs. Similar arguments can be found in [13,14,15]. From the linear property encoding discussed previously, it should be clear that having a zero value between any two consecutive input x's or interleaving two jobs will not change our scheme at all. In other words, even with $\frac{N}{2}$ PEs (a zero value between any two x's) or N PEs (two jobs are interleaved), the linear property encoding will remain valid. That is, we still can fully utilize all the PEs without leaving any PE idle during the operation even for the case of bidirectional systolic arrays. Considering this, those schemes which duplicate the operations and compare the results of these operations to detect the faults (discussed in Section I) will certainly mean at least 100% time redundancy. □

EXAMPLE 2: Elimination of a subdiagonal of a band matrix [20].

A systolic array to eliminate a subdiagonal of a band matrix is shown in Figure 5(a). Here, we use N to represent the number of PEs in the repetitive part of the systolic array. For example, in Figure 5(a), $N = 4$ (the extra PE is not included).

The procedure to incorporate CED into this systolic array is described in the following three steps:

Step 1: Check the function (in the repetitive part of the array) of each PE to make sure that it is a linear cell. From the equation in Figure 5(b), it is easy to show that this condition is true.

Step 2: Identify which variables are part of the coefficient vector or input vector of the linear cell. In this example, the coefficient vector is (c, s), and the input vector is (x_i, y_i). The coefficient stream, i.e., the (c, s) stream, passes through the array from left to right without being modified.

Step 3: Add extra variables and an extra PE into the systolic array.

The way to add the extra variables and an extra PE is analyzed as follows. Consider a coefficient vector (c_p, s_p) which passes through the array from the left end to the right end of the array without being modified. When (c_p, s_p) reaches PE_i, PE_i becomes $L_{(c_p,s_p)}$ (i.e., a linear system L with coefficient vector (c_p, s_p)), and the input vector is (x_i, y_i). That is, (c_p, s_p) meets input vector (x_1, y_1) at PE_1 to generate (x_1', y_1'), meets input vector (x_2, y_2) at PE_2 to generate (x_2', y_2'), ..., meets input vector (x_N, y_N) at PE_N to generate (x_N', y_N'). Thus, the independence goal has been achieved. Here we use (x_i, y_i) to represent the input vector that (c_p, s_p) meets at PE_i. Thus, at each PE_i,

$$L_{(c_p,s_p)}(x_i, y_i) = (x_i', y_i').$$

According to the linear property encoding, we want to compare

$$L_{(c_p,s_p)}(x_1, y_1) + L_{(c_p,s_p)}(x_2, y_2) + \cdots + L_{(c_p,s_p)}(x_N, y_N)$$

with

$$L_{(c_p,s_p)}(\sum_{i=1}^{N}(x_i, y_i)).$$

That is, to compare

$$(\sum_{i=1}^{N} x_i', \sum_{i=1}^{N} y_i') \qquad (5)$$

with

$$L_{(c_p,s_p)}(\sum_{i=1}^{N}(x_i, y_i)).$$

Note that

$$L_{(c_p,s_p)}(\sum_{i=1}^{N}(x_i, y_i))$$

$$=(c_p \sum_{i=1}^{N} x_i + s_p \sum_{i=1}^{N} y_i, -s_p \sum_{i=1}^{N} x_i + c_p \sum_{i=1}^{N} y_i). \qquad (6)$$

However, it will be proved in this example that it is easy to implement the PE such that any faulty multiplier or adder will cause at most one component of vector (5) or vector (6) to become erroneous. Therefore, instead of comparing vector (5) with vector (6) we can simply compare

$$(\sum_{i=1}^{N} x_i' + \sum_{i=1}^{N} y_i') \qquad (7)$$

with

$$(c_p \sum_{i=1}^{N} x_i + s_p \sum_{i=1}^{N} y_i - s_p \sum_{i=1}^{N} x_i + c_p \sum_{i=1}^{N} y_i). \qquad (8)$$

That is, we can simply compare the sum of of the two components of vector (5) (i.e., term (7)) with the sum of the two components of vector (6) (i.e., term (8)). Therefore, it is clear that we need an extra PE to compute term (8), and, thus, we also need to pass $\sum_{i=1}^{N} x_i$ and $\sum_{i=1}^{N} y_i$ to this extra PE for the calculation of term (8). Finally we also need to pass term (7) to this extra PE and compare it with term (8).

Based on the above analysis, a CED scheme is proposed. Along with the propagation of each (c, s) to the right of the array, three new variables are added:

$$XI' = XI + x_i,$$

$$YI' = YI + y_i,$$

$$val\,1' = val\,1 + x_i' + y_i'.$$

This is shown in figure 5(c). Here, the XI, YI, and $val\,1$ which enter PE_1 are all 0. Finally, at the right end of the array, there is an extra PE (shown by a dashed box in Figure 5(a)). Inside this extra PE (at the right end of the array), we compute

$$val\,2 = c\ XI + s\ YI - s\ XI + c\ YI.$$

Then we compare $val\,2$ with $val\,1$, any inconsistency will reveal that there is a faulty PE (will be discussed in Lemma 2). From the implementation of XI, YI, and $val\,1$, we have, at PE_{N+1} (this is the extra PE, i.e., the dashed box in Figure 5(a)),

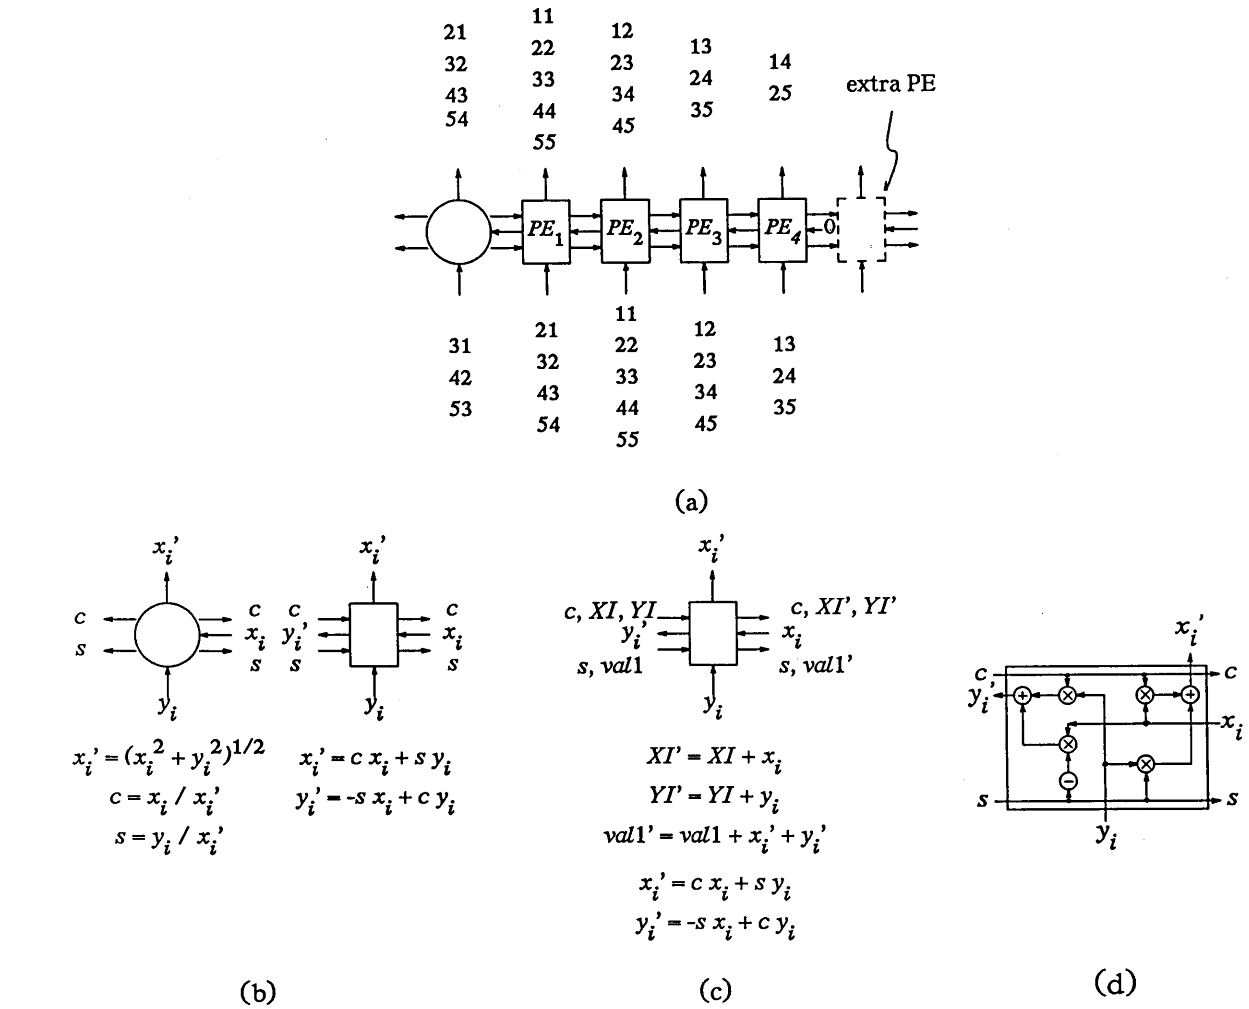

Figure 5(a). A systolic array to eliminate a subdiagonal of a band matrix. (b). PE used in the original (non-CED) design. (c). PE used in the CED design. (d). Circuit diagram for the regular PE in Figure 4(b).

$$XI = \sum_{i=1}^{N} x_i ,$$

$$YI = \sum_{i=1}^{N} y_i ,$$

$$val\,1 = \sum_{i=1}^{N} (x_i' + y_i').$$

It is easy to see that, under normal operation, *val* 1 will be equal to term (7), and *val* 2 will be equal to term (8). Note that the boundary *PE* at the left end of the array needs to be duplicated and outputs compared to make sure that it functions correctly.

LEMMA 2: In the above design, by using different adders to compute *XI'*, *YI'*, and *val* 1', if there is a faulty adder or multiplier in the array, then we have *val* 1≠*val* 2.

PROOF:

If the linear property is satisfied,

$$\sum_{i=1}^{N} x_i' + \sum_{i=1}^{N} y_i' = val\,1$$

will have to be equal to

$$(c_p \sum_{i=1}^{N} x_i + s_p \sum_{i=1}^{N} y_i - s_p \sum_{i=1}^{N} x_i + c_p \sum_{i=1}^{N} y_i) = val\,2.$$

That is, *val* 1 will have to be equal to *val* 2. By using the same argument as we did for IIR filter (due to the limited space, it will not be given here), it is easy to show that any faulty adder or multiplier will cause either *val* 1 or *val* 2 to become erroneous (but not both). Thus, we have *val* 1≠*val* 2. □

Note that the same adder should not be used to calculate *XI'*, *YI'*, and *val* 1'. Otherwise, it is possible that a faulty adder will cause both *val* 1 and *val* 2 (at PE_{N+1}) to become erroneous. Since we assume that a faulty unit will result in a random output, it is possible that the error will be masked. However, the possibility of a fault being masked due to the reason that we use the same adder to calculate *XI'*, *YI'*, and *val* 1 is very small as is discussed in the example of IIR filter. By using the same approach to analyze the communication lines as we did for the previous IIR filter example, we can show that only some lines need to be treated by a coding scheme (e.g., parity bit). All other line faults will be detected by the linear property encoding at PE_{N+1}. Due to limited space, this analysis will not be shown

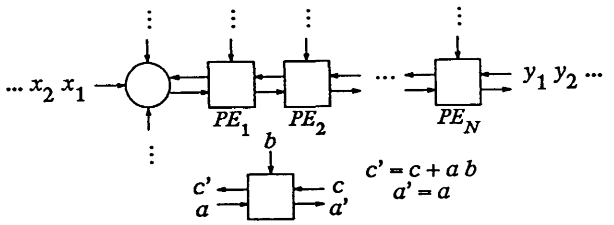

Figure 6. A systolic array to solve linear systems.

here.

Since each coefficient vector (c, s) will need four multiplications and two additions in each *PE*, while each *XI*, *YI*, and *val* 1 just does one addition in each *PE*, we can time-share the busses for the (c, s) stream to pass *XI*, *YI*, and *val* 1 as discussed in the example of IIR filter. However, the boundary *PE* (whose structure is different from all other *PE*s) must be duplicated or specially designed to make sure that it functions correctly. Generally speaking, the hardware redundancy is about $\frac{2}{N+1}$. The time redundancy in terms of performance is almost zero (i.e., the throughput is the same as before). However, if we consider the total job latency (between the time a job enters the systolic array and the time this job leaves the systolic array), the redundancy is less than $\frac{1}{N}$. □

Example 3: Solving linear systems [14].

The systolic array to solve this problem is shown in Figure 6. Here, each *PE* is again an inner product cell (which has been shown to be a linear cell), and the a stream is the coefficient stream flowing from the left end to the right end of the array without being modified. Therefore, the same scheme as in the previous examples can similarly be applied to this example. □

From the above examples, we know that the key point of the CED design is that each *PE* has to be a linear cell, and coefficient stream flows through the whole systolic array without being modified. The question arises as to whether this will become a serious restriction to the above design. The answer is no, since most all the existing systolic arrays for numerical computations do share this common feature. In other words, the design proposed in this section can be similarly applied to many other systolic algorithms, including those for convolution [21], Finite Impulse Response (FIR) filter [22], matrix multiplication [14], polynomial multiplication [23], polynomial division [23], polynomial evaluation [24], Kalman filter [25], etc.

V. CED FOR TWO-DIMENSIONAL SYSTOLIC ARRAYS

The key point in designing a CED for two-dimensional systolic arrays is to partition the array by rows or by columns, and to let each row or each column function like a one-dimensional systolic array which has been discussed in Section IV.

Example 4: LU decomposition [14-15].

In LU decomposition, a given matrix C is decomposed into $C = A*B$, where A is a lower- and B is an upper-triangular matrix. The recursions involved (from [15]) are

$$c_{ij}^{(k)} = c_{ij}^{(k-1)} - a_i^{(k)} * b_j^{(k)},$$

where

$$a_i^{(k)} = \frac{1}{c_{kk}^{(k)}} c_{ik}^{(k-1)},$$

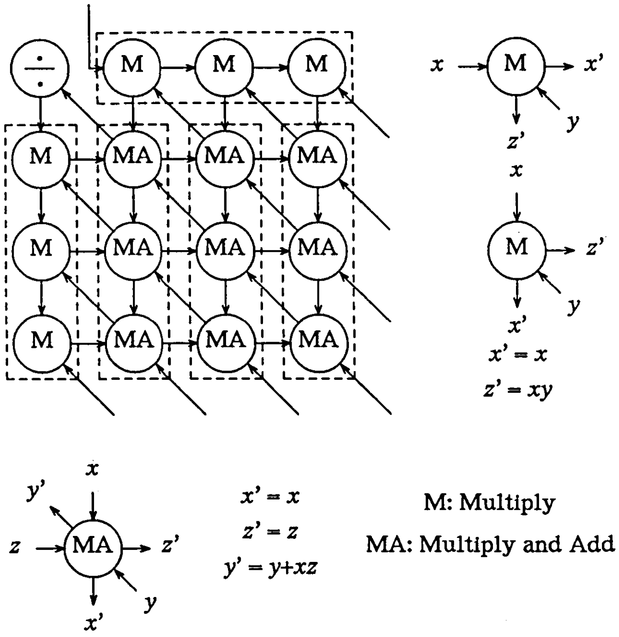

Figure 7. A systolic array to solve LU decomposition.

and

$$b_j^{(k)} = c_{kj}^{(k-1)},$$

for $k = 1, 2, \ldots, n$; $k \leqslant i \leqslant n$, $k \leqslant j \leqslant n$.

The systolic array for the above iteration is shown in Figure 7 [14-15]. The whole n by n array is divided into n columns and one row, each of which is identified by a dashed box, where each *PE* is an inner product cell (which has been shown to be a linear cell) and an unmodified coefficient stream flows through each one-dimensional systolic array (shown by the dashed box). Therefore, the scheme proposed in the previous section can be individually applied to each of these one-dimensional systolic arrays. Since the divider at the left top of the array does not contain the same structure as the others, we will have to duplicate it. The hardware redundancy is about $O(\frac{1}{n})$. The time redundancy in terms of the performance is almost zero (i.e., the throughput is the same as before). However, if we consider the job latency, the redundancy is less than $\frac{1}{n}$. □

Example 5: Orthogonal Triangularization [26].

A systolic array to perform orthogonal triangularization is shown in Figure 8 (x' is the updated value of x), where each dashed box denotes a one-dimensional systolic array, with each *PE* being a linear cell and with an unmodified coefficient stream flowing through each one-dimensional array. Thus, by using the same scheme as for one-dimensional systolic arrays, a systolic array with CED for orthogonal triangularization can be designed. Notice that all the boundary cells (which are not linear cells) represented by circles should be duplicated to make sure that failures in them will be detected. □

Other examples to which the scheme proposed in this section can similarly apply include QR decomposition [27], least square minimization [28-29], eigenvalue computation [30], two-dimensional convolution [31], etc.

Before finishing our discussion of CED, one thing should be especially noted; that is, even though all the above examples in Sections IV-V are confined to the discussion of systolic arrays,

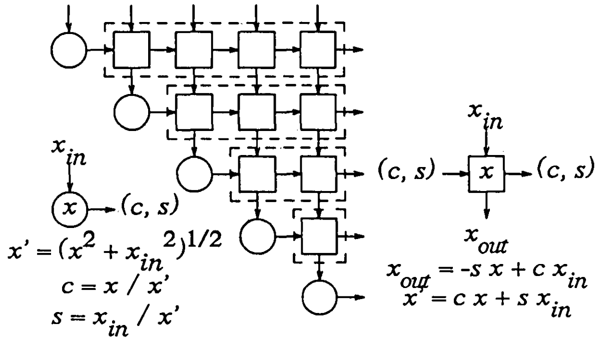

Figure 8. A systolic array for the orthogonal triangularization.

the same scheme can be similarly used to more general cases, for example, wavefront array processors [32], and general multiprocessor systems. The reason that we specifically emphasized systolic arrays is that it is quite difficult to design systolic arrays with CED capability due to their local interconnections, simple structure for each *PE*, and synchrony of the whole system.

VI. FAULT LOCATION AND RECONFIGURATION

A successful recovery from a hardware failure is essential to ensure continuous system operation. To achieve this i.e., to design a fault-tolerant system, three things have to be done: (1) Concurrent Error Detection (CED), (2) fault location, and (3) error correction and reconfiguration. Among these three steps, CED is the most important factor which affects the performance of the whole system, because it is necessary to continuously check for errors during the normal operation of the system. Therefore, it is always important to use as little time redundancy as possible during the CED phase. However, most existing schemes proposed [11-12][33] use duplicated operation as described in Section II. This will take too much time redundancy even under the fault free condition and may not be suitable for high performance special-purpose machines. Other schemes such as Triple Modular Redundancy (TMR) with voting [34] and Hybrid Redundancy [35] require several times the hardware of a single machine. However, the CED design proposed in the previous sections requires overheads of only about $O(\frac{1}{n})$ in hardware redundancy, and almost zero in time redundancy (the throughput is the same as before).

Fault location, correction, and reconfiguration in our design are performed only after an erroneous signal has been detected. Upon detecting the erroneous signal, we can choose one of the following two methods to recompute and obtain the correct result, while identifying the faulty unit.

Method 1: Recompute the operation by adding a weighted linear property encoding to pass along with the normal linear property encoding, i.e., without weighting. Note that during the normal CED phase, the linear property encoding is

$$L_a(X_1)+L_a(X_2)+\cdots+L_a(X_n)= L_a(\sum_{i=1}^{n} X_i),$$

where a is a coefficient vector flowing through the array, and X_i is an input vector to PE_i which meets a at PE_i during the propagation. That is, the weighting for each term is 1. Now, we have a weighted linear property encoding passing along with the normal encoding. In other words, the weighted linear property encoding

$$L_a(w_1X_1)+L_a(w_2X_2)+\cdots+L_a(w_n X_n)= L_a(\sum_{i=1}^{n} w_i X_i),$$

is also applied.

For the convenience of description, we again take the IIR filter as an example. At each PE_i (where $1 \leq i \leq N$), add four variables to pass along with the l coefficient stream, i.e.,

$$IS' = IS + m + n ,$$

$$OS' = OS + m' + n' ,$$

$$NIS' = NIS + w_i (m + n),$$

$$NOS' = NOS + w_i (m' + n').$$

At the extra *PE* (at the right end of the array) and its adjacent *PE*, we compute

$$IS + l(\sum_{i=1}^{N} a_i + \sum_{i=1}^{N} b_i) \tag{9}$$

and compare it with *OS*, and compute

$$NIS + l(\sum_{i=1}^{N} w_i a_i + \sum_{i=1}^{N} w_i b_i) \tag{10}$$

and compare it with *NOS*. Suppose PE_k $(1 \leq k \leq N)$ is faulty, the amount of difference detected with the first comparison is D_1, and the amount of difference for the second comparison is D_2. Then it can be shown that $D_2 = w_k D_1$. Thus, by dividing D_2 by D_1 we can get w_k. Therefore, if we choose $w_1 w_2 \cdots w_N$ to be N distinct values, then as soon as we get the value w_k, we can identify the faulty *PE*. However, the calculation of term (9), term (10), and the subsequent comparison should be performed by two different *PE*s (e.g., PE_{N+1} and PE_N), and the results are compared to make sure that the operation is correct. Thus, if PE_{N+1} becomes faulty, it will be detected. This finishes the fault location phase. Immediately following the fault location phase, we can simply bypass the faulty *PE* by using the schemes shown in [2-7][36-37] and continue the operation (of course, the last job should be recomputed).

Method 2: Each single operation is performed by two adjacent *PE*s and compared to each other to locate the fault. Then, continue the operation as described in Method 1.

Therefore, through either Method 1 or Method 2, the system can resume its normal operation, after bypassing the faulty unit.

VII. CONCLUSION

Low overhead fault-tolerant schemes have been proposed, which are applicable to most existing numerical systolic arrays. Partitioned by rows or by columns, two-dimensional arrays are similarly treated as one-dimensional arrays.

By using the schemes proposed in this paper, the function of each *PE* remains unchanged (except for the added variables) after becoming a fault-tolerant systolic array. Moreover, the structure of the systolic array is almost the same as before. All the designs proposed in this paper are based on optimal systolic arrays; therefore, the fault-tolerant systolic arrays are also optimal. All the schemes proposed in this paper can be readily extended to wavefront array processors and general multiprocessor systems.

Abstract

This paper presents the design analysis and tradeoffs that drove the design of a very high speed backplane interconnect in a new, tightly-coupled multiprocessor system. The involvement of cache and memory subsystem designs with the interconnect architecture are explored. The various tradeoffs in arbitration techniques and bus protocols are analyzed. In addition, a discussion of atomic operations in a multiprocessor environment are covered. Finally, an innovative technique for interrupt vector handling in a multiprocessor system is described.

Introduction

Through improving technology and innovative CPU architectures, the performance capability of modern computing systems is growing at a rapid pace. As the CPU's computing capabilities increase, the rest of the system's requirements tend to scale up with it. The physical and virtual memory capacity, the I/O bandwidth, and the secondary storage traffic generated all increase.

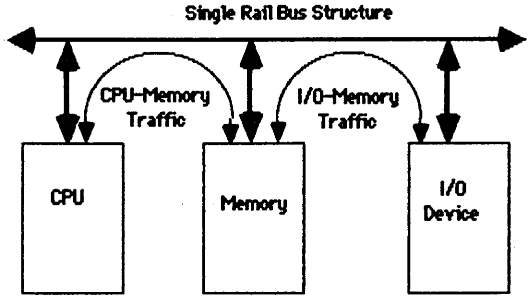

Figure 1 - The Von Neumann Bottleneck

These developments aggravate the traditional Von Neumann bottleneck between the Central Processing Unit (CPU) and the program/data memory subsystem, illustrated in figure 1. Current trends in computer architecture are towards multiprocessors, and in particular tightly-coupled multiprocessors, where many CPUs share a common memory subsystem. Tightly-coupled systems increase the pressure on the bottleneck by creating even higher memory bandwidth requirements, as illustrated in figure 2. In addition, a common memory computer system which contains more than one CPU complicates memory contention logic because there is now a need to arbitrate fairly among the many CPUs, as well as among the I/O devices accessing memory.

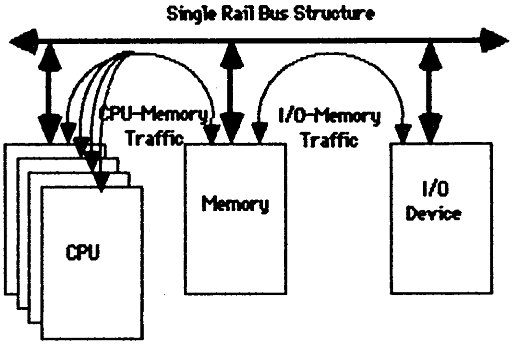

Figure 2 - The Von Neumann Bottleneck in an Mp System

The traditional method for addressing this bottleneck involves the design of a memory subsystem, an interconnect, and module interfaces (CPU and I/O) that will support the theoretical bandwidth required. In the design of the Nanobus,

CH2345-7/86/0000/0410$01.00 © 1986 IEEE

the interconnect used in the Encore Multimax (a tightly-coupled multiprocessor), a different approach was taken. The Nanobus interconnect and the memory subsystem were actually designed as a single, integrated unit.

The Multimax - An Architectural Overview

The Multimax is a classic tightly-coupled, Multiple Instruction Multiple Data (MIMD) computer system. Figure 3 illustrates its architecture.

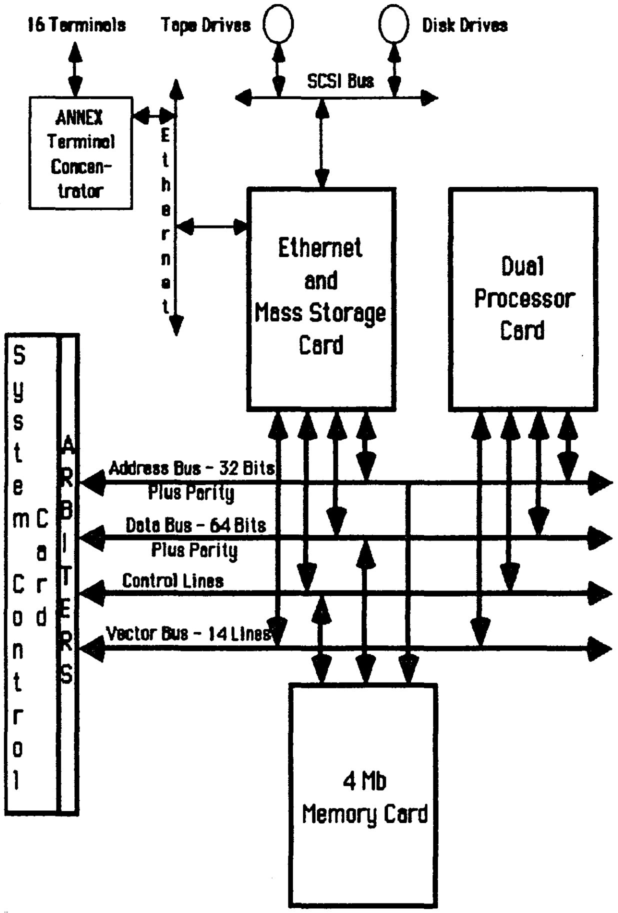

Figure 3 - The Multimax System

To reduce project risk and enhance time to market, the design philosophies of the Multimax were simplicity of hardware design and ease of program development; features which created programing restrictions were avoided whenever possible. Some examples of hardware features implemented with this goal of simplicity are:

- A bus design that is non-multiplexed and very wide, rather than employing complex (and potentially error prone) protocols, and multiplexing addresses and data.
- Complete parity protection on every operation and memory element in the system, to help detect any design problems.
- Identical bus interfaces on all modules in the system, so that only one interface type needed to be designed and debugged.

Some system features implemented to provide the simplest software interface possible are:

- Caches which were made software transparent, so cache concurrency was always handled by the hardware.
- Semaphores which were implemented to allow their placement anywhere in physical memory, not to restrict them to certain special regions or to restrict their number.
- Hardware which was designed to allow load leveling and directing of interrupt vectors to the "most interruptible" CPU.

All Multimax mass storage operations are handled through an intelligent Ethernet/Mass Storage Card, which needs only high level commands. All terminal traffic interfaces to the Multimax from an Ethernet connection through an intelligent terminal concentrator box called the Annex. Each Annex interfaces with up to sixteen simple RS-232 type terminals.

Memory Subsystem Design

In most new supermini computers, the memory subsystem usually consists of a single memory controller with multiple attached memory array cards. The former contains all of the bus interface and control logic, and the latter contains only arrays of memory chips with some driver/receivers. The problem with such an architecture lies in the contention that occurs for the single controller. The VAX family, from the 11/750 on up, uses buffering and FIFOs to reduce the busy state of the controller. However, this technique is valuable only for a system where one or two CPUs are generating traffic. In a large, tightly-coupled multiprocessor, these techniques would prove inadequate for handling the high volume of memory traffic generated.

Cycle Number	1	2	3	4	5	6	7
CPU	Request and Grant Cycle	Transfer Address	If Write Operation, Transfer Write Data		Receive Accept or Reject Response	Retry Request and Grant Cycle	Transfer Address
MEMORY			Decode Address	Send Accept or Reject Response	Return Read Data		

Figure 4 - CPU and Memory Data Transfer States

Examining the problem yields the following analysis: Since the lowest indivisible level in the memory subsystem is really one row of RAM chips, it is ideally at that level only that one would want contention to occur. Therefore, the ideal memory subsystem would have one controller and bus interface per row of memory chips. This would allow the maximum overlapping of memory operations since each bank could cycle independently. Unfortunately, this is also clearly the most expensive solution. In compromising between these two extremes, by grouping just a few rows of memory chips on each controller, one can achieve a reasonable tradeoffs between cost and contention. The current Multimax memory subsystem groups four rows of RAM chips per controller, and builds a memory subsystem out of multiple cards, each of which contains its own controller. Note that this very much mirrors the traditional mini-computer memory architecture, where each memory card contained its own controller.

The design of the memory subsystem had to insure that the memory subsystem and the Nanobus would function as a single, synchronous unit. The usual synchronizer delays, bus interface protocol overhead, and general mismatch in performance between the RAM controllers and the bus had to be avoided. The solution was to have the memory cards actually derive all of their internal clocks from the Nanobus itself, and they therefore run completely synchronous to the bus. This not only eliminates any lost access time due to synchronizer delays (which would be present if the memory was clocked asynchronously to the bus), but also makes memory access time deterministic. As a result, the bus protocol on the Nanobus was designed specifically around the ability of a memory controller using 150 nsec access time RAMs to receive addresses, validate them for both range and parity errors, and respond. As can be seen in figure 4, the bus protocol allows for the transfer of an address in cycle 2 and, if a write operation is being performed, the write data in cycle 3. Both are checked for range and parity errors, and the internal state of the memory card is checked to see if the requested bank is available. If all these tests are passed, an accepted signal is returned in cycle 4. If a read operation has been requested, and a refresh or a bank busy condition has not occurred, the data will be ready for return in cycle 5. As can be seen from the figure, memories can cycle every four bus cycles. The Multimax supports data transfers at the full bus bandwidth by supporting four way interleaved memories.

By designing the bus protocol to match the memories, and by running the memories synchronously to the bus, the memory system functions as a direct extension of the bus. This yields the optimum performance interface between the memory subsystem and a CPU or I/O card.

Nanobus Structure

The Multimax's Nanobus is designed to support eight memory and twelve requester (CPU or I/O) modules for a total of twenty interfaces. The target bandwidth for the Nanobus was 100 Mb per second to allow for a minimum of a five year product life, and to support very high bandwidth custom modules, such as high speed video interfaces, array processors, and custom compute engines.

It was intended that 100 Mb per second be the actual data transfer rate through the system, not just a theoretical protocol limit, i.e. using zero access time memories. To insure support for such a transfer rate, a data path width of eight bytes (64 bits) would have to be clocked at 12.5 Mhz. However, maintaining the 100Mb data transfer rate on a single bus would not allow time slots for multiplexing addresses and data, so separate address and data buses are used. The physical address space of the Multimax is four gigabytes (2^{32}), so the Address Bus contains 32 bits of address. Even interrupt vectors do not contend for the Data Bus - there is a separate 10 bit wide bus dedicated to the transfer of vectors.

The technologies that made the Nanobus speeds possible are the new Advanced Schottky and Fast technologies. Bidirectional bus data signals are driven by 74AS652, and most other tri-state bus signals are driven by 74AS821, 841. Bus control lines are driven by 74AS821, except for open collector signals which are driven by 74AS756.

The Nanobus was designed as a pended bus, so that after a read address is transferred to the memory, the bus is released. This makes the bus available for other address/data transfers while the requester is awaiting the return of the requested read data from memory. To insure guaranteed delivery of addresses and write data, an accept/reject handshake is built in to the Nanobus so immediate confirmation of delivery is received. A rejected cycle is then automatically retried by the bus interface. However, a pended bus adds a new dimension to the traditional address/data bus. Addresses transferred to memory are typically used to identify which memory location is being read or written. But when the read data is ready to be returned by the memory to the requester, the requester has already released the bus. Therefore the data must be "addressed" back to its requester. To support this function, a second set of addresses, that of one of twelve possible requestors, is also implemented on the Nanobus. This address is referred to as the "Requester I.D.". This feature has some innovative implications when dealing with caches, as discussed later.

All address, data and protocol paths are parity protected, to insure reliability. A module receiving a parity error can reject the bus cycle, and the bus interface will retry the operation. Retrys on errors are performed automatically by the bus state machines, and are therefore transparent to the rest of the system. Although all address and data lines are tri-state, some critical control lines are open collector, including the retry signal. This is important to note because it allows any module that detects a parity or protocol error on the bus to assert signals which cause the errant cycle to be re-tried. A system with distributed caches requires this capability. Since all the distributed caches monitor the system bus for addresses of data that is locally cached, a cache must be able to cause a cycle to be retried if it detects an address parity error and therefore cannot validate the address of the transfer in process.

Distributed Cache Support

The Nanobus was designed specifically to support tightly-coupled multiprocessing. Such a system must support cache memories at each processor module to achieve acceptable performance. The Multimax integrated support for a multiprocessor's distributed caches into the system bus itself, to ensure that cache concurrency can be simply and absolutely maintained. The first Multimax system CPU modules were built using caches employing a standard write-through algorithm. A write-through cache forces all write operations to pass through the cache to main memory, regardless of whether or not the data is cached. The data in a write-through cache may be updated or invalidated, and the cache may or may not be allocated. In the Multimax system, write-through data is updated on a cache hit, and the cache is allocated on a longword write. This algorithm produced the highest cache hit ratio. Regardless, a write-through cache's advantage is that it is the simplest cache algorithm to implement from a hardware perspective. However, this scheme is less than optimal. It incurs performance penalties at the CPU level (because all write operations require bus and main memory access) and on a system level (Because all CPU write traffic appears on the system bus and at the memories).

Maintaining data consistency across the distributed caches and main memory is an absolute requirement. In order to ensure consistency, each write-through cache in the system always monitors the Nanobus for bus write operations. Write operations to main memory can create cache consistency problems since they modify the contents of main memory without explicitly modifying the potentially distributed cached copies of a location. When a main memory write is monitored to a location that is cached, the monitoring cache must update or invalidate its local copy of the data. In the Multimax design, the decision was made to invalidate the local copy, because this minimized the interference with the local CPU. Updating instead of invalidating would require the bus interface to obtain access to the CPU cache at the expense of the CPU. Simply invalidating the location requires access only to the Valid bit of the cache tag store, a feat which is much easier to accomplish because the Valid bit is just one bit. The net result of the Multimax implementation of write-through is that at any point in time there may be many copies of a memory location distributed among the many caches in the system. However, once a modification to that memory location occurs, all but two copies of the data anywhere in the system will be invalidated - the copy in main memory, and possibly a copy in the cache of the CPU performing the write.

The Nanobus also supports caches implementing a non-write through, or write-deferred algorithm. A write-deferred algorithm allows write operations to be performed only in the cache. Such an algorithm enhances the CPU and system level performance by filtering write operations from the system bus and main memory. However, a write-deferred algorithm in a multiprocessing system aggravates the problem of data consistency across the system. When a write-deferred cache allows a write operation to take place only in the cache, the cached content of the memory location now no longer agrees with the main memory location, or with any other copies of this location in other CPU caches.

This data consistency problem can be solved through implementing a concept of data ownership. One method of implementing data ownership was discussed by Dr. Goodman, and one commercial application of data ownership was implemented by the Synapse Computer Corporation in their N+1 computer system. Past solutions to the data ownership problem have been usually been complex. As an example, the Synapse N+1's implementation required extensive additional hardware. The concept of ownership was implemented with extra data bits in memory and in the caches.

The scheme planned for the Multimax involves using a "Public Read" to satisfy all cache misses. When a write operation is attempted, a "Private Read" occurs to main memory. All other caches monitoring a "Private Read" will invalidate their local copies. By performing a "Private Read", the non-write through cache now "owns" the data. Ownership is maintained through a familiar mechanism (as seen in write-through caches) - monitoring the bus for addresses that have been privately read. If a bus read is attempted by any other device in the system on a privately owned location, the monitoring cache signals the memory to ignore the pending read request.

The write-deferred cache will now access the locally modified (and therefore owned), cached data, and write it back to main memory, updating the system and ensuring consistency. On write-back to main memory, the address on the Address Bus always specifies the memory location that is being updated. During a write operation which does not transfer data ownership, the "Requester I.D.", described previously, that is supplied with the write data, is not set to match any card in the system. The data is therefore transferred only to main memory. However, during a write operation which does transfers data ownership, the "Requester I.D." is set to match the I.D. of the card whose pended read operation started the whole write back process. In this manner, the data is simultaneously, in one bus operation, returned to both the memory and the new "owner", another cache.

Bus Access Arbitration

The Nanobus consists of three primary buses - the Address Bus, the Data Bus, and the Vector Bus. Access arbitration for each of these three buses bears examining, as each presents a unique set of problems.

Access to the Address Bus by CPUs and I/O devices determines the basic "fairness" of sharing the bottlenecked resource - the memory - because data transfers to or from the memory are always stimulated by addresses. To insure true fairness in Address Bus access, the Address Bus arbiter implements a dynamically modified round robin scheme.

Once a module has been granted access to the Nanobus Address Bus, it then becomes the lowest priority module in the round robin. However, the Nanobus protocol specifies that four bus clock ticks after an address is transferred, notification of its acceptance or rejection is returned by the addressed memory. At this time, if the address has been rejected, the Address Bus arbiter dynamically re-assigns the rejected module as the highest priority module at the same time the rejected module retries its request to the Nanobus during the next bus cycle. Therefore, the module's access to the bus is guaranteed.

Once a module has been retried at least once, its asserts a signal labeled "Priority". This halts new entries to the bus request round robin until all outstanding requests have been satisfied. The priority signal ensures that modules being retried are never caught in a potential lock out situation where it is continually retried and never gets access to the memory due to other modules interference between its retrys.

The implementation of the address arbiter is also unique. It is a combination of both a centralized and a distributed arbiter. The centralized section of the arbiter decides which module is to be granted the bus according to the retry rules previously described. The distributed part of the arbiter, which exists on each module, determines when and if a module will retry its request, or whether to holdoff due to the priority signal being asserted, as well as other conditions. This split arbiter allows the advantages of both centralized and distributed arbitration to be combined. The centralized arbiter avoids the need for every module to know the external state of every other module in the system, i.e. whether any other module in the system was requesting the bus. This would have required a large number of signal lines and redundant hardware on each module. The distributed arbiter allows local decisions to be made based on the state of the local module without the need to communicate this information around the system. The resulting implementation is both fast and simple.

The Vector Bus arbiter implements the same dynamically modified round robin algorithm as the Address Bus arbiter. However, since there is no concept of a "busy memory" on the Vector Bus, the retry mechanism is meaningless and not implemented. Once granted the Vector Bus, a transfer occurs only once.

The Data Bus arbiter is much simpler than the Address Bus arbiter. The Data Bus is used by memories wanting to return read data, or by CPU's or I/O devices sending write data. Memories must request access to the Data Bus through the Data Bus arbiter. This arbiter is very simple and grants access based on fixed priority due to a module's physical position in the backplane. The requests to the Data Bus, because they are stimulated by the "fair" addresses, tend to be fair themselves, and therefore a truly fair arbiter for the Data Bus is unnecessary.

However, there are some perturbations to the fairness of the Data Bus. Nanobus protocol requires that a write address on the Address Bus be followed during the very next bus cycle by the write data on the Data Bus. It is therefore possible that a memory might be granted access to the Data Bus to return read data just as a CPU or I/O device is transferring write data on the Data Bus. Clashes on the Data Bus are avoided by having the memories monitor the type of address that is transferred on the Address Bus. If a write address is detected, a memory will abort an attempt to return read data during the next Data Bus cycle, even if it has been granted the Data Bus by the Data Bus arbiter, and thereby avoiding a clash. Another perturbation to the fairness of the Data Bus happens because of refresh conflicts at the memories, which may delay the return of read data from some memory modules.

These perturbations to fairness can result in pathological conditions whereby a low priority module (due only to physical location) can be locked out from returning its read data for an extended period of time. To overcome this case, an UNJAM signal is available to all memories. When a memory has not been able to return requested read data for several bus clock cycles following its request, it asserts UNJAM until it is able to return its data. Asserting UNJAM causes the Address Bus arbiter to suspend granting the Address Bus (this eliminates write data traffic), and all memories not already requesting the Data Bus hold off posting new requests (eliminating more read data traffic). These changes to the arbiters allow the Data Bus bottleneck to unjam and the system to clear itself.

Atomic Operations

Due to the MIMD architecture of the Multimax, all system resources are shared and can be dynamically re-assigned by the operating system. Therefore, ownership identification of every system resource must always be clear and unambiguous, and arbitration for a shared resource must always have one and only one winner. Traditional methods for ensuring only one winner is through the use of indivisible flags or software locks in main memory. An indivisible, or atomic operation on a flag location typically requires a test-and-set function.

The atomic test-and-set function allows the CPU to read the state of a lock and then set it, while guaranteeing that there are no intervening operations by other devices between the read and the set, or write, operation. If such an operation by another device were to occur, the lock could be corrupted.

In the past, there have been several basic approaches to implementing atomic operations. The simplest has been to lock the entire system, bus and memory, between the read and the write of the atomic operation. While this may be adequate on a non-pended bus, or in a system of only moderate performance, this was neither possible on the Nanobus due to its pended design, nor desired because of the performance implications of locking the entire system bus for a period of time. Other typical solutions involve creating special hardware, either in the memory system or the I/O space, that either allows artificially partitioning memory into blocks and locking various blocks of memory for the atomic operation (Synapse N+1), or allows the creation of "special" dedicated semaphores that are not in memory (Sequent's Balance). None of these solutions were deemed acceptable because they imposed software restrictions on the architecture of the operating system.

To create semaphores in the Multimax, Nanobus memories incorporate a design feature to implement atomic test and set operations <u>at the memory chip level</u>. Since the memory chip is the least divisible memory element in the memory subsystem, atomic operations at this level will by definition always be indivisible. When an address is received by a memory with an indication that the addressed byte is to be atomicly read and set, the memory conducts a read operation and returns the data to the requester. However, before it completes the memory chip cycle, it performs a write cycle and sets the contents of that byte to all ones. This performs the atomic bit test and set function without having ever locked the bus or the memory controller, and without restrictions on the software as to the number, location, or use of semaphores. The only limitations are on the composition of the semaphores, which must be an entire byte, rather than (potentially) one bit, and that the "set" condition of the semaphore be all ones.

Resetting a semaphore is by its nature atomic, since if the set technique is successful in only ever allowing one owner, only one CPU will ever clear the semaphore.

Vector Bus Vector Arbitration

The Vector Bus vector arbitration on the Nanobus is unique in that it supports two types of vector transfers. In directed vector mode, interrupt vectors are addressed to one specific module, and therefore they pass directly from one module to another. In this mode, the Vector Bus functions as a standard data transfer bus. Directed vectors are very useful for an application typified by real time requirements, where the user may want to dedicate one processor to only execute an interrupt driven task or set of tasks to minimize execution latency.

The Vector Bus also supports a second mode of operation whereby the vectors <u>themselves</u> are arbitrated for. This mode allows the broadcast of a vector to one of three software controlled classes of modules, and then allows the hardware of all modules within the selected class to arbitrate among themselves as to which module should receive the vector. This mode is very useful for interrupt services that want to be spread across more than one processor to maximize the compute power that can be applied to an event, and to allow a variable amount of compute power to be applied dynamically as needed. An example of one such operation is the handling of terminal traffic. In a large system such as the Multimax, which can support hundreds of terminals, one would want to apply varying amounts of compute power to terminal service depending on the dynamics of the load.

Arbitrating for a vector is an important feature of the Multimax system because it causes the interrupt vector always to be directed by the hardware to the most interruptible module within a software selected class. All modules capable of receiving vectors have vector FIFOs for storing received vectors until they can be processed by the CPU. The vector arbitration allows the leveling of vectors in the FIFOs among modules, i.e. the module with the least number of interrupts in its FIFO and the lowest software set priority is the candidate for the interrupt vector.

This method for arbitrating among a variable number of modules for interrupt vectors is made possible because the Vector Bus is an open-collector bus. In order to arbitrate for a vector, all modules of the selected class assert on the Vector Bus a binary number representing the number of vectors in their FIFOs, and their physical slot number. All selected modules asynchronously compare each received data line from the Vector Bus with the data that it itself is driving onto the bus. The comparison starts with the most significant bit and works towards the least significant bit.

When a mismatch of any bit is found, the module disqualifies itself from the arbitration and stops driving the Vector Bus. Only one module in the system will walk down all the Vector Bus lines with a successful comparison. (Including the physical slot number in the arbitration process breaks any ties between modules in identical classes with the same number of vectors in their FIFOs.) This comparison technique is asynchronous, and results in a settling out between all of the modules in a class, leaving one and only one winner. Since the Nanobus is a synchronous bus, this asynchronous event is allowed to occur over multiple Vector Bus cycles, and during this time the synchronous state machines controlling the Vector Bus simply wait for a winner.

This Vector Bus design yields a very high performance system capable of supporting 1.2 million directed interrupts per second, and 500,000 arbitrated vectors per second.

Conclusions

The observed behavior of the Multimax system, and the Nanobus, have to date verified the analytical model that has been presented, though so far only write-through caches have been used in the system. The current system with 20 National Semiconductor 32032 CPUs uses an average of 11% of the available bus bandwidth. The hardware and software have required little tuning to achieve nearly linear increases in performance for each additional CPU added because of the simplicity and no restrictions guidelines around which the system was designed. A twenty processor system yields over nineteen processors worth of performance. The system has been proved capable of maintaining the 100 Mb throughput that it was designed for. The architectural concept of integrating the memory and interconnect design has proven very successful.

When designing a new interconnect system, one is sometimes tempted to concentrate the solution on only the problem immediately at hand, i.e. not designing for significant future expansion. Designing a point solution will almost always lead to a simpler and cheaper interconnect, but the penalty will be readily apparent when a second or third generation product is attempted and the foundation that has been laid is found to be inadequate. While the Nanobus design goals resulted in a system whose foundation is capable of delivering nearly ten times the throughput that the current system requires, and consequently results in slightly higher cost and longer development time, the next several generations of products now have a solid foundation on which to grow. This should yield computer systems which can expand significantly in performance, yet which can be developed within a short development cycle.

About the Author

David J. Schanin received a B.S. degree in Computer Science from The City College, CUNY, in 1973, and an M.S. in Systems Engineering from Boston University in 1976. He has spent eleven years in industry, including over seven years at Digital Equipment Corp. Mr. Schanin was the founder and chief systems architect of Hydra Computer Systems, the company that was acquired by Encore Computer Corp. to build the Multimax computer system. He is currently president of Infinity Systems Inc., a consulting company specializing in in the design of multiprocessor computer systems, and high speed buses.

Mr. Schanin is an Adjunct Associate Professor at the Boston University College of Engineering, presently on leave. He is a member of the IEEE.

Optoelectronic Devices for Computing

By

Fred J. Leonberger

United Technologies Research Center
Silver Lane
East Hartford, Connecticut 06108

ABSTRACT

The status of a variety of optoelectronic devices for optical computing is reviewed. Most of these devices are useful for optical interconnects at the chip, intraboard and interboard level. Emphasis in the review will be on optical sources, detectors and switches. Materials and device technology that lead to integration with electronic devices will also be described. Finally, a brief overview of optoelectronic spatial light modulators useful for processing two-dimensional optical inputs is reviewed.

Optical techniques have a promising future in computing, with initial impact in the interconnection area.[1] This stems from problems using conventional electronics ranging from those at the chip and board level (pin-out limitations, wiring-dominated speed, loading, etc.) to the back plane (ground loops, terminating resistors, etc.). The rapid progress of optoelectronics and fiber optics can be brought to bear on these issues. Many computer companies are already installing fiber links, optical isolators, etc., and fiber optic local area networks will soon follow. Here, we will focus on recent research and development results to give an indication of future trends.

Illustrative data distribution examples from the areas of free space, guided wave and fiber optic technology are presented to show the range of optoelectronic technologies that could impact the interconnect problem. Figure 1 illustrates a free space/holographic approach. Here GaAs source arrays are hybridized with Si chips that incorporate photodetectors. This approach leads to large fan out and the possibility of dynamic interconnects if the hologram were replaced with a reflective spatial light modulator. Initial work on hologram requirements[2] as well as independent work on surface emitting lasers[3,4] has been reported. A second concept is the use of planar waveguide technology to achieve fixed but global interconnects for such problems as the perfect shuffle as shown in Figure 2. Here, source and detector arrays allow interconnections on Si wafers. Progress in this area include low-loss glass waveguides[5] and the demonstration of laser and detector arrays.[6] A third type of interconnect utilizes the high speed of GaAs electronic and optoelectronic components to time multiplex signals from an array of Si circuits, as shown in Figure 3. This method is well suited for fiber communications across large boards and between boards.

In all of the above examples, the rapid development progress of efficient optoelectronic components makes the approaches worthy of investigation. For example, lasers with efficiencies of ~ 30 percent with power dissipation of a few mW can lead to signals of 100 mW from photodiode-transimpedance amplifiers (detector quantum efficiency ~ 70%, f < 100 MHz). Only a few transitors are required for the detector circuit and subsequent amplification of logic levels, so it is not unreasonable to consider integrating such circuits where necessary in VLSI wafers and boards. These high performance devices can be combined with advanced hybridization techniques that minimize bond-lead parasitic effects. Further enhancement is possible with advances in GaAs monolithic optoelectronic integrated circuits.[7] An exciting possibility for the longer term is the monolithic integration of GaAs and Si devices on a common substrate. Much progress has been made in the past year in GaAs/Si heteroepitaxy as well as a demonstration of GaAs lasers on Si[8] and negligible degradation of Si CMOS transistors following the growth of GaAs layers and formulation of FETs on a common substrate.[9]

Integrated optic devices for switching fiber optic signals are also under development and have numerous computing applications. These switches are formed monolithically on wafers of electrooptic material using microelectronic technology. They are useful where fast (multi-GHz) low voltage (< 10 V) switching between fibers is required for single or small switch array applications. A schematic of a

CH2345-7/86/0000/0419$01.00 © 1986 IEEE

2 x 2 directional-coupler switch is shown in Figure 4. $LiNbO_3$ switches and modulators have received the most attention in recent years and are therefore more highly developed than their semiconductor parts. Drive voltage for a single device is generally < 10 V. Low insertion loss is an important parameter in designing any practical integrated optic device, and fiber pigtailed modulators with < 2 dB insertion loss (fiber-chip-fiber) have been achieved. Multiple devices integrated in the form of arrays of 4 x 4 directional coupler switches have been reported by several groups and recently and 8 x 8 switching has been demonstrated.[10] A 4 x 4 device has been pigtailed[11] and exhibited crosstalk of -25 dB, excess loss of 5 dB and switching voltages of ~ 30 V. In another area, arrays of Mach-Zahnder interferometers have been used to demonstrate analog-to-digital conversion at 4 bits and 1 Gigasample/sec, which is faster than currently achievable by electronic means.[12]

In GaAs switches, much recent progress has been made in developing low loss channel guides (~ 0.2 dB/cm at 1.3 μm) with low fiber coupling loss (up to 70% coupling efficiency). GaAs directional coupler switches with 30 dB extinction and Mach-Zehnder modulators with 3 GHz bandwidth have been demonstrated. Typical switching voltages are ~ 20V. In principal such devices can be integrated with electronic devices on a common substrate. Recently the use of GaAs/GaAlAs quantum-well devices has led to the potential of high efficiency electrooptical waveguide modulators as well as the prospect of practical all-optical switching devices. The latter would be particularly attractive in computing applications provided adequate switching contrast ratio and fan-out can be demonstrated.

The last device to be described is the spatial light modulator. This in general is a two dimensional device that allows programmed control (modulation, transmission or reflection) of each pixel. Devices under development utilize optical or electrical control. Here, we will focus on devices that use CCDs as part of the structure. Such devices are of special interest in optical processing because they allow lines of data to be scrolled (line transfer) which is attractive for a number of algorithms. Devices which are under development include those utilizing Si CCD/deformable membranes[13] and GaAs CCD/electroabsorption.[14] Figure 5 shows a schematic of one such device.

In summary, a large variety of optoelectronic devices are under development that can have important roles in computing. Initial applications are in interconnection, but the future impact will be in actual computation.

McLean, VA.22102

ABSTRACT

The operation of multiplying two matrices is one of the fundamental operations that is frequently encountered in signal processing, image processing and numerical computations. This operation can be performed by optical systems employing parallelism. This paper discusses different architectures for optical processors performing this operation. The architectures are divided into several classes according to the degree of parallelism entailed and the type of interconnections employed.

INTRODUCTION

The operation of multiplying two matrices is one of the most common operations encountered in signal processing, image processing, and numerical computation involving solutions of a system of linear simultaneous equations. This operation is mathematically defined in equation 1 below:

$$C_{ij} = \sum_{k} A_{ik} B_{kj} \qquad [1]$$

For i=1 to N and j=1 to N

In FORTRTAN , this operation can be coded by the following program:

```
    DIMENSION  A(N,N),  B(N,N),   C(N,N)
    DO 10 I=1,N
    DO 10 J=1,N
    DO 10 K=1,N
    C(I,J)  = C(I,J)  + A(I,K)  *  B(K,J)
10  CONTINUE
```

It should be noted that there are three DO loops in the program with N passes per loop. Since the operations performed in the loops are multiplication and addition, this program involves N^3 multiplications and additions. The indices I and J orrespond to the array index of the output matrix C, and the index K is the common array index for the input matrices A and B, over which summation is performed

Optical processing systems are capable of performing the operations of analog multiplication and addition in parallel between one- or two-dimensional array of positive real numbers and achieve global communication between them. This property of optics has been used in the past for signal processing and image processing operations primarily based on Fourier transforms. Recently, optical processing systems have been investigated for performing matrix operations in parallel, which will make them more widely applicable. The large variety of optical architectures reported in the literature can be classified into three different categories according to the level of parallelism:

(i) one-dimensional systems performing N operations in parallel
(ii) two-dimensional systems performing N^2 operations in parallel
(iii) two-dimensional systems employing multiplexing performing N^3 operations in parallel.

The first two categories can be further subdivided according to which of the DO loops in the program for matrix multiplication are implemented in parallel. The optical processors in each subcategory can be implemented with different technologies, such as integrated optics, acoustooptics, electrooptics etc. A further classification results when one considers which parameters - e.g. time or space, temporal or spatial frequency - are used to multiplex the operations and which are used for summation/integration. A truely comprehensive study which includes a detailed analysis of all of these variations will indeed be massive. In this paper we will briefly discuss the different optical architectures in a generic way. We will place particular emphasis on the types interconnects involved in each of these archietctures since it will high light the special advantages offered by the use of optics.

Other details can be found in the articles that are referenced at the end of the paper.

N-PARALLEL OPTICAL SYSTEMS:

The optical processor in this category perform N multiplications and/or additions in parallel. If we look at the program listing, we will get three choices for the DO loop index that we could implement in parallel with an optical system. The indices I and J correspond to the array indices of the output matrix C, and hence are equivalent for the purpose of this analysis. Hence there are two choices, (i)parallelizing the DO loop over index I (or J), and (ii)parallelizing the DO loop over index K.

(i) This choice of the DO loop index (I) leads to optically performing N multiplication in parallel and the summation over the K index and the DO loop over J sequentially. The resulting optical architecture is shown in Figure 1. This system contains a one-dimensional (1-D) spatial light modulator (SLM), a point modulator, a 1-D time-integrating detector array, and collimating optics (for signal broadcasting) and imaging optics. The basic operation that this processor performs in one clock cycle of the 1-D SLM is that of scalar-vector multiplication defined by equation 2:

$$\underline{c} \quad = \quad a\ \underline{b} \qquad [2]$$

It should be noted that this system uses an interconnection network for broadcasting in one dimension.

(ii) This choice of the DO loop index (K) leads to performin N multiplications and additions in parallel. The resulting architecture is shown in Figure 2. This system contains two 1-D SLM, a point detector, and focussing optics (for fan-in) and imaging optics. The basic operation that this processor performs in one clock cycle of the 1-D SLM is that of vector inner product defined by equation 3:

$$c \quad = \quad \underline{a}^T\ \underline{b} \qquad [3]$$

It should be noted that this system uses an interconnection network for fanning in N-data channels in one dimension.

Both of these optical architectures do not fully exploit the 2-D parallelism of optics. However, their 1-D nature allows for an integrated optic implementation that allows for higher speed operation (100 MHz) in a small and rugged package. It should also be noted that the operations described above are of interest in and by themselves for signal processing/symbolic processing operations and do not have to be considered in the context of matrix multiplications alone. The scalar-vector multiplication is is useful in calculating a weighted version of a given input and the vector-vector inner product can give a similarity measure between the two vectors to be compared.

N² -PARALLEL OPTICAL SYSTEMS

The optical processors in this category perform N² multiplications and/or additions in parallel and hence fully exploit the 2-D parallelism offered by optics. If we look at the program listing, we will get two distinct choices for the two DO loops that we can implement in parallel with an optical system. (i) this choice involves performing the DO loops over I and J index in parallel, (ii) the second choice involves performing the DO loops over I (J) and K in parallel.

(i) This choice of DO loop indices (I and J) leads to performing N² multiplications in parallel and the summation over the K index sequentially. The resulting optical architecture is shown in Figure 3. This system contains two 1-D SLMs arranged orthogonal to each other, optics for collimating and focussing simultaneously along orthogonal directions, and a 2-D time-integrating detector array. The basic operation that this processor performs in one clock cycle of the 1-D SLM is that of a vector-vector outer product defined in equation [4]:

$$C' \quad = \quad \underline{a}\ \underline{b}^T \qquad [4]$$

where C'is a rank one matrix that is NXN in dimension. It should be noted that this optical architecture uses two 1-D input arrays and yet calculates a 2-D output array. The interconnections utilized by this system are quite complex in that they involve broadcasting along one spatial dimension and fanning-in along orthogonal spatial direction. One element of the 1-D SLM encoding one element of the vector $\underline{b}$ is simultaneously accessed by N elements of the other input vector $\underline{a}$ without contention. The data path for an element of vector $\underline{a}$ retains its identity. So after being multiplied by an element of vector $\underline{b}$, it is directed to a specific location on the 2-D time-integrating detector array as shown in Figure 3. This system can be considered to be a spatially multiplexed version of the 1-D scalar-vector multiplier depicted in Figure 1.

(ii) This choice of DO loop indices (I and K) leads to performing N^2multiplications and additions in parallel and performing the DO loop over the remaining index (J) sequentially. The resulting optical architecture is shown in Figure 4. This system contains one 1-D SLM, one 2-D SLM, one 1-D non-integrating detector array, and optics for imaging/collimating on the input side and for imaging/focussing on the output side. The basic operation that this processor performs is that multiplying a column vector of matrix B by matrix A defined in equation [5]:

$$\underline{c} = A\,\underline{b} \qquad [5]$$

The interconnections utilized by this system involve broadcasting the vector $\underline{b}$ to all rows of matrix A on the input side and fanning in the product of a row of A and vector $\underline{b}$ on to a specific detector element on the output side. This system can be considered to be a spatially multiplexed version of the 1-D vector-vector inner product processor depicted in Figure 2.

The optical processors in this category do utilize the 2-D parallelism of optical systems by employing the spatial variables for multiplexing and/or for integration. These two operations are also useful in and by themselves in signal and image processing. The operation of outer product is critical in synthesizing a complicated matrix (e.g. an image) from several simple "primitive" images corresponding to rank one matrices. The vector-matrix multiplication implements a generalized linear transformation on a 1-D input. The optics utilized by these systems contains off-the-shelf components like spherical and cylindrical lenses to give different properties along the two orthogonal directions.

N^3-PARALLEL OPTICAL SYSTEM:

The optical processors in this category perform N^3 multiplications and additions in parallel. Since the matrix-matrix multiplication involves N^3 multiplications/additions this class of optical processors will perform the operation in one clock cycle of the active devices involved. Since we are performing all the DO loops in parallel, there is only one way of formulating the processor mathematically. Different architectures result, however, when designing such a system optically.

The schematic diagram of the N^3-parallel optical system is shown in Figure 5. This system uses two 2-D SLMs for inputing matrices A and B and a 2-D detector arrayfor detecting the output matrix C. The optics involved is complicated and has to be implemented via computer generated holography.

One intriguing feature of this architecture is that it employs only N^2 active elements and still performs N^3 operations in parallel. Therefore the efficiency of this architecture as a parallel processor (computational speedup / number of processing elements) is N which can be much larger than 1! In most other designs for parallel processors the goal is to achieve an efficiency of 1, indicating a linear speedup with the number of processors. This indeed represents a unique feature of optics in that it utilizes the parallel, contention free, multiple-access communication capability of optics to add an extra dimension to the computational power of a paralle processor. Since the operation of matrix-matrix multiplication is a well structured operation with little interdependance between the calculations of the elements of the output matrix, this feature of optical systems can be exploited to fullest extent to achieve superlinear speedup in a parallel architecture.

The N^3-parallel optical processor can be viewed as a multiplexed version of the N^2-parallel optical architectures. Since in the earlier section we discussed two different optical systems for those architectures, we can view the N^3-parallel architecture as multiplexed versions of either the outer product optical processor or the vector-matrix optical processor. It should be emphasized that this division is strictly for conceptual clarity and is not indicative of a deeper category.

Figure 6(a) shows the schematic diagram of an N^3-parallel optical processor viewed as N outer product optical processors that are spatially multiplexed. In the system depicted in Figure 3 the addition of the outer product matrices for calculating the output matrix C was performed by integration in time on the 2-D detector array. In Figure 6(a), all the outer products are simultaneously calculated and are therefore added by integration of N terms in space by fanning in the apropriate signals emerging from the elements of the second matrix B. Each column of matrix A is encoded by a light beam traveling at an apropriate angle so as to interact with the correct row of matrix B as indicated in Figure 3. On the output detector array, the results of the different outer products performed in parallel converge thus performing the final integration. Figure 6(a) shows the optical paths for only two outer products for clarity.

Figure 6(b) shows the schematic diagram of the N^3-parallel optical processor viewed as a spatially multiplexed version of the optical vector-matrix multiplier shown in Figure 4. In that system, the operation of vector-matrix multiplication was performed in one cycle generating one row of the output matrix C. The full answer was calculated by generating different rows of matrix C in a time-sequential fashion. In the system depicted in Figure 6(b), all rows of matrix A are available simultaneously while the matrix B is used in N different vector-matrix products simultaneously. The resultant N rows of the output matrix C are spatially separated and are detected by the rows of the output detector array. In this processor, each row of matrix A is encoded by a light beam traveling at an appropriate angle. At matrix B, all rows of A are simultaneously accesing the elements of B while keeping their distinct identity. The unique encoding of the light beam for each row of A causes the output to be separated on the detector array thus providing all rows of matrix C in parallel.

CONCLUSION

Optical processors offer the unique features of two-dimensional parallelism in the basic arithmetic operations of analog multiplications and additions and global, parallel, and contention-free communication between the two-dimensional array of simple processing elements. These features can be exploited to build optical processors for performing the general operation of matrix-matrix multiplication. In this paper, we outlined several different architectures of parallel optical processors for performing this operation with varying degree of parallelism. In each category the type of communication involved were emphasized. A unique optical architecture was described that uses the contention-free communication offered by optics to obtain a speedup of N^3 with a system containing only N^2 active processing elements.

OPTICAL REALIZATIONS OF NEURAL NETWORK MODELS

Demetri Psaltis

California Institute of Technology
Department of Electrical Engineering
Pasadena, CA, 91125

INTRODUCTION

The optical implementation of computing systems whose structure and function are motivated by natural intelligence systems is a subject that involves optical computing and neural network models for computation. These are two areas that have individually received attention in recent years and they share the common property that they promise to provide solutions for fundamental problems in computation. In the case of optical computers the limitation that is being addressed is communication. With optics it is possible to have large arrays of processing elements communicating with each other without connecting a wire between each pair. The need to provide wires for communication in an electronic circuit is perceived as a major technological limitation of VLSI [1]. The primary justification for optical computing is therefore to extend the communication capability in computers [2,3]. It is not clear however precisely how this global communication capability can be put to good use. Through free space interconnects and volume holograms we can have thousands of computing elements all talking to each other at the same time. Is it possible to do useful computation in such a system? We look at neural network models for an answer to this question.

NEURAL NETWORK MODELS OF COMPUTATION

Natural systems of intelligence are being examined as a possible source of inspiration for building computers, partially because of the persistent difficulty we have had in performing tasks such as simple pattern recognition problems. Such problems appear trivial for humans but very cumbersome for conventional computers. Moreover these problems have not become substantially easier to solve as the processing power of computers has increased and allowed them to tackle problems that are well beyond the capability of a human. There is a suspicion therefore that the way in which these problems are tackled by neural networks is fundamentally different from the way we approach these problems in conventional computers. If we understand what these differences are this will help us design better computers to solve these problems.

An electronic computer and a neural network have some morphological similarities. They both consist of a large number of simple processing elements (neurons versus gates) that are connected to each other. In both systems the individual computing elements perform simple operations but the organization of the simple elements into a large system allows complicated tasks to be performed. The most striking **difference** between a neural network and an electronic circuit in a computer is the degree of connectivity. Each neuron is connected to thousands of other neurons whereas in an electronic computer typically each gate receives inputs from few (two or three) other gates. The type of connectivity that exists in a neural network allows thousands of neurons to collectively and simultaneously influence the state of each neuron. The role of this extensive and complex communication network must play a prominent role, indeed the dominant role, in providing neural networks their computing power. Another basic difference is the role of time. In conventional computing time is paramount. The number of steps required for the execution of a program is the primary measure of complexity. The speed-up that one obtains by breaking down a problem to many smaller tasks that are executed in parallel is the driving force for most of the developments in computer architecture. Certain computations are done quickly with neural networks because they process information collectively. We draw the distinction here between parallel and collective processing. In a parallel computer a problem is decomposed into small pieces that are individually worked upon. In the computations that we envision being performed by networks, a set of neurons collectively work on the same problem. The global communications allow each node (neuron) to change its state in response to the state of the entire network. The transitions from one state to another are determined in part by the operation of the neurons themselves but principally by the connections amongst them. The **program** is stored in the communication network. Neural nets modify their structure to fit the requirements of the problem. The distinction between software development and hardware organization is almost entirely removed.

CH2345-7/86/0000/0428$01.00 © 1986 IEEE

The highly abstract neural network models which are of primary interest to us share two properties. The first is the Hebbian [4] hypothesis which states that information is stored by modifying the strength of the connections between neurons. The second is that the nonlinear operation performed by the neurons is relatively simple, often assumed to be a thresholding operation [5]. Accordingly an optical realization of a neural network model requires two main components: an array of optical nonlinear elements to simulate the action of the neurons and a system to specify the optical interconnections among the processing elements (neurons); since the connections in this case constitute the memory, they must be modifiable. A diagram of a generic optical implementation of a neural network is shown in Fig.1. We envision that the processor array will be fabricated using planar technology (most likely semiconductor technology) and thus the array of neurons is arranged on a two dimensional planar configuration. The merit of the optical approach is that the interconnections are specified externally to this plane. The three dimensional construction of the optical system is the key feature that allows us to a) fully utilize the real estate on the processor plane for the simulation of neurons and b) possibly use the volume of a nonlinear crystal to record a hologram that specifies the interconnections. In what follows we will discuss candidate emerging optical technologies for simulating neurons and their interconnections and review optical implementations of associative memories.

OPTICAL REALIZATIONS

There are three candidate device technologies for optically simulating the nonlinear mapping performed by the neurons: spatial light modulators [6], integrated optoelectronics [7], and arrays of nonlinear optical switches [8]. Spatial light modulators have been investigated for many years primarily for optical image processors. A practically useful device is not yet available, but several decvices suitable for laboratory experiments exist. Most of the SLM's can be operated in a high contrast mode, producing a two dimensional light modulation that is proportional to a thresholded version of an image, thereby simulating the action of neurons in network models that are based on threshold logic. These devices are playing an important role at this stage, because they allow us to perform meaningful experiments. They will continue to play this role in the foreseeable future but in the long term optoelectronics and nonlinear optics appear more promising.

The optoelectronic approach to simulating an array of neurons involves the integration of two dimensional arrays of detectors and light emitters (LEDs) on a single (possibly hybrid) chip. The output of each detector can then be connected via a saturating amplifier, or an appropriate analog circuit that perfroms the required nonlinear mapping, to the corresponding LED. Thus the combination of the detector, the LED, and the intervening electrical circuit comprise the neuron. There are several advantageous features of this approach. First, it is technologically the most straightforward. The integration of optical devices and electronic circuits is currently being pursued for providing optical interconnections to VLSI circuits. The devices required for simulating an array of neurons are particularly simple and regular and therefore they ought to be relatively easy to manufacture. It is worth pointing out that the only electrical connections that would be required to such an optoelectronic chip are to provide power. The second interesting aspect is the relative flexibility there is in specifying the action of the neurons by designing the electronic circuit. Probably the most difficult problem in manufacturing practical devices of this type is power dissipation. Nevertheless, we believe that optoelectronics is the technology that is most likely to provide us with devices that are practically useful for implementing optical networks.

In recent years we have seen dramatic improvements in the area of nonlinear optics that has led to numerous demonstrations of optical switching including two dimensional arrays of swithches. The major problem with these arrays at present is the very high power required to switch each element making large arrays impractical. These optical switches are intended either for optical communications or digital optical computing. Therefore most of the work in the literature deals with using these devices to implement simple Boolean gates. With these applications in mind, most of the research effort has been directed towards increasing the switching speed and this high speed operation results in exceedingly high power requirements. For a neural network simulation, speed is not essential. The time response of neurons in the brain is in the millisecond range. What is required is ever larger arrays that switch slower and thus have reduced power requirements. Therefore, with the thrust of the research in nonlinear optical switches being almost orthogonal to what is needed for the netrwork implementations, we feel that nonlinear optics will not play a significant role in this area in the near future, unless some of the research is appropriately redirected.

We now turn our attention to interconnections, the second major component of an optical network. A crucial consideration here is that we must be able to simulate plasticity, i.e. modify the interconnections. In neural net models, the strength of the interconnections is used to store the "program" and the data; it is the memory of the system. Moreover, a particularly interesting feature of many of the models is supervised learning (as opposed to software development) as well as self organization (a form of unsupervised learning). These features emerge as a result of continuous dynamic modification of the interconnections and thus optical implementations of such models also require interconnections that can be modified continuously. The second important considerations in selecting such a medium is its storage capacity, i.e. how many resolvable spots can be recorded in the area or the volume of the material. This directly determines the number of interconnections that are being simulated which in turn determines the amount of information that can be stored in the network. For the networks we envision, we would like to be able to arbitarily interconnect at least 10^4 neurons which translates to 10^8 connections. This consideration eliminates several candidates, such as spatial light modulators, from being considered as a variable dynamic interconnection medium for neural network simulations. We will discuss two separate optical technologies that we believe are the most promising for this purpose: magnetooptic memory disks and photorefractive crystals.

Write-only optical memories are already being used for video and audio recording and increasingly in computers. Magnetooptic disks, which can be erased and rerecorded, are not yet commercially available however this should happen in the immediate future. We can have billions of resolvable spots on a single optical disk and we can reconfigure the recording magnetically. Presently such optical disks are used as mass storage devices in electronic computers. Information is accessed from these memories serially by focusing a single laser onto a single bit (out of several billion that may be recorded on the same surface) and measuring the reflected light on a single detector. By mechanically spinning the disk and moving the laser head we get access to any one bit. The potential exists for accessing information stored on the disk much faster and much more effectively if the same disk is used to store information such that the connections between several thousand lasers and detectors are specified. In the following section we will discuss a specific model of associative memory and an optical implementation that can be implemented using optical disks.

Historically, holography is the first link between optics and neural network models. Van Heerden [10] and Gabor [11] both discussed holography as an associative memory and mentioned the possibility that there are analogies between holography and the way information is stored in the brain. In holography a pattern is reconstructed by illuminating the hologram with the reference beam that was used during recording. Thus a hologram is a form of associative memory. It is also known that a reconstuction can be obtained from only a part of a hologram a property that is shared by many types of associative memory. More recently holography is being considered as a method for providing optical interconnections [3,9] in an optical or optoelectronic computer. Such connections can be made programmable by recording the hologram on photorefractive (PR) crystals [6]. When a PR crystal is exposed to light, free charges are photogenerated and eventually retrapped. This process results in the redistribution of the charge within this crystal in a pattern similar to the pattern of the illuminating light intensity. The presence of spatially varying charge density induces internal fields in the crystal which in turn modify the index of refraction. Thus a phase hologram is recorded which can be reconstrued by illuminating the crystal with a light beam. PR crystals represent the second major candidate for realizing programmable optical interconnects. The advantages of PR crystals over magnetooptic disks are the optical rather than magnetic recording and the potential for volume storage. The number of optical connections that can be specified with a volume hologram is proportional to the volume of the crystal divided by the wavelength cubed. The principal advantage of magnetooptic disks on the other hand is the relatively advanced state of the art of the technology, which will continue to mature since there is a well identified commercial application for this technology.

The device technologies that are needed for the optical realization of a neural network that were outlined above all require further development before they can be used in practical systems. However the progress being made in these device technologies breeds sufficient optimism for the future outlook and this has led to designs and laboratory demonstrations of optical architectures [12-18] to simulate neural network models of associative memory [19]. In the following section we focus on a particular auto-associative memory model [20-22] and present experimental demonstrations of it.

OPTICAL ASSOCIATIVE MEMORIES

Let $v_i^{(m)}$ $i = 1, ...N$ $m = 1, ...M$ be binary (+1,-1) valued vectors. Then a matrix T_{ij} is formed by summing the outer products of all the vectors:

$$T_{ij} = \sum_{m}^{M} v_i^{(m)} v_j^{(m)} \quad , \quad T_{ii} = 0 \qquad (1)$$

Multiplying the matrix T_{ij} with any one of the stored vectors results in the reproduction of a noisy estimate of the same vector:

$$\sum_{i}^{N} T_{ij} v_i^{(1)} = (N-1) v_i^{(1)} + \sum_{m \neq 1}^{M} \sum_{i \neq j}^{N} v_i^{(m)} v_j^{(m)} v_i^{(1)} \qquad (2)$$

The first term in the above sum is the "correct" term amplified by N whereas the second term is unwanted interference whose value on the average is approximately $\sqrt{(N-1)(M-1)}$. Thus if M is sufficiently larger than N the first term will dominate and the output will look like the input. If this is the case then with high probability thresholding will eliminate the cross talk term and reproduce the input vector.

In the biological interpretation of the model the matrix T_{ij} represents the strengths of the connections among neurons and the thresholding describes the action of the neurons. The final characteristic of this model is feedback.

The output of each neuron (threshold element) becomes one of the inputs to all the other neurons in a fully connected network. We model this by making the binary vector that is produced by the thresholding operation the input vector to the matrix T_{ij} for the next iteration thereby making the correctly stored vectors (i.e. input vectors that are reproduced at the output) stable states of the network. A block diagram of this model is shown in Figure 2. The network is initialized by setting the state of the neurons according to an external input and allowing the network to reach a stable state. The system usually chooses the stable state that is most similar to the initial vector. Thus initial vectors that are distorted or partial versions of one of the stored vectors result in the stable state to be reached that is equal to this stored vector.

The most straightforward optical implementation of the Hopfield memory is by adding nonlinear feedback to an optical vector-matrix multiplier [23]. The system is shown in Figure 3. A linear array of detectors/saturating electronic amplifiers/light emmiting diodes is used to simulate the array threshold units. The strength of the interconnections between neurons is specified by the tranmittance of a two dimensional mask placed between the LEDs and the detectors. The details of this implementation and its experimental demonstration can be found in references [12] and [13]. In this paper we discuss a holographic implementation that is a modification of an architecture that is presented in reference [12] and was recently demonstrated experimentally by Paek and Psaltis [24].

Examination of equation (2) reveals that the read-out process in this associative memory can be decomposed as a cascade of two steps: An inner product between the input and all the stored vectors (the summation over i in Eq.(2)) followed by a summation of all the stored vectors each weighted by the corresponding inner product. An optical system that implements this associative memory is shown in Figure 4. An input image illuminates the system through a beamsplitter. The array of optical thresholding elements is placed immediately following the beamsplitter. The combination of the Fourier transforming lens L_1, the first hologram placed in plane P_2 and transforming lens L_2 comprise an optical correlator [25] that is used to form inner products between the thresholded input image and a library of stored references. The Fourier trasnsforms of the reference images are stored in the first hologram each on a separate spatial frequency carrier such that the inner products appear spatially separated at plane P_3. A pinhole array is placed at P_3 with each pinhole located at the position where one of the inner products forms. The light transmitted through each pinhole is collimated by lens L_3 and it illuminates a second hologram in plane P_4. The Fourier transforms of the same set of reference images are also stored in the second hologram. The arrangement of the pinholes with respect to the spatial frequency encoding that is used in the second hologram results in the reconstruction of all the stored images overlapping at plane P_1, and each weighted by the appropriate inner product. After thresholding the image at P_1 the light is fed back into the loop until a stable state is reached. This final state can be probed on the other side of the beam splitter as shown in Figure 4.

ABSTRACT

The need to drastically increase the processing rate of artificial intelligence (AI) systems, coupled with the limitations of current uniprocessor architectures, has resulted in a major research impetus to develop a new generation of parallel systems. Similar to a number of electronic symbolic computers being developed, optical computing systems can be viewed as a representative of the class of fine-grained, tightly-coupled architectures. This paper addresses potential roles of optical systems in symbolic computing and suggests future optical implementations of these architectures.

INTRODUCTION

The need to drastically increase the processing rate of artificial intelligence (AI) systems, coupled with the limitations of current uniprocessor architectures, has resulted in a major research impetus to explore parallelism in modern computing systems. Applications of these AI systems are placing stringent demands upon the underlying computer architectures. To meet these challenges, a new class of parallel computer architectures are emerging, structures which seek to optimize the processing and retrievel of symbolic information.

One promising group of AI-driven architectures can be described as tightly-coupled, fine-grained multiprocessor systems, and are characterized by both a dependence on complex interprocessor communications and flexibility in the interconnect topology.[1] This means that the architectures are composed of a large number of similar, relatively noncomplex processors,[2] which are coupled in such a manner that given processor can communicate with any other. The driving features behind this new generation of computer architectures are equally applicable to optical computing systems, which are also characterized by tightly coupled, finegrained elements with a high degree of communications flexibility. Optical systems also provide a form of two-dimensional parallelism which appears are attractive for symbolic processing operations. At the present time, we believe that optical systems can be adapted to the types of operations and data structures encounted in AI, and offer the promise of enhanced computational throughput to overcome bottlenecks in existing AI systems.

This paper will first describe some of the aspects of symbolic computing which drive the need for these new architectures. As a case in point, opto-electronic interconnnects are already being investigated for interprocessor communications in computer architectures. Potential roles for optics in multiprocessor systems will then be addressed. The paper will conclude with a discussion of current efforts to utilize optics in symbolic computing, both at the interconnect and processor levels, along with proposed optical implementations which look promising for general purpose symbolic processing.

MULTIPROCESSOR SYSTEMS AND SYMBOLIC COMPUTING

Symbolic processing is typically refers to on going research and development in four functional areas: speech recognition, vision or image understanding, natural language understanding, and expert systems. All four disciplines are characterized by the following three attributes: symbolic representations of knowledge; a high degree of interaction with a stored grouping of symbolic knowledge; and some level of reasoning capability, which draws conclusions by comparing inputs to the system with elements retrieved from the knowledge base. At the present time, each of these factors, retrieval of knowledge, representation of knowledge and reasoning, limits the computational throughput rate of AI systems. The remainder of this section will use expert systems as an example of a symbolic processing domain.

An expert system is a machine with mimics or emulates the thought and reasoning processes

CH2345-7/86/0000/0434$01.00 © 1986 IEEE

of human expert. It seeks to utilize the solution techniques which a human expert in a given discipline would use to solve particular problem in that domain. Knowledge appropriate to the discipline is placed into the machine, forming what is known as the knowledge base, enabling the system to understand the problem. Besides this knowledge base, the expert system consists of the "reasoner" or "inference engine", which manipulates the symbolic information stored in the knowledge base so as to "infer" new knowledge on its road to deriving a conclusion to a particular problem.

Retrieval in expert systems may be considered at four hierarchical levels: search of unorganized data, search of organized data, content addressing, and heuristic searching. The amount of symbolic information stored in a practical knowledge base is too large to even consider an exhaustive search of unorganized data. Considerable improvement can be realized by organizing the data to form data bases, and current expert systems make extensive use of data base management techniques to facilitate the retrieval process. But this technology is still based on von Neumann architectures which greatly hinder both the management and access to data bases of the size that will be needed for expert systems of the future. This problem has led to considerable interest in content addressable memory implementations of artificial neural systems and in logic-enhanced, or smart, memories for accomplishing heuristic searches.

Both the artificial neural systems and the logicenhanced memories fall into the category of tightly-coupled, fine-grained architectures. That is, they consist of thousands (or even millions) of switching or processing nodes (finegrained) which are interconnected to a high degree (tightly-coupled). The nodes of the neural network are just memory elements, but these elements are interconnected in a global fashion, so that processing associated with data retrieval may be distributed over all of the interconnected nodes. Although such networks will likely see use for symbolic computing, especially for associative recall of knowledge base information, neither the individual nodes nor the networks themselves have the processing power needed for advanced expert systems. Architectures with actual processing elements at each node represent the latest thinking of computer scientists dealing with artificial intelligence. These systems have been labeled with such names as logic-enhanced memories, smart memories, and connection machines.

Logic-enhanced memories avoid the von Neumann bottleneck by intermixing the processing and the memory funtions. This can be viewed either as distributing the memory among a large number of tightly-coupled processors, or as providing some processing capability to each element of a memory (hence the name logic-enhanced memory). This permits such powerful functions as interconnect reconfiguration and internodal relationship designation (e.g., for semantic network representations - to be discussed). These memories have such a broad processing power that they may be categorized as fine-grained, tightly-coupled multiprocessors.

Both the neural networks and the logic-enhanced memories are parallel processors; that is, any number of nodes or any of the interconnects can be active at any given time. It should also be noted that several optical implementations of neural networks and logic-enhanced memories have been developed, including associative processors[3,4] and memories incorporating a feature known as attention.[5] These systems all take advantage of the fine-grained nature of the optical devices and the types of global communications operations which are possible in optical computing systems.

A classification of parallel systems has been developed by Seitz,[6] a modified version of which is shown in figure 1. It provides an interesting categorization based on the number of processors and the relative degreee of processor complexity. Conventional uniprocessor architectures are plotted as a point of reference representing high complexity in a single processor. As one moves up to more than one processor, the trend is toward reduced complexity within each processor, a trend that is driven by total system cost and reliability, on the one hand, and by an escalating overall system complexity on the other hand.

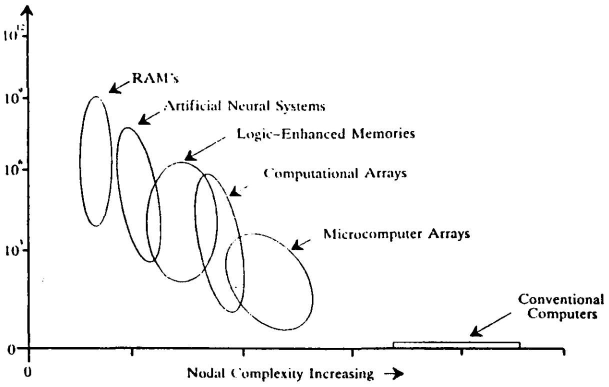

Figure 1
Classification of Parallel Processors by Nodal Complexity

Microcomputer arrays are basically a set of computers that send messages to one another via a communication network. Such systems are usually loosely-coupled; that is, the individual computers do not share main memory and I/O devices, although one computer can always draw upon another's resources through the communication network. The application of such systems in symbolic computing will likely be in solving problems that involve interactions between more than than one knowledge base. Each processor can work on a given part of the problem in such a way as to minimize the need for interprocessor communications.

Computational arrays are systems whose processing elements have been designed for tasks of comparable complexity to floating-point operations. Systolic arrays, for which the processors are connected in regular patterns that match the flow of data in the computations, compromise most of the architectures in this category.

As mentioned above, the architectures of most interest to knowledge base retrieval are the more fine-grained, tightly-coupled systems, such as logic-enhanced memories and neural networks.

Random access memories are shown in Figure 1 as a point of reference on the fine-grained ends just as uniprocessors were shown as a reference for nodal complexity.

To this point the discussion has centered on the knowledge base retrieval process so fundamental to expert system operation. The second major aspect of expert systems, as mentioned above,is knowledge representation. Figure 2 illustrates one popular method for representing knowledge, known as a semantic network. A semantic net may be characterized as a graphical representation scheme in which the graph nodes represent objects or concepts and the links represent inference procedures that relate the nodes. The importance and complexity of connectivity in these knowledge representation schemes has resulted in serious consideration of the tightly-coupled multiprocessor architectures for symbolic computing and expert systems implementations. The processing power at each node can, for example, be used to define the internodal relationships of the semantic network.

The similarity of these highly connected architectures to neurological systems lends credence to their importance in symbolic processing. We are very aware of the power of the brain in performing intelligent operations such as reasoning and pattern recognition, yet the brain consists of relatively slow switching elements. The biological switch is the neuron, and it operates in the millisecond range - about a milllion times slower than current electronic switching speeds. The difference lies in the large degreee of connectivity between biological switches, leading to a high degree of parallel processing. Neurons in the brain can have upwards of 10,000 synapses (biological connectors), whereas electronic switches in today's computers typically have only a few connections to other switches. There is strong evidence to suggest that the processing power of the brain is related to the high degree of connectivity between the neurons, permitting parallel processing and thereby compensating for the slow switching speeds.

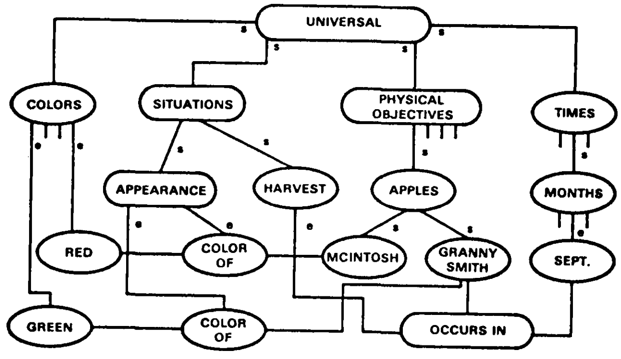

Figure 2
Semantic Networks

The next section will focus on potential roles for optics in multiprocessor systems. This will lead to a discussion of current efforts to couple optical computing with AI, and will conclude with two proposals for optical architectures which could significantly enhance the computational throughtput of fine-grained, tightlycoupled, multiprocessor systems. Such opticallybased systems, if realized, could open up a whole new field of opto-electronic computing directed toward artificial intelligence applications.

OPTICS AND MULTIPROCESSORS

Any approach to optical architectures must give serious consideration to what can be accomplished with existing technologies, namely VLSI electronics.
Optical computing will not seriously threaten electronic computing unless it can offer several orders of magnitude improvement in some critical measurement criterion, such as the power-speed-cost product, in a given problem domain. Therefore, a good starting point in addressing the application of optics to symbolic computing is to identify problem areas for electronics.

It is not surprising that the relative weaknesses and strengths of electronics and optics are traceable in one way or another to the fundamental physics of inter-electon and inter-photon interactions. Relatively speaking, the interaction between photons is weak; hence, electrons are good for the switching operations so fundamental to computing and photons are good for the interswitch communications, providing links which are free from detrimental coupling effects that lead to crosstalk and capacitive loading. Subscribing to such reasoning, however, is impractical due to the quantum losses which accompany both the electron-to-photon and the photon-to electron conversions. There is research and development underway to replace some of the longer interconnect links within computers with optical channels because it is the longer interconnects that create severe power, speed, and space problems for electronics[7]. But such a capability stops far short of using optics to its full advantage in multiprocessor architectures appropriate for symbolic computing.

Consider the electronic-switching/optical-communications positions as representing one of the four corners of the square shown in Figure 3. The sides of the square represent a continuum of combinations between the extremes of the corners. The upper left corner represents all-electronic systems while the bottom right represents all-optical. Since movement toward the bottom left corner not technically practical, the focus is along the upper and right sides. Upon considering computing systems for which switching is the predominant function, the trade-off between optics and electronics is seen to fall somewhere along the upper edge; that is, all electronic switching with some optical links. However, symbolic processing places a strong emphasis on connectively as was discussed above. The de-emphasis on switching (fine-grained architectures with low nodal complexity) and the emphasis on communications (tightly-coupled systems) leads one to consider architectures for which the communcations is optics and only some of the switching is done with electronics. It is this category of electronic/optical hybrid architectures that can have a significant impact on symbolic computing.

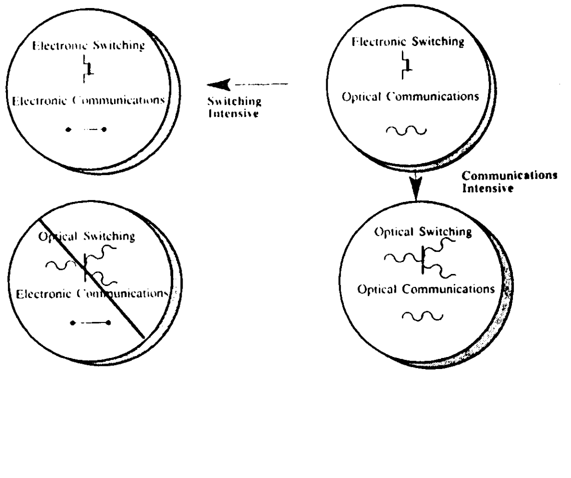

Figure 3
Electronic Versus Optical Computing

The upper right hand corner of figure 3 refers to the set of architectures which utilize optical switching for interconnect recongifuration and eletronic switching for logic operations.[7] Optics proves to be especially valuable in providing both the longer and the more global interconnects in processing, due to the combined power-speed-space-crosstalk penalties associated with electronic interconnects. Several examples of the use of optical interconnects for these in advanced architectures are currently under development, both in coarse and fine-grained computer structures. The interest in optics arises from the high bandwidth communications requirements between the individual nodes and the number of parallel channels which can effectively be multiplexed over a single optical link. The Texas Reconfigurable Array Computer (TRAC),[8] for example,is studying fiber optics for internodal board to board communications at bandwidths between 100 and 500 Mbps, and the WARP system[9] is investigating the use of optical interconnects for intercell communications at a rate of 0.5 1.0 Gbps and 32:1 multiplexing. Another example, that of a finegrained electronic symbolic computer under development, is the Connection Machine.[2] It is composed of 65,536 individual processing elements (PEs), organized as a large array of printed circuit boards, each of which contain 512 PEs equally divided between 32 chips. Both guided and unguided optical interconnects are being studied for overcoming challenges to this architecture, such as clock skew, 1.0 - 3.0 Gbps communication rates over 32:1 multiplexed links, and interprocessor broadcast.

Over the longer term, architectures such as that shown in Figure 4 could be developed to effectively integrate opto-electronic components in computer systems. Such a hybrid structure would use optics for most communications requirements and electronics for processing element functions. For the sake of simplicity, the illustration shows only two of the many possible boards and only four chips/board. If this were a fine-grained processor, each chip could contain many PEs.

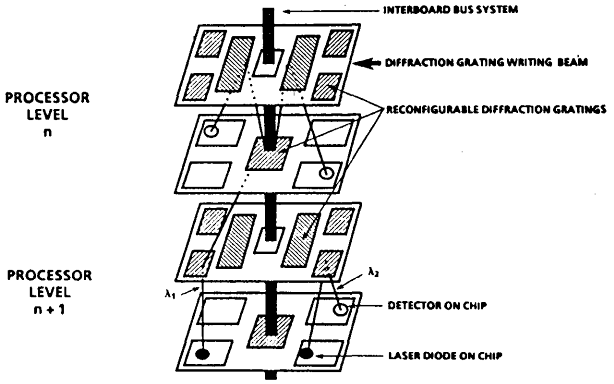

Figure 4
Hybrid Optical/Electronic
Multiprocessor Architecture

Each board in Figure 4 contrains four optoelectronic chips and one frequency selective filter (hologram). In between each board is a planar array of reconfigurable diffraction gratings, which perfom the majority of the switching operations involved in the interconnection process. This particular architecture employs wavelength division multiplexing (WDM) to direct optical bit streams to the appropriate board. The beam labeled illustrates this operation. The hologram directly above of the transmitting chip directs the beam to the center of the next board, where it is superimposed on the main beam which travels to all of the systems boards. Upon reaching the intended board, the frequency selective filter diffracts the beam to a bus-to-board hologram which directs the beam to its final destination.

The intra-board and intra-chip interconnects would be handled by the plane of holograms above the board, as illustrated by beam . The logistics of handling a large number of muliplexed beams will not be discussed here, other than to say that the optical switching most likely will be achieved through nonlinear wave mixing. For example, four wave mixing may be used to generate holograms[10] which can be rapibly varied to permit interconnect reconfiguration. Diffraction grating writing beams would contain the desired information for changing the holographic gratings. Note that some of the switching actions of such an architecture are being performed optically rather than electronically.

As one moves toward the bottom right corner of the classification scheme presented in Figure 3, the percentage of optical implementation increases until an all-optical architecture is achieved. While a number of efforts are underway to develop such all-optical structures, the research is currently directed at defining the appropriate computational primitives for optical symbolic processing. Thus the present focus is constrained to identifying and protoyping systems which can process the fundamental operations associated with symbolic computing--namely, the performance of correlation, searching, and pattern matching operations on symbolic data.

Typical of a class of research applications are the optical inference machines.[11,12] Here, the emphasis is on developing optoelectronic architectures which can perform the fundamental matching and logic operations encountered in retrieving symbolic data from a database. These sets of operations are both language and representation specific, so that architectures are being analyzed for several of the major different AI programming paradigms. Examples of other representations being investigated by optical computing researchers include semantic networks, graph theoretical representations, symbolic substitution for binary data,[13] and shadowcasting structures.[14]

Figure 5
All-Optical Multiprocessor Architecture

An example of a fine-grained, tightly-coupled optical symbolic computer of the future is shown schematically in figure 5.[7] Although no one has built such a computer, it is technically believable to achieve such a system consisting of 1 million parallel channels. This does not mean that the system would be configured necessarily with 1 million nodes, since such this implies that the planar array of logic elements (designated as the gate array) would have just one logic element per channel. Instead, several logic elements would usually be interconnected via the interconnect media to form a processing element. For example a square array of n x n logic elements (gates) may comprise an arithmetic logic unit, several registers, and possibly some cache memory. An example of this type of structure is shown in figure 6, where individual elements in a 2-D SLM have been assigned the necessary functions to comprise a computational processing element. Taking an n of 5 (25 logic elements/processor) would lead to a machine with 40,000 nodes large enough to be practical as a symbolic computer.

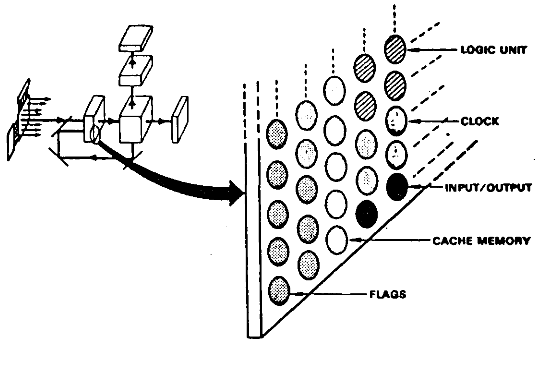

Figure 6
An All-Optical Processing Element
(Detail of Figure 5)

Input to the optical computer could be via either an array of independently addressable laser diodes or a two-dimensional spatial light modulator (2D SLM). The diode array would be capable of much higher modulation speeds, but would involve more complex circuitry, especially if operation requires uniformity over the complete array. If the input already exists as a two dimensional light pattern, such as might be output from a vision processor, an input device may not be needed (depending on the compatiblility of the two processors).

The logic element array could be either a 2D SLM exhibiting a nonlinear response or an array of optical bistable switches. The latter device will ultimately lead to much higher switching speeds, but current realizations of optical bistable switches require impractical power levels. Improved nonlinear optical materials are needed to achieve widely utilized optical bistable devices.

The interconnect element will likely employ wave mixing in a nonlinear optical medium, similar in operation to that mentioned previously fo the hybrid architecture. However, due to the much larger number of channels that must be handled, the switching may be done in a multistage fashion, in which multiple parallel planes of real-time hologram arrays would be exercised.

The detector will be a major technological challenge. In the most general case, one would like a one million channel device, with each channel operating around 1 MHz (projected speed for 2D SLMs). However, the requirements will be much less for most practical processor designs. If the problem domain were to require, say, 100 iterations or more (e.g., semantic network searches to depths of at least 100), an output would be required only once every 100 microseconds. This reduces the throughput rate of the detector to 10^{10}, a number more in line with projections for GaAs microelectronics. Another example would be where each processor consists of a block of n x n channels as discussed above. Assuming an n equal to 4 and that each processor has just one output channel, the throughput requirement of the detector would be 6.25 x 10^{10}. Some combination of these two designs should yield a detector requirement that would be well within near technical feasibility.

The last major component of this all-optical architecture is the memory. The practice in electronics of co-locating some of the memory with the logic elements cannot necessarily be transferred to the optical computing domain because of the greatly reduced communications delays. Thus, Figure 5 shows the main memory as the single block, equally shared by all of the processors.

CONCLUSION

The ultimate objective of artificial intelligence is to expand the power and reasoning processes in computing machines, allowing these machines to emulate and achieve capabilities typically associated with intelligent behavior in humans. However, efforts to achieve these goals have been severely constrained by today's serial architectures and by the separation of the processing and memory functions. Fine-grained, tightly-coupled multiprocessors appear to be a viable class of architectures for symbolic processing. Optical techniques, in the form of opto-electronic interconnects and optical computing, are being investigated as a means of alleviating computational bottlenecks in these systems.

Opto-electronics may play a major role in making these systems a reality, either as a supplement to an existing architecture or as part of an integrated opto-electronic computer. Research to date has demonstrated the viability of optical interconnects, and a number of efforts are underway to incorporate opto-electronics into existing architectures. At another level, the potential exists for developing all-optical symbolic processors as part of a larger scale computational environment. This appears particularly promising, since the 2D SLMs are in fact fine-grained PEs in a tightly-coupled environment. Such an all-optical system could serve as a co-processor in symbolic processing systems, and research is underway to identify the appropriate computational primitives and compatible representations.

Interestingly enough, at the present time, the numeric "supercomputers" execute AI functions at a greater rate than dedicated AI machines.[15] This may imply that raw speed is an important component in overcoming existing AI computational bottlenecks. It also may indicate that architectures designed to improve numeric throughput may also be useful in symbolic computation, and vice versa. Regardless of which of these paths are developed, the utilization of optics in symbolic processing represents an exciting new direction for optical computing.

P.O Box 226015, MS 238, Dallas, TX 75266.

ABSTRACT

Desired features for a high performance machine are listed and include extendability, flexibility, and reliability. These features are hard to satisfy simultaneously with almost all existing and proposed parallel machines. A previously proposed optical crossbar interconnected processor is reviewed. It has properties that enable extension to larger systems by the addition of more processors, crossbar switches and exchange switches. These properties include: fine granularity, high communciation bandwidths, and reconfigurability. A method of doubling the size of the system without losing performance is described. It would appear that doubling may be repeated recursively until physical or other constraints arise. The performance of the resulting machine and the degree to which it satisfies the desired features are discussed.

INTRODUCTION

Desired features for multiprocessor

A high performance multiprocessor is desired that is extendable to more processors with a corresponding increase in performance. It must also be flexible and reliable. Extendability implies that more processors may be added to the multiprocessor together with corresponding interconnections without requiring new software and with performance approaching linear improvements with increasing number of processors. This will enable the same architecture and associated software to apply to a wide product range and provide longer life for customers and products. This implies that high performance versions of the machine must be built initially and that the machine must be capable of further extension to satisfy demand for many decades.

High performance involves considerations of throughput and latency. High throughput is suitable for many large problems because repetitive computations are often required. However, minimum latency is also required because of those situations where results are needed before subsequent computations can be performed. Flexibility implies that a wide range of algorithms must run efficiently. Also, new algorithms and as yet undiscovered algorithms must be easily entered into the machine and run efficiently. Reliability is required in any complex system.

Difficulties of achieving desired features

Parallelism is required to meet the requirements for future computer performance, even with the fastest technology components[17]. The number of parallel processors that may be used efficiently is limited in today's prototype and proposed systems by the communication delay and interconnection complexity. These systems are not generally extendable. I showed earlier, by analysis of a 3-D finite element computation, that attaching processors to a bus is straightforward but not extendable. Efficiency fell to 7% for 32 processors connected to a 37 MHz bus, where each processor has a computation rate of 10 Mflops[16].

Flexibility to efficiently run a wide range of algorithms may be achieved by reconfigurability[3],[20]. Reconfigurability also enables software to readily adjust to an extended system. However, reconfigurability introduces large delays and high control overhead in most proposed systems. This severely restricts the number of processors that may operate efficiently. Also, the throughput of the system is reduced and the latency increased.

Systolic configurations use nearest neighbor connections and prearrange dataflow so that input and output occurs at the edges of the processor array at each cycle[5]. Latency is increased relative to serial machines and this causes difficulties for general purpose numeric and symbolic computing. Also signal processing often involves situations that are adaptive or require rapid response. The number of elements in an array may be increased without altering the bandwidth at an input or output connection. The nearest neighbor connections also provide fast communication. This permits large numbers of processors to be efficiently used in parallel, thus providing high throughput and extendablity. However, the nearest neighbor connections limits the flexibility or range of algorithms that may be implemented efficiently. For example, many fast algorithms use doubling which results in

CH2345-7/86/0000/0441$01.00 © 1986 IEEE

complex non nearest neighbor communications, e.g. FFT, recursive doubling.

Extendability to larger high performance systems increases the likelihood of interference because of longer cables. This reduces the reliability. Reliability is often accomplished by means of redundancy in software, hardware, time and/or space. This is detrimental to satisfying performance for a given cost. It also limits extendability.

REVIEW OF SINGLE CROSSBAR SYSTEM

Prior research

An optically interconnected system was selected after examining a number of different architectures[17], including systems performing optical computation[11]. I previously showed how to efficiently implement basic signal processing algorithms such as an FFT, systolic filter, and matrix-vector multiplier on the proposed optically interconnected processor[12]. The crossbar switch permits fast algorithms, such as those involving doubling, to be implemented more efficiently than on a nearest neighbor or systolic array[5]. The improved performance justifies the cost of the switch. Previous investigations illustrated the implementation of Levinson's algorithm for optimal least square filtering[6], the implementation of Levinson-Durbin's, Burg's and Schur's algorithms[10], and texture classification[7], and the implementation of conjugate-gradients[9]. The crossbar switch makes possible close coupling between symbolic and numeric processing[8].

System

Figure 1 shows a preliminary organizational structure for an optical crossbar signal processor[12],[15]. Hundreds of processing elements, P_i, $i = 1$ *to* $N/4$, are connected to an optical switch of size $N/2$ by $N/2$ by means of commercially available fiber optic links of bandwidth 160 MHz or more. The processors perform elementary operations such as multiply or add and therefore have two input connections for the two operands. This fine granularity permits the maximum amount of parallelism to be extracted from algorithms. The processing element output is converted from parallel to serial in a shift register and used to drive a laser diode. A second output is provided for convenience. The laser diodes are connected via optical fiber links to the optical crossbar switch. Fibers returning from the switch connect to light sensors at the processor inputs. A second fiber optic loop between processors and main memory banks provides input/output. The logic permitting input/output, marked **w** and **v**, may be mounted alongside the processor.

Optical switch and interconnections

Optics is used for interconnections because photons are inactive, having non interfering characteristics. Also, optics provides sufficient bandwidth to support fine granularity parallel processors so that high levels of algorithm parallelism may be extracted.

Each intersection in a crossbar switch, figure 2a, has a switch permitting a horizontal input line to be coupled with a vertical output one. One output receives information from one input but one input may broadcast to several outputs in a *generalized* crossbar switch. Figure 2b shows a diagrammatic crossbar switch implemented with a spatial light modulator (SLM) and dots indicate transparent regions consistent with the closed switch settings marked by dots in Figure 2a. An optical lens system is

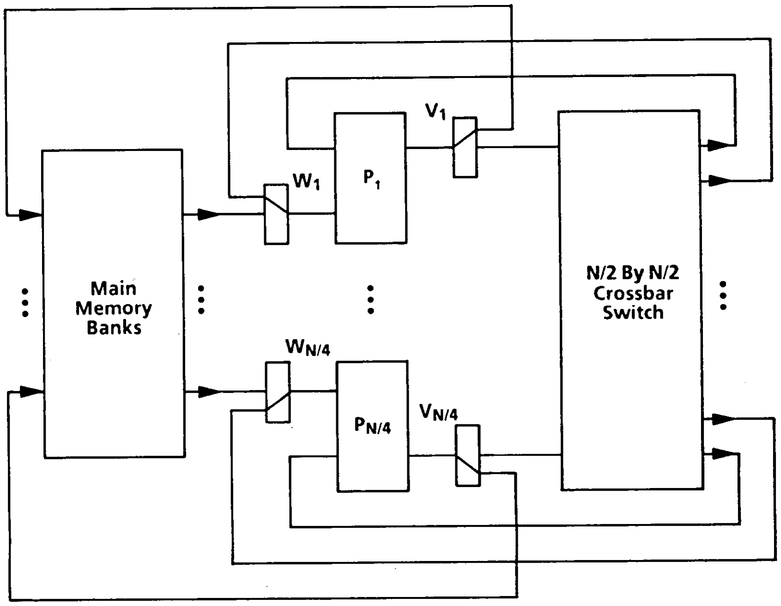

Figure 1: **Single crossbar system**

used to spread the light from the input sources horizontally without spreading the light vertically. Light passing through the spatial light modulator is collapsed onto receiving diodes by means of a lens system which focusses vertically without spreading horizontally. In addition to being a directional generalized crossbar switch, the optical switch permits *inclusive OR* operations by allowing different inputs to feed an output.

A reflecting membrane covers the surface of an array of transistors on a silicon chip, figure 3, to form a deformable mirror device (DMD). Figure 2b showed a transmissive spatial light modulator. The DMD is reflective and requires a beam splitter to separate the reflected light from the incident light. The mirrors are drawn as though they are transmissive light modulators for clarity. Activation of a transistor causes the membrane to dip above the transistor. A collimated beam of light striking the DMD will result in concentrations of light just above each of the activated transistors. This array of light and dark pixels is imaged to another plane for viewing or further operation. A Schlieren system uses a stop in the frequency domain to remove low spatial frequency light arising from reflection from regions between mirror deflection pixels. Imaging and performing spectral analysis with a Texas Instrument's DMD of size 128 by 128 has been published[18]. It takes one microsecond per row to load the DMD while still using the previous deflections. A few microseconds are required to switch to the new settings.

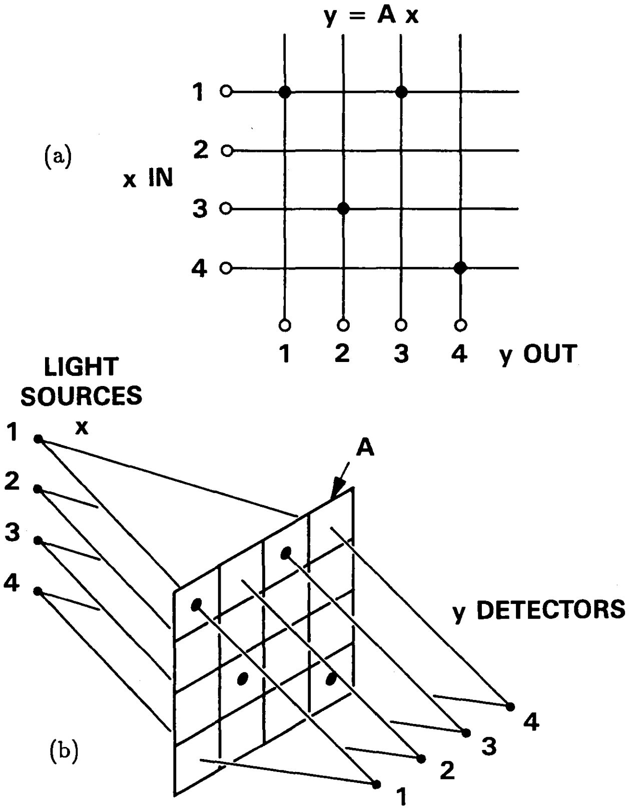

Figure 2: **Diagrammatic optical crossbar switch**

(a) Switch settings
(b) Spatial light modulator crossbar switch

Commercially available fiber optic links are available at the transmission rates required to keep up with available processing elements. It is anticipated that faster links will be commercially available as the processing element speeds increase. Optical links increase the immunity to interference relative to using cables.

Software and programming approach

The flow of data is prearranged so as to minimize run time overhead[7]. A static dataflow approach is used to minimize run time overhead for signal processing algorithms. The use of a high throughput crossbar switch will make it possible to map algorithm graphs onto the system more easily and more efficiently than onto constrained interconnection networks such as hypercube[19] and multistage networks[4]. This suggests that automatic mapping will be feasible for our machine. The throughput for a wide range of algorithms is also expected to be higher than for other architectures, including current prototype message passing dataflow machines[1].

Figure 4 illustrates an executable flow graph for the Levinson-Durbin algorithm unrolled for pipelining[7]. Nodes marked with subtraction imply the subtraction of the right hand input from the left hand input. Flow is down the page. The triangular arrows indicate negation or unary minus which may be accomplished at the input to the appropriate node rather than with an extra node. Identity instructions marked "Ident" support the fanout of operands so that an input connects to a processing el-

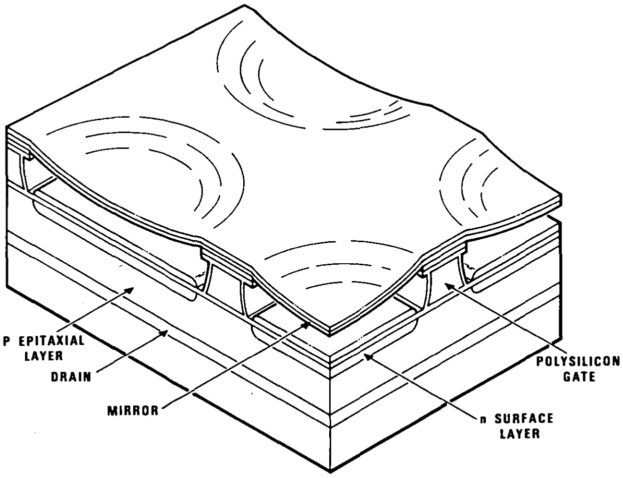

Figure 3: **Deformable mirror device**

ement before going through the crossbar. Each operator must forward its results on every clock. Consequently, unit delays are inserted on any edge of the graph which "crosses a level" without being used. The number of unit delays is a number at the input to an instruction indicating the queue at an existing node. Parallelism is evident in the flow graph by the number of nodes that occur side by side. A 100% efficiency is achieved once the pipeline is filled[7].

The flow graph is mapped directly to the machine without coding in a higher level language. However, as many algorithms exist in coded form, it is desirable to be able to create flow graphs from the code and display the graph. The level of parallelism may be observed and algorithm changes made to increase the parallelism[9]. Nodes in the flow graph are assigned to processing elements in the system and links in the flow graph to settings of the crossbar switch. A compiler is being developed for this mapping. Data flows into the switch during operation and is routed to the appropriate processor. A processor will perform the operation for which it is programmed on the next clock cycle after receiving its operands. The output is routed via the switch to the next processor.

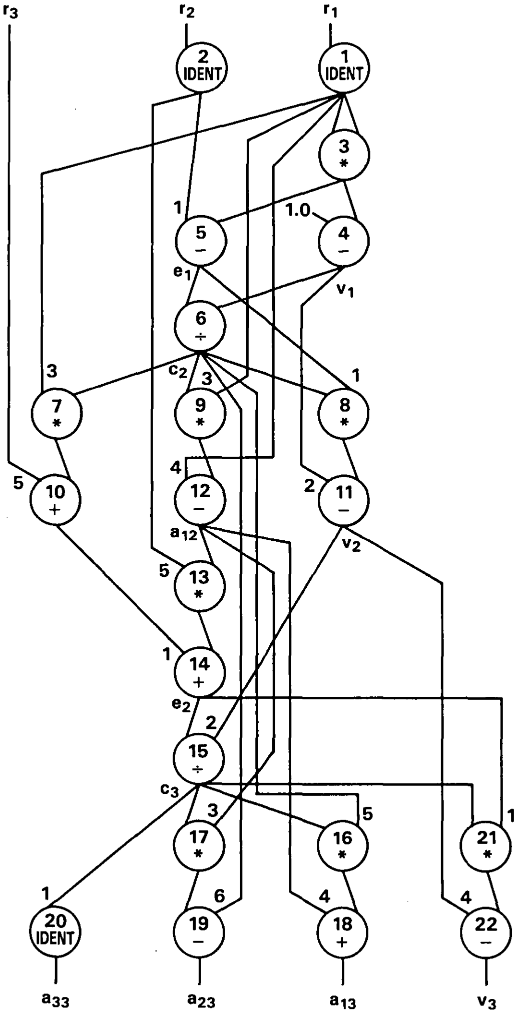

Figure 4: **Flow graph illustration**

EXTENDED CROSSBAR SYSTEM

Illustration of a double-crossbar system

A specific approach is illustrated for extending the single crossbar system described previously to double the size. Alternatives are considered in the next section. A second identical single-crossbar system is placed next to the first, figure 5. The optical fiber connections into and out of the crossbar switches are opened and exchange switches **s** and **u** inserted respectively.

The switches that implement the exchange switch at the input to the crossbar are marked s_1 through $s_{N/2}$. The second part of each switch is marked s_1' through $s_{N/2}'$. Consider the activity between the input to a switch, say s_1 and s_1', and the input to the crossbar switches. The effect is that of a 2 by 2 switch for which the two inputs are either connected directly to the two outputs or in an exchanged configuration. An example is provided by the top output for processor P_1 and the top output of processor $P_{N/4+1}$. If P_1 is connected to the top input of the top crossbar switch then $P_{N/4+1}$ is connected to the top input of the lower crossbar switch. In the exchanged position (as shown in figure 5) P_1 is connected to the top input of the lower crossbar switch and $P_{N/4+1}$ is connected to the top input of the upper crossbar switch.

An exchange switch, u_1 through $u_{N/2}$, is similarly incorporated between the output of the crossbar switches and the input to the processing elements. An example is provided when the top output from the upper crossbar switch is connected to output 1 at the right, then the top output of the lower crossbar switch is connected to output $N/2 + 1$ at the right side. In the exchange position, the top output of the upper crossbar switch is connected to output $N/2 + 1$ at the right and the top output of the lower crossbar switch is connected to output 1 at the right.

An electro-optic switch may be used to implement the exchange switch **s** by directing light into one of two fiber channels. A combining coupler is used at the input to the crossbar switch to permit light to pass from either channel. The switches **v** may be implemented with similar electro-optic cells. Similarly, the output exchanges switches **u** may be implemented using a reverse electro-optic cell. Only one of the input light channels is permitted to generate an electronic signal. The electronic signal is then converted to light for transmission back to the processor.

Interconnection alternatives for extendablility

Alternative approaches to extendability are considered. Four crossbar switches of size $N/2$ by $N/2$ may be used to construct a double size N by N crossbar switch system. $N/2$ inputs are connected in parallel into crossbar switches one and two and the other $N/2$ inputs are connected in parallel into switches three and four. The outputs of switches one and three are connected in parallel to produce $N/2$ outputs and the outputs of switches two and four are connected in parallel to produce the other $N/2$ outputs. OR capability is maintained.

An alternative is to use only two $N/2$ by $N/2$ switches together with two sets of $N/2$ switches[2]. This increases control complexity but uses less switches than the four crossbar switch system. If two by two optical switches, such as DMDs, are used, for which OR operations are possible, all the original features of the optical switch are maintained for the larger size. Hence, from a software point of view the system is identical to the previous single-crossbar system, except for doubling in size. The resulting system will lack OR capability if generalized two by two switches are used with no OR capability. Futher, some broadcast capability is lost if exchange switches are used permitting only permutations and not broadcasting. For example, the system now permits inputs to broadcast to only half the outputs. This case was described in the last section. Only one control bit rather than two is required for control of the two by two switches. The crossbar switch is still complete or nonblocking and provides N^2 well defined mappings from input to output.

If we omit the exchange switches at the crossbar output, **u**, it is still possible to reach any output from any input. However, blocking may now occur and the total available mappings are only N! This is illustrated using Figure 5. Suppose it is desired to connect via the crossbar

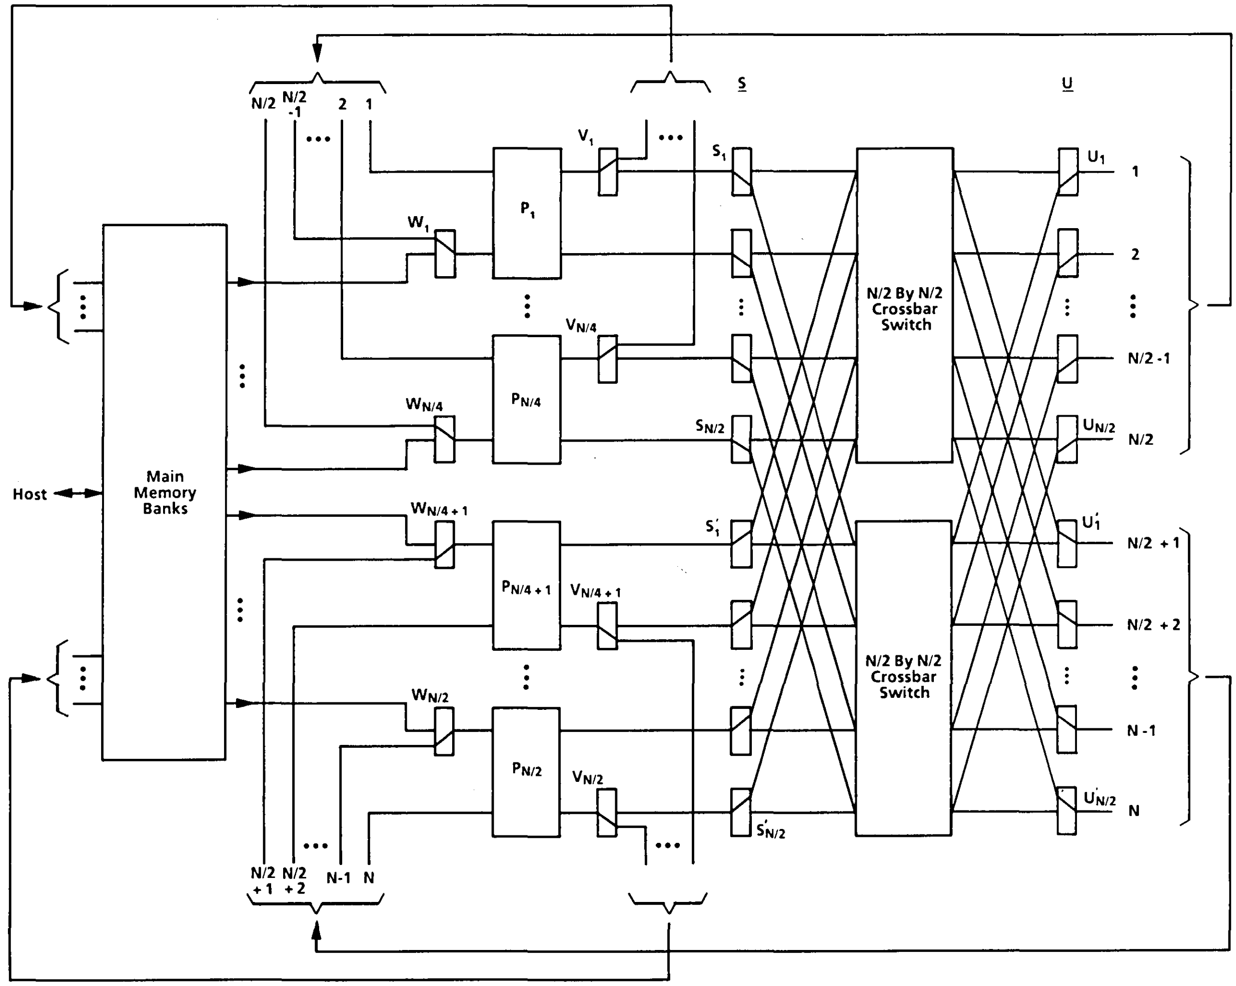

Figure 5: **Double crossbar system**

switches the top output of processor P_1 to the input of processor $P_{N/2}$ and at the same time the top output of processor $P_{N/4+1}$ to the input of processor $P_{N/4+1}$. The first connection may by accomplished be setting switch s_1 to the downward switch position (as shown in Figure 5) and $u'_{N/2}$ to the downward switch position (opposite to that shown in Figure 5). Consequently, the other half of the first switch s'_1 is set upward. In order to accomplish the second connection u'_1 must be set upward. Absence of this latter switch would result in blocking of this second connection by the first.

The system may be doubled in size again by placing a second system like that in figure 5 beside the first. The inputs to switches **s** and outputs from exchange switches **u** are now broken and further exchange switches inserted. Doubling may be applied recursively until physical constraints arise. Depending on the properties of the two by two switches some features relative to a single larger DMD optical switch may be increasingly lost as the amount of switching in the two by two switches increases relative to that in the optical DMD switches. The complete or nonblocking feature is maintained.

Finding, isolating and correcting faults

The use of multiple crossbar switches permits a degree of fault tolerance. Diagnostic programs and data may be run through the system periodically to verify correct operation. Failure to respond correctly to diagnostics is followed by testing each crossbar separately with the same diagnostics. Testing with the exchange switches interchanged will further determine whether processors or switches are at fault. In the former case reconfiguration will be made with the offending processing element disconnected. In the latter case, the system performance will be reduced if the switch is no longer permitted during reconfiguration. Repair of offending processors or switches should be possible without stopping the system.

PERFORMANCE ASSESSMENTS

Did the system meet desired features?

Sections of a computation often involve global communication or are not divisible into sufficiently large parallel pieces for efficient computation on a parallel machine. This becomes more of a problem as the number of processors is increased because the parallelizable parts are performed faster and the difficult parts become more of a bottleneck. Fine granularity and the broadcast capability of the crossbar switch permit these difficult parts to run efficiently on the proposed optically interconnected system. Consequently, the crossbar switch system may be extended to more processors without this difficulty.

Optical interconnections are needed to provide the high bandwidth required for fine granularity parallelism. Photons are inert compared to electrons, therefore the proposed sysem has a higher immunity to interference than electronic systems. This assists in extendability where distances to new processors and memory are likely to be further than for a smaller number of initial processors. Greater immunity to interference is important for enhancing reliability. Packaging is simplified when components need not be very close.

The optical crossbar provides reconfigurability, in fact N^2 well defined links, between processing elements. Reconfigurability enables a wide range of algorithms to be efficiently implemented as is required to meet the flexibility requirement. The large number of alternative paths assists reliability because failure of a processing element degrades performance only slightly after reconfiguration. The processing element or switch may even be repaired without stopping the system. The system may be extended by adding more crossbar and tow by two switches to emulate larger crossbar switches. Consequently, the same software may be used after extension. The optical switch has a higher throughput than conventional electronic crossbar switches and does not require N^2 interconnections. It is easier to map algorithms onto a full crossbar switch than onto a constrained or reduced switch, thus making automatic mapping of algorithms by means of a compiler feasible. Otherwise a directed graph for an algorithm must be mapped onto a directed graph for a processor interconnection system.

Static dataflow permits prior arrangement of data flows. This significantly reduces run time overhead. Conventional architectures require the computation of addresses for the operands for an operation and then the finding of these addresses and the fetching of the data. An instruction must then be decoded, the operation performed and an address computed for storing the solution.

Comments on computing performance of extended processor

Previous research showed that some algorithms, such as conjugate gradients[13],[14] for solving large sets of linear equations, may be implemented with over 90% efficiency even when there is a mismatch between the number of processing elements and the dimension of the problem[9]. This is still true for an extended processor having more crossbar switches and processing elements because both communication and computation are increased in the same proportions. Rapid solution is not critical for problems much smaller than the machine unless there are a large number of them. In this case the processor may be reconfigured to provided pipelining or parallel computation of the small problems and will achieve very high efficiencies.

Algorithms, such as Levinson's[6],[10], that are iterative with increasing dimension and the number of iterations are determined during computation, are difficult to implement efficiently on parallel machines. The extended machine will still speed up computation in proportion to the incease in processors, no matter what the efficiency. Unrolling loops of the iteration provides faster speeds because control for these loops is no longer required at run time. This may be beneficial even if the occasional problem does not require all the loops. Tags are used in the architecture to indicate when processing elements should not operate on data for reasons such as this. Algorithms, such as Levinson's, may be implemented with 100% efficiency by pipelining when there are many cases of known dimension[7].

CONCLUSIONS

Desirable features for a high performance processor include extendablility, flexibility and reliability. These features are difficult to achieve at the same time as indicated. An optical crossbar interconnected processor proposed earlier was shown to be extendable by recursively doubling the system. Processing elements, switches and crossbar switches are added in the same proportions. The advantages of the system are carried through to the new system and proportional increases in performance with increasing number of processors is anticipated. Extendablility would not be possible without the specific features of the machine. Fine granularity enables parallelism to be extracted where other machines could not. Therefore, for such cases, the other machines would exhibit severe degradation in performance with increased numbers of processors. The high bandwidth optical interconnections make it possible to have fine granularity. Reconfigurability of the crossbar permits the extended system to operate with the same software. It also provides algorithm flexibility for adjusting to the change in the relative dimensions between problem and machine because of the changing number of processors. Reconfigurability, high levels of parallelism, multiple crossbar switches and optical links provide the opportunity for high reliability. This architecture is considered promising for future computers.

Minneapolis, MN 55414

Abstract

Conventional interconnect and switching technology is rapidly becoming a critical issue in the realization of systems using high speed silicon and GaAs-based technologies. Optical interconnect technology promises to enhance performance, provide relief from the pinout problem, decrease implementation complexity, and provide improvements to the flexibility of systems by allowing real time reconfiguration of these systems. In recent years, rapid progress has been made in VLSI/VHSIC technology that improves on-chip density and speed while packaging these high speed chips is becoming extremely difficult and in some cases limiting system performance. By releasing the bandwidth constraints on interconnects and packaging, the full processing speed capabilities of silicon and GaAs logic can be exploited to dramatically improve system throughput. A number of University, governmental and industrial laboratories have been developing technology for on-chip/on-wafer, chip-to-chip and board-to-board high speed optical communication. Both guided wave and free space communication media are being developed. In this paper, a review of the technological developments, current status and future projections for optical interconnects will be presented.

Introduction

There is a growing demand to increase the throughput of high-speed processors and computers. To meet this demand, denser, higher-speed IC's and new computing architectures are being developed. Electrical interconnects and switching have been identified as bottlenecks to the throughput of computing systems. Two trends brought on by the need for faster computing systems have pushed the requirements on various levels of interconnects to the edge of what is possible with conventional electrical interconnects. The first trend is the development of higher speed and denser switching devices in silicon and GaAs. Switching speeds of logic devices are now exceeding speeds of 1.0 Gb/s, and high density integration has resulted in the need for interconnect technologies to handle hundreds of output pins. The second trend is the development of new architectures for increasing the parallelism, and hence, the throughput of a computing system.

A representation of processor and interconnect complexity for present and proposed computing architectures[1] is shown in Figure 1. The dimension along the axis is the number of processors required for the architecture. On the left end of the axis is the Von Neumann type architecture which has very few processors, but the processors tend to be very complex. Progressing to the right, the number of processors per system increases until it reaches a neural network requiring millions of processors but the processors are much less complex than the Von Neumann case. From looking at Figure 1, it becomes apparent that as the number of processors increases, the number and complexity of the interconnects within the system increases dramatically. In fact, at the far right of this scale, the interconnects become an integral part of the computing architecture, and the boundary between the processors and the interconnects becomes blurred.

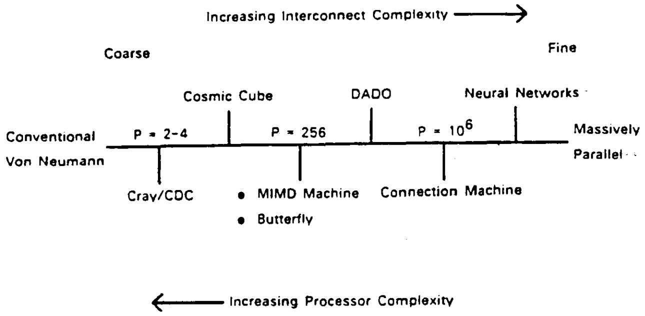

Figure 1 Granularity of Processing [Ref. 1].

Optical interconnects have long provided the telecommunications industry with a high speed, low weight, low volume, long distance transmission media[2]. Optical interconnects can also be applied, at least conceptually, at many levels within a computing architecture. On a physically large scale, optical interconnect technology has been used in local area networks to connect computers. At the next level down in physical size is the interconnection between systems within a computer such as a memory to processor connection. This is classified as a board-to-board or backplane interconnection. Next there are the interconnections between individual chips on a single board or between chips in a multi-chip package. Finally, there are the interconnections between devices within a single chip or on-chip clock distribution.

CH2345-7/86/0000/0448$01.00©1986 IEEE

A number of researchers have been developing the technology for optical routing techniques, packaging of optical and electronic components, high speed opto-electronic devices and optical clock distribution leading to optical interconnect demonstrations. A discussion of these technology developments, as well as some optical interconnect system demonstrations, will be the subject for the remainder of this paper.

Optical Routing Techniques

There are basically two types of routing techniques being explored - guided and free space. The guided interconnect technique could use optical fibers for distributing the optical signals or optical waveguides integrated on a substrate. Fibers for optical input/output (I/O) shows promise because of its well established technology, low cost and ease of coupling to the fibers. Since the distances to be travelled by the optical signals for applications discussed in this paper are short (<1 km), multi-mode fibers can be used even for data rates of several Gb/s. This will significantly ease the fiber to chip alignment and packaging constraints. A general scheme for using optical fibers[3] for I/O is shown in Figure 2. Fibers are sufficiently flexible and low volume to provide random routing with little crosstalk for backplane communications. For chip-to-chip interconnects on a single board or even intrachip communication, fibers become cumbersome. In this environment, fibers and their bending radius become large in comparison with typical electrical interconnects and the size of the devices. An alternative is to use integrated waveguides in the packaging to increase density and reliability.

The fiber optic routing scheme shown in Figure 2 shows two possible configurations. The first is a point-to-point communication link with a single optical source linked to a single receiver having a fanout of one. The second shows a multiple fanout with one source communicating to several detectors.
