Figure 2 Scheme for using optical fibers for I/O showing a fanout (bottom) of one and multiple fanout (top) [Ref. 3].

In the area of high-speed communication busses, there is a practical limit for speed and fanout in implementing high speed electrical bus structures. These busses span printed wiring boards, between boards and between systems. The difficulty arises when an electrical interconnect is required to fanout to multiple distributed loads. As the number of fanouts increase, several parameters effect the electrical interconnect. The two most notable effects of fanout[4] are the lowering of the effective characteristic impedance and the increase of the propagation delay. While the increase in characteristic impedance is not fundamentally limiting since drivers can be designed to provide the required power, it does increase the required on chip power and decrease available chip real-estate, both of which are undesirable. The effect of the decrease in propagation delay decreases the critical line length. The critical line length is the maximum length that an electrical interconnect can be without termination, so that ringing on the circuit is minimized.

Using optical fibers as the transmission media, the effect on fanout is quite different. The number of fanouts for optical interconnects are limited primarily by the available power to the detectors. The actual power available to the detectors is determined by the power of the source and losses throughout the distribution system. Optical fanout is achieved by power splitting of the optical channel as shown in Figure 2, which can be achieved by star, tree or tap networks. The maximum fanout for an optical channel can be determined from the minimum power required by the detector (for a given bit error rate), optical source power and losses throughout the system. Figure 3 shows a comparison of optical and electrical fanouts versus clock frequency[4] for a bussing structure.

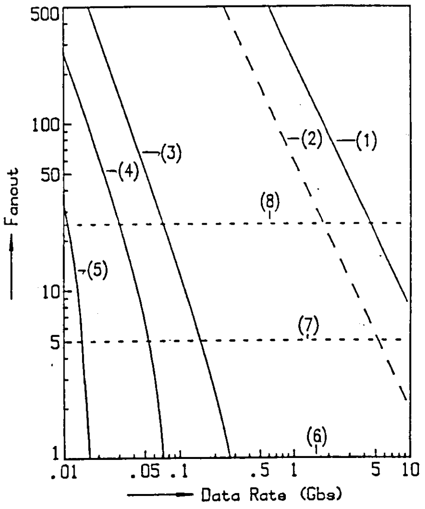

Figure 3 Optical and electrical fanout limitations versus data rate for various conditions (1) maximum theoretical optical fanout (2) practical limitation to optical interconnects assuming a 6dB design margin (3), (4) and (5) represent 2, 10 and 50 cm unterminated electrical lines respectively and (6), (7) and (8) represent 2, 10 and 50 cm terminated electrical lines respectively [Ref. 4].

Using un-guided or free-space techniques for directing the light to its destination is a method that shows a lot of promise. The use of free space allows the density of the interconnects to increase to the fundamental diffraction limit of optics with minimal crosstalk. One can use either unfocused or focused free space interconnects. The unfocused technique simply broadcasts the optical signals carrying the information over the entire electronic chip. However, this type of interconnect is inefficient since only a small portion of the optical energy falls on the photodetectors and the rest is wasted. Also, optical energy incident on portions of the chip where it is not wanted may induce stray electronic signals that cause errors and improper operation.

Using holographic techniques as shown in Figure 4, the optical source can be imaged onto a multitude of detector sites simultaneously[5]. This should significantly increase efficiency and reduce stray electronic signals, provided the hologram can be made with large diffraction efficiency. The primary disadvantage of using focused interconnect techniques is the high alignment precision that is needed to assure that the focused spots are striking the appropriate places on the chip[6]. A number of holographic imaging techniques for optical interconnects has been investigated by Goodman[7] et al. The configuration that appears to have the most flexibility is shown in Figure 5, since it can have a large number of independent channels and spatially variable fanout[7]. In this proposed technique, each facet is illuminated sequentially with a number of diverging object beams and a converging reference wave. The positions of the object beams can be moved automatically with a computer controlled stepper motor drive and the beam ratios can be adjusted to provide optimized diffraction efficiency.

Bergman[8] et al have been looking at reflection holograms fabricated as a surface relief in silicon. The holographic pattern is recorded in photographic film and then contact printed onto a layer of photoresist on a silicon substrate. After developing the photoresist, the silicon is chemically etched and then coated with aluminum. To date, they have achieved 20 percent diffraction efficiency with a promise of higher efficiency in the future.

Free space optical interconnects provides the potential of implementing reconfigurable interconnects. Figure 6 shows one possible implementation of a nonblocking crossbar network[9]. The input LED's or lasers represent the inputs of "n" different channels, while the detector array is the output to "n" channels. The spatial light modulator which may be electro-optic, magneto-optic or acousto-optic, can be programmed to connect any one of the inputs to one or any combination of outputs.

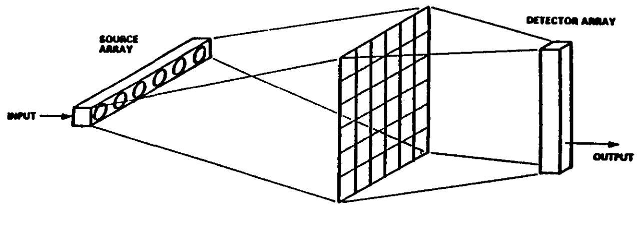

Figure 6 Free space optical interconnect implementation of a crossbar network [Ref. 9].

Packaging Techniques

For optics to be used in computing systems, packaging methods must be developed to allow high-speed silicon and GaAs digital components to be packaged with opto-electronic components and waveguides[9,10]. Unique packaging problems arise when optical interconnects are used with high speed electronics. The coupling between opto-electronic components and waveguides requires critical alignment tolerances of less than a micron. In addition, thermal conditions on the chip carriers must be tightly controlled to keep the opto-electronic devices from drifting.

A technique has been developed and demonstrated at Honeywell[4] to align several fibers to a multiple detector array. Figure 7 shows the optical coupler which was developed to align and attach multiple fibers. V-grooves were etched in silicon[11] to provide an excellent alignment fixture since the spacing between the V-grooves can be delineated exactly to match the detector spacing. As shown in Figure 7, the exit end of the fiber is polished at an angle such that the light strikes the end of the fiber and is total internally reflected through the bottom of the fiber. Since the fiber used in these experiments was multimode (50 um core diameter), the end of the fiber must be polished at 58° so that all of the modes are total internally reflected. It is interesting to note that since the fiber has a cylindrical geometry, the fiber acts as a lens to focus the light into an elliptical spot in the detector plane. This allows the detector size to be smaller than the fiber core diameter which could be important for very high speed systems.

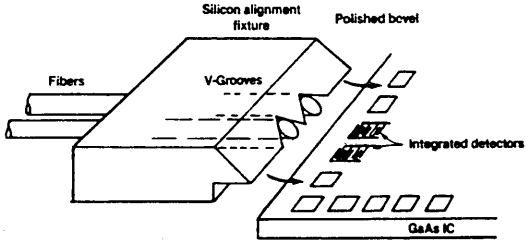

Figure 7 Fiber to detector alignment technique utilizing silicon V-grooves [Ref. 9].

Maximum efficiency is limited to about 70% using this technique, due to Fresnel reflection from the surface of GaAs. This could be reduced by introducing an index matching fluid or depositing an anti-reflection coating on the surface of the detector. Without using index matching fluid, anti-reflection coatings or taking any special precautions, an efficiency of 60% has been demonstrated[9].

A different fiber to chip technique shown in Figure 8 has been demonstrated[12] that allows vertical bonding of the fiber to the chip. A high aspect ratio hole is etched in the silicon substrate by using a frequency-doubled argon-ion laser at a wavelength of 257 nm for laser-assisted etching in a 5% aqueous solution of HF. The diameter of the hole is controlled (to first order) by the diameter of the laser beam. In this case, the diameter of the hole was 12 um. Due to the nature of light guiding during the etching process, the side walls of the etch are nearly vertical.

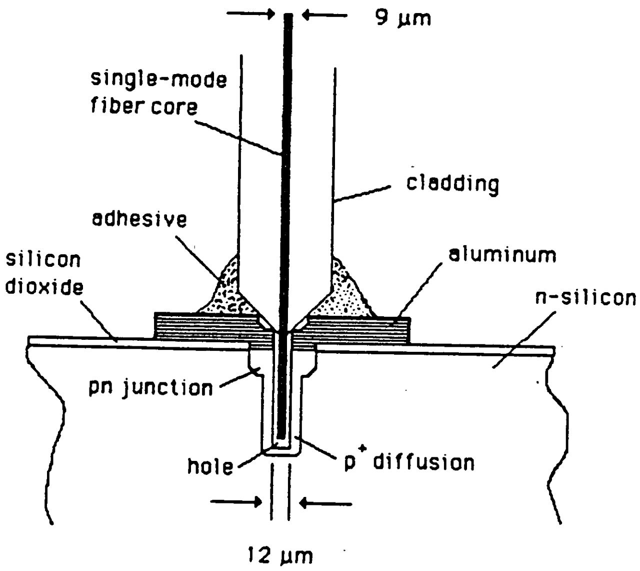

Figure 8 Schematic cross-section of a vertical mounted fiber optic coupler [Ref. 12].

Once the hole has been etched, a pn junction detector is fabricated in the hole using standard semiconductor device fabrication techniques. A single mode fiber is chemically etched down to its 9 um diameter core by immersion in buffered solution of HF for approximately 2 hours. The etched fiber is then inserted into the detector well and attached to the chip using epoxy. This system was tested by coupling a He-Ne laser emitting at a wavelength of 6328nm into the fiber using a microscope objective. By measuring the IV characteristic of the photodiode, the responsivity was determined to be 0.13 A/W corresponding to a quantum efficiency of approximately 25%.

The advantage to using this technique is the flexibility to put the optical detectors at any position on the chip. This allows the flexibility to receive information at any position. This technique is not planar, therefore, an unconventional package needs to be implemented to use this technique. This particular development was demonstrated in silicon, however, it could also be used for GaAs circuits.

A packaging technology based upon multichip integration is being developed at MIT Lincoln Laboratories. Individual die or chips are imbedded in a potting compound and cast[13] as shown in Figure 9. By using standard photolithographic processes, defining connections between the chips becomes fairly routine. Choosing the potting compound is crucial to ensure chemical and thermal compatibility with photolithographic processing steps. A breadboard demonstration was built which consisted of a commercial GaAs shift register (HMD-11141), a mass-transported GaInAsP laser diode[14], a 6-dB attenuator, and an outer-conductor DC block. The laser had a threshold current of 18.5mA and a 3dB frequency of 6GHz at a current of 50mA. Using a clock rate of 1.4GHz to the input of the GaAs shift register, a chip risetime of 150 ps and a falltime of 120 ps was measured.

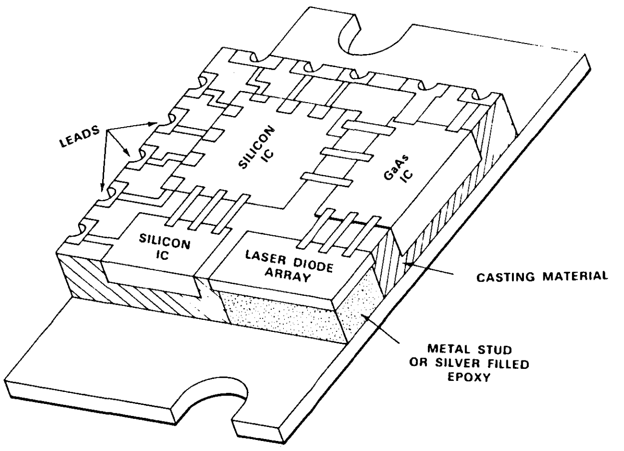

Figure 9 Multichip packaging technique of silicon, gallium arsenide, and opto-electronic components [Ref 13].

Opto-Electronic Device Development

In addition to optical routing, the effective use of optical interconnects also requires high performance, low power opto-electronic transmitters and receivers. The use of discrete components for the opto-electronic transmitter and receiver suffers from two disadvantages[15]; one is the difficulty of controlling parasitic reactances and the second is the high cost of manually fine tuning each module to create reproducible performance at high frequencies.

It is anticipated that in order to realize the full performance of an optical interconnect system, there would be a distinct advantage if the opto-electronic components were monolithically integrated with the high speed electronics. The excess capacitance and inductance with the bonding pads and wires would be eliminated. This translates to higher speed, less power and lower noise than its hybrid counterpart. GaAs provides an attractive material for monolithic integration since both GaAs digital integrated circuits and AlGaAs/GaAs opto-electronic devices are being developed at numerous laboratories. There have been a number of demonstrations of laser diodes integrated with either a single or a few GaAs IC components [16-20]. Although these devices demonstrated the feasibility of the monolithic integration of lasers with a small number of transistors, these techniques have not been suitable for integrating a laser with a large GaAs IC.

For the past several years, Honeywell and Rockwell have been developing the technology to integrate opto-electronic devices with complex GaAs circuits[15,21-24]. One structure that has been demonstrated[15] is shown in Figure 10. The components in the structure are a transverse junction stripe (TJS) laser, a field effect transistor (FET) driver, and a 4:1 multiplexer (MUX). The mux and driver active regions are formed by selective ion implantation into the semi-insulating GaAs substrate while the TJS laser is fabricated by liquid phase epitaxial growth in a well that is etched into the substrate. The rear laser mirror facet is formed by using a microcleave process developed at the California Institute of Technology[25]. A cross sectional view of the microcleave process is shown in Figure 11. The small horseshoe shaped wing at the end of the laser is formed by chemically etching under the AlGaAs. The wing is broken off to form a smooth cleaved mirror facet. Measurements have shown that lasers with undercut mirrors have operating characteristics (laser threshold ~ 37mA) identical to similar lasers having two cleaved mirrors. The opto-electronic chip having a size of 1.8 mm x 1.8 mm operated at speeds up to 150 MHz[26].

More recently, a 1 Gbit/sec opto-electronic receiver chip was demonstrated[27]. The receiver chip was designed to digitally multiplex four high speed input signals. Two of the inputs are electrical and two are optical. The receiver consisted of two back-to-back Schottky diode detectors, two amplifiers, a 4:1 multiplexer and a laser driver. All of the components are fabricated on a semi-insulating GaAs substrate using direction implantation MESFET technology.

The photodector was fabricated directly on the semi-insulating substrate, thus eliminating the need for epitaxial growth. A pulse response of the back-to-back Schottky photodiode[28] is shown in Figure 12 for a reverse bias voltage of -15V. The rise and fall times of the photodetector response observed for a range of bias voltages between -10V and -15V were under 100 ps, which is sufficient for a 1 Gbit/sec operation of the receiver. The responsivity of the detector was measured to be 0.2 A/W for a wavelength of 0.84 um. The output of the detector is fed into a three-stage amplifier: a preamplifer, a gain stage and a buffer stage. The preamplifier translates the current into a voltage and amplifies to the proper GaAs logic levels by the gain stage and the buffer stage is used as a line driver to drive the input of the 4:1 multiplexer. The preamplifier had a gain of 20dB with a feedback around the second stage to improve its frequency response.

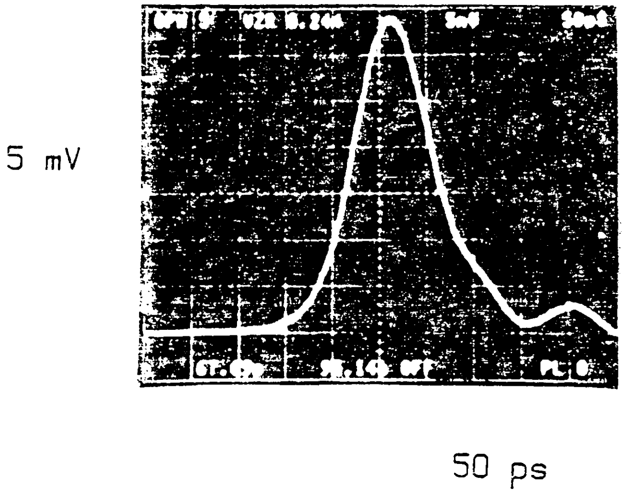

Figure 12 Pulse response of back-to-back Schottky photodiode for bias voltage of -15V [Ref. 26].

A similar effort on monolithic integration using a multiple quantum well (MQW) laser with a ridge waveguide structure[24] in shown in Figure 13. The MQW laser structure was grown by MOCVD and consisted of five 100 A GaAs wells separated by four 40 A $Al_{0.2}$ $Ga_{0.8}$ As barriers. The ridge waveguide was ion milled having a width of 5 um. These integrated devices have shown room temperature operation with 15 mA threshholds and differential quantum efficiences of 60%. For this particular integration scheme, the laser will be implemented as a surface emitting laser as shown in Figure 14. The laser light is coupled from the laser to a passive AlGaAs waveguide. The light in the waveguide is coupled from surface either with an etched V-groove or a grating as shown in Figure 14. This technique allows the user to fabricate lasers at any position on the chip rather than only at the edge of the chip. This method is more difficult to implement if fibers are to be used as the transmission medium. However, it does provide the flexibility for utilizing the third dimension and directing the optical signals via holographic techniques.

The photodetector used in this development is a PIN photodector grown by MOCVD. The structure is a 6 layer stack consisting of GaAs and AlGaAs layers. Initial tests on this device have shown a dark current [24] of less than 10pA and a breakdown voltage of 80 V. A current gain of 10 was demonstrated at a voltage of 95% of breakdown.

Optical Interconnect Demonstration

There are a number of university, government and industrial laboratories developing analytical tools, technology, packaging techniques and system demonstrations. One system demonstration nearing completion is a hybrid model designed for point-to-point communications between chips and boards. A block diagram of the interconnect demonstration is shown in Figure 15. The board consists of four ECL Fairchild 100K series shift registers, each of which provides an 8-bit psuedo-random word at 250Mb/sec. The outputs of the four high speed ECL chips are connected to a GaAs 4:1 multiplexer which has an output of 1 Gbit/sec. Two of the ECL chips are packaged with an AlGaAs laser, laser drivers and an optical fiber. The other two word generators are packaged alone such that the GaAs chip has two optical inputs and two electrical inputs. The GaAs 4:1 multiplexer package consists of two optical fiber inputs, two electrical inputs, the GaAs chip with 4:1 multiplexer, detectors, preamplifier, laser driver and a separate laser coupled to an optical fiber. The optics was designed to have a minimum impact on the existing high-speed package, but still provide rigid and efficient coupling to the opto-electronic components.

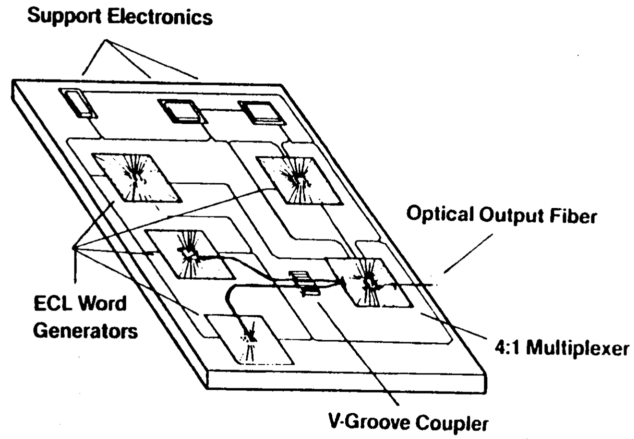

Figure 15 Layout of chip-to-chip and board-to-board Optical Interconnect Demonstrations [Ref. 1].

The full system test has not been completed; however, key components in the system have been tested. The GaAs receiver chip was tested and found to be fully functional. An optical fiber was positioned over one of the two detectors, and one of the four data channels was successfully modulated with an optical input. The 4:1 multiplexer on the GaAs chip was implemented using a complementary clocked dual shift register architecture. This architecture makes it possible to have an output data rate (NRZ) that is twice the clock speed. All of the shift registers in the multiplexer were designed using a differential current-mode-logic structure to minimize the delay and device count in the shift registers[27]. The complete GaAs chip consists of 807 depletion mode transistors and 325 level shifting diodes.

A test fixture was developed to test the high speed GaAs receiver. Tests were performed to determine the maximum data rate that the 4:1 multiplexer was capable of handling. The bandwidth of the test equipment was the limiting factor in determining the maximum data rate of the chip. The maximum data rate measured on the receiver chip was 2 Gbit/s (NRZ). The size of the GaAs chip is 2.82 mm x 2.04 mm and it dissipated 3.5 watts of electrical power at 1 Gbit/sec. It is anticipated that test data for the full optical interconnect demonstration will be presented at the conference.

Another optical interconnect demonstration is being developed at the Naval Ocean Systems Center[29]. Figure 16 shows the concept where an optoelectronic switch will be used in a time division muliplexing (TDM) scheme. This is being investigated as an output from a VLSI chip where the timing comes from adjusting the length of the fiber. A side view of the optoelectronic switch is shown in Figure 17. The metal interconnect stripline has a small discontinuity such that the signals cannot be transmitted to the edge of the chip. The connection is made by shining a high speed laser pulse at the position of discontinuity. This increases the conductivity of the semiconductor sufficiently to short the discontinuity. By adjusting the length of the fiber several of these microstrip lines can be multiplexed to a high speed serial output. This technique has been demonstrated in silicon but could also be implemented in GaAs.

Conclusions

As can be seen by the discussion presented in this paper, there are numerous researchers developing the concepts and technology for advanced optical interconnects for high speed computing applications. A lot of attention is being given to packaging high speed silicon VLSI devices with high speed GaAs integrated electronics, opto-electronics and optics. The optimum method for routing the optical signals has yet to be determined. However, fiber optics for the board-to-board and local area network applications and free-space holographic techniques for the intrachip and chip-to-chip communications appears to have the most promise. The monolithic integration of opto-electronic components with electronics is making rapid progress, yet a number of technical hurdles such as ultra-low threshold lasers, reliability, yield and low power, need to be solved before these devices can be implemented in computing applications.

The results to date are encouraging for optics to become an integral part of future high throughput computing systems. For the near term, we can expect several demonstrations of optical interconnects using hybrid components. As the packaging of electrical and optical components becomes more common, we will learn which applications and which high speed circuits will benefit from this technology.

ABSTRACT

Optical techniques have great potential for applications in the dynamic interconnection of digital parallel processing systems. In this paper, we review some of the relevant advantages of optics, including high signal bandwidth, inherent parallelism, and low mutual interference. Specific optical realizations of dynamic generalized crossbars and other types of networks are presented. One way to implement crossbar networks is to utilize optical matrix-vector multiplier architectures; several designs are compared. The systems may use acousto-, electro-, or magneto-optic spatial light modulators as the active controlling element. Other optical digital processors that can realize crossbars and multistage networks are also described.

1.0 Introduction

This paper is concerned with the application of bulk (3-D) optical components and optical architectures to interconnection problems in digital systems. Efficient communication among the elements of these systems is recognized as the key to faster computing through the use of parallel processors and shared resources. This paper concentrates on dynamic, rapidly time-variable interconnections at the spatial scale size of processors (10^0-10^3 m) and boards (10^{-1}-10^0 m).

Several multiprocessor systems incorporating a large number of processors are in various stages of development [COMP 82], [COMP 85]. A crossbar network is very desirable for interconnections among these processors because every processor can communicate with every other processor with no conflicts. However, the electronic implementation of crossbar networks of large size is difficult due to constraints on VLSI technology. The parallel nature of optics, its high available signal bandwidth, together with its relative freedom from interference makes it attractive for implementing large crossbar and other networks that do not suffer from many of the limitations of their electronic counterparts.

1.1 Need for Parallel Interconnection Architectures

Any multiprocessor system that applies several processors to a job must be designed to allow efficient communication between processors, and between processors and memories, or else the advantage of multiprocessing is offset by the communication bottleneck. A crossbar interconnection network allows every processor to communicate with every other processor with no conflicts in the network (we use the term "crossbar" here to refer to networks which are strictly non-blocking, in which a unique path exists from every input to every output; the complexity of such networks grows as the square of the network size N) - however, the electronic implementation of large crossbar networks has been considered impractical due to technological constraints. This fact forced researchers to proceed in one of two directions: (i) design interconnection networks with less than $O(N^2)$ complexity, which are feasible to build and easy to control, and, at the same time, provide reasonable performance; or (ii) design new algorithms or modify existing algorithms to suit the limited interconnection structure, so as to utilize the available interconnection structure most efficiently. Due to their inherent 3-dimensional nature, low mutual interference between channels, and high bandwidth, optical switching systems offer great potential for multiplexing data from thousands of processing elements over a single optical channel without causing a speed bottleneck.

1.2 Interconnection Considerations

Dynamic reconfigurable interconnection networks are desirable for interconnecting a large number of processors (or PEs) to memories or to other processors. Connecting every PE to every other PE (or memory) with a fixed, dedicated line is not viable because of the number of lines and connections required. Networks range in complexity from a simple bus to a crossbar. In this section we define some important interconnection network characteristics and describe how they differ in electronic and optical implementations.

Number of Lines. This parameter, N, defines the number of input and output lines. Implementing moderately large crossbars (>100×100) in electronics is difficult due to bandwidth, power and reliability contraints.

Bandwidth. This refers to the bandwidth of each line in the network. In passive optical networks (which do not detect and regenerate optical signals internally), the bandwidth is limited by external sources and detectors, which can easily operate at 1 Gb/s rates or higher. Sources (laser diodes) and detectors are available at 20 GHz and 40 ps, respectively. 1-D arrays of these devices are presently limited to lower values; existing detector arrays with parallel outputs operate at approximately 50 Mb/s. In contrast, electronic systems typically operate at 10 Mb/s for each line.

Reconfiguration Time. Reconfiguration of optical networks is limited to approximately 1 μs for moderate or large networks, with existing or near-future technology. Optical device arrays presently have switching times of 1 μs for each switch at best. For an electronically controlled optical switching array, it is a matter of switching time *and* addressing schemes to control all of the switch states: Practical electronic switches can typically switch in 50-100 ns for each switch. Fast reconfiguration of the network is needed in an environment where the switching permutations change rapidly. However, slow switching could be tolerated in applications where each connection is followed by the transfer of large blocks of data.

CH2345-7/86/0000/0457$01.00 © 1986 IEEE

Broadcast Capability. Broadcasting is the ability for one processor to simultaneously send information to more than one other processor. If the interconnection network is capable of achieving broadcasts in one step, the overall time-complexity of many parallel algorithms can be reduced. In electronic implementations, the provision of broadcasting involves higher control complexity, a larger number of pins, and/or slower operation. In some optical systems, the addition of broadcast capability involves only very minor increases in complexity.

Data Format. The switching process as well as the transfer of data can be performed either synchronously or asynchronously. Synchronous operation requires strobing or capture of data at precise instants of time in the system; data buffers are generally required.

Type of Detector. Three major kinds of multichannel optical detectors, namely real-time, shift/add and time-integrating are required to implement these systems. The data bandwidths of systems with a vector array of real-time detectors is limited by the response time of each. Limitations on shift/add and time-integrating detectors are generally due to multiplexing electronics needed to provide the electronic output.

1.3 Electronic Crossbar Networks

We note very briefly that a few electronic crossbar switch units with as many as 512×512 switches have been designed and/or constructed for experimental special-purpose parallel processor systems [BURG 83], [DENN 82], [BROO 84], [SAWC 85], [SAWC 86]. These systems are generally physically large, dissipate a great amount of heat, and have questionable reliability.

2.0 Crossbar Interconnections with a Matrix-Vector or Matrix-Matrix Processor

Suppose that N serial data input lines (each one-bit wide) are to be connected to a set of N serial data output lines (each one-bit wide). The data bits on each line can be thought of as flowing synchronously, although, for some of the techniques described, this synchronism is not necessary. The data on the input lines at some instant of time is represented by the column vector $\vec{b}$ of length N. The data on the output line of the interconnection network is represented by the column vector $\vec{c}$ of length N, and both these vectors have only binary elements. The state of the switch is described by the $N \times N$ matrix A whose elements are also 0's and 1's. Matrix A is a generalized permutation matrix; an entry of 1 in row i and column j of A means that input j is connected to output line i. The overall operation of the interconnection network is represented by

$$\vec{c} \doteq A\ \vec{b} \qquad (2.0\text{-}1)$$

which is a matrix-vector multiplication. As an example of this we have (for $N=4$),

$$\begin{bmatrix} 0 \\ 1 \\ 0 \\ 1 \end{bmatrix} = \begin{bmatrix} 1&0&0&0 \\ 0&0&1&0 \\ 0&1&0&0 \\ 0&0&0&1 \end{bmatrix} \begin{bmatrix} 0 \\ 0 \\ 1 \\ 1 \end{bmatrix} \qquad (2.0\text{-}2)$$

Note that each row and column of A must have only a single "1" entry for the switch to act as an ideal one-to-one crossbar permutation network. The system can perform broadcasting (one input connected to two or more outputs) if there are two or more 1's in a column of A. However, two or more 1's in any row of A implies contention, as several inputs attempt to communicate with one output. Once the physical connection described by the matrix A is made, the data transfer can be synchronous or asynchronous.

This idea can be generalized for the interconnection of N parallel input lines (each M bits wide) to N parallel output lines (each M bits wide). In this case, the input lines are represented by an $N \times M$ matrix B, the output lines are represented by an $N \times M$ matrix C, and the interconnection matrix A is the same as before. All matrices (A, B and C) have binary entries as before, and the switching operation is

$$C = AB \qquad (2.0\text{-}3)$$

Thus, systems capable of performing matrix-vector or matrix-matrix multiplications with binary entries as given in Eq. (2.0-1) or Eq. (2.0-3) are suitable for use as a crossbar interconnection network. There are many techniques available for this purpose in optical signal processing. In some of these systems, the physical switch may be analog and passive (a switchable reflective or transmissive element); thus bit synchronism is not required and the data bandwidth is limited only by the optical sources and detectors used. In other systems, the matrix-vector multiplication is implemented by active electro-optical or acousto-optical components, implying the detection and regeneration of optical signals. In such systems the switch itself may limit the data bandwidth. In the remainder of this section we discuss some of these systems.

2.1 N^2-Parallel Inner Product Processor

Figure 2.1-1 schematically shows a system capable of performing optical matrix-vector multiplications of the form of Eq. (2.0-1) in an inner product format [ATHA 83]. The N input lines drive a 1-D array of N light emitting diodes (LEDs) or laser diodes with a binary signal, so that a binary 1 is represented by light of a fixed intensity, and a binary 0 is represented by a lower (or zero) intensity. An optical system to the right of the input vector spreads the light from each input source into a vertical column that illuminates the crossbar mask shown. The crossbar mask consists of an $N \times N$ array of windows representing the entries in the $N \times N$ permutation matrix A. An entry of 0 in A corresponds to zero light transmission, or an opaque window in the mask. An entry of 1 in A corresponds to full light transmission or an open window. In the systems we are investigating, the crossbar mask is an electrically-controllable shutter array that is time-variable through the application of external control signals. Several different technologies are available for this purpose, including mechanical, electro-optic, and magneto-optic.

Following the crossbar mask, the next set of optics collects the light transmitted by each row of the mask, and sums the mask output onto a 1-D vertical array of N photodetectors corresponding to the N output lines. Thus the system performs a parallel matrix-vector multiplication. There are many possible ways to actually implement this schematic design, some of which use discrete optics or optical waveguides.

This N^2-parallel inner product architecture has an optical light efficiency of $1/N$ at most, when used for the usual crossbar operation. This occurs because $(N-1)/N$ of the light from each input source does not pass through the crossbar mask. A matrix-vector operation is completed in just one clock cycle. A matrix-matrix multiply takes N clock cycles. Since it is a passive interconnection, once the mask is set, the data can flow through synchronously or asynchronously, can be analog

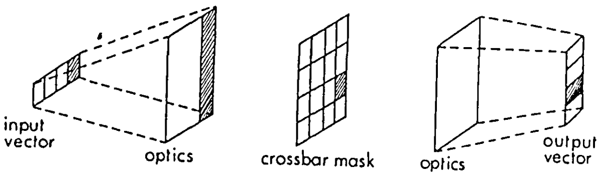

Fig. 2.1-1. N^2-parallel matrix-vector inner product processor.

or digital, and has a bandwidth limited only by the sources and detectors. The inputs and outputs can also be directly coupled to optical fibers; in this case the sources and detectors can be some distance from the system. Another advantage of this system is that no input or output buffers are required. Broadcasting is possible, providing a generalized crossbar interconnection. The control is external and could be optical or electronic; this architecture is useful primarily for circuit switching applications.

2.2 Systolic Architectures

Systolic architectures have the advantage of providing for rapid reconfiguration of the network, i.e. they can be reconfigured at the bit rate of the data (neglecting any overhead in calculating the needed states of the crossbar matrix elements). In systolic systems, though, the input data must be configured appropriately for the matrix multiplication to proceed; this will require electronics at the input that can buffer the signals and send them into the switch in the appropriate sequence and at appropriate times. In some cases, only minimal buffering is required, e.g. when the data is originally time-division multiplexed bit by bit.

An N-parallel systolic matrix-vector multiplier is shown in Fig. 2.2-1 and implements the matrix-vector multiplication of Eq. (2.0-1) [ATHA 83].

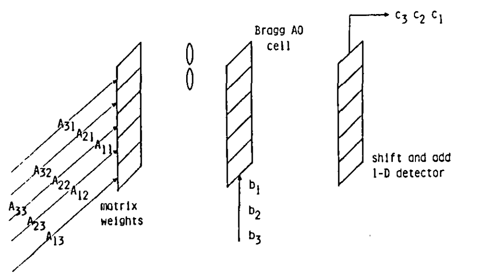

Fig. 2.2-1. N-parallel systolic matrix-vector multiplier.

The matrix elements A_{ij} conceptually flow in from the left. (Each pair of matrix elements along a line is actually separated by a 0.) They can be realized physically by a 1-D array of LED's. The vector elements b_j enter the end of the acousto-optic (AO) cell. (The b_j's are interlaced with 0's). The signals are synchronized so that A_{11} is emitted from the center LED when b_1 reaches the center of the AO cell. The system is arranged so that the light from each LED passes through the corresponding pixel of the AO cell, and results in the product $A_{ij}\ b_j$ of these elements at the corresponding element of the 1-D detector array. A shift/add detector (e.g., 1-D CCD) will accumulate the appropriate elements and output the resulting vector elements c_i serially. For example, in the first cycle $A_{11}\ b_1$ will appear at the middle detector. In the second cycle $A_{11}\ b_1$ will have been (electronically) shifted down one detector, element A_{12} will appear on the corresponding LED and b_2 will have moved up to the corresponding AO cell location, resulting in $A_{11}\ b_1 + A_{12}\ b_2$ on this detector. In this manner all terms of c_1 are accumulated by the time it reaches the end of the detector array.

Compared to the inner product architecture above, systolic architectures yield crossbars that are more light efficient, have shorter reconfiguration times, but have lower bandwidth. A number of these 1-D elements in the N-parallel multiplier can be placed in parallel however, permitting each line to be M bits wide, thereby increasing the effective bandwidth by a factor of M ($M \approx 100$ with current devices). Because a new matrix is essentially read in for each new bit or word, the system can be reconfigured rapidly.

An N-parallel systolic matrix multiplier requires $N(4N-3)$ clock cycles to complete one matrix-matrix multiplication, or one arbitrary switching operation on N input lines, each N bits wide. In this time 1 (N-bit) word on each line passes through the network. An N^2-parallel systolic arrangement can do this in $4N-3$ clock cycles. The detector in these cases is a shift-and-add detector, instead of the parallel readout detector needed in the parallel inner-product multiplier above. In most cases, these detectors will limit the system bandwidth. Also the bandwidth of each line decreases as the number of lines is increased. The potential application for this configuration is in switching time-division multiplexed signals. The data is digital in these systems and the operation is strictly synchronous. Also, the light efficiency can be substantially higher than the inner-product processor discussed above. The use of these systems is primarily when the number of lines is not too large, the bandwidth requirements are not extreme, and the reconfiguration is rapid.

2.3 Engagement Architectures

Engagement architectures such as that shown in Fig. 2.3-1 use time-integrating (instead of shift/add) detectors, preferably with parallel outputs.

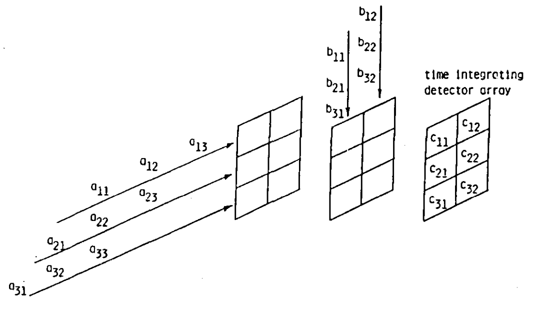

Fig. 2.3-1. Engagement architecture for matrix multiplication.

With sufficiently fast input and output devices, the acousto-optic (AO) cell used as a spatial light modulator (SLM) will limit the bandwidth of each individual line to ν_0/N, where $\nu_0 \approx$ 1 Gb/s. The matrix elements of A enter into a 2-D source array or a multichannel AO cell, skewed and formatted as shown. The data, or elements of B, enter a second, crossed AO cell from the top. A 2-D stationary integrating detector array then accumulates the results and outputs them in parallel.

An N-parallel engagement matrix multiplier requires $N(3N-2)$ clock cycles to complete one matrix-matrix operation or one arbitrary switching operation on N N-bit wide lines, approximately the same as the (N-parallel) systolic case. An N^2-parallel engagement arrangement [BOCK 84] takes $3N-2$ clock cycles. The input data formatting requirements are similar to the systolic case, but interleaved 0's are not required. The N-parallel case uses time multiplexing again. We can think of the width of each functional input line as being equal to the word length so that an M-bit wide line can transfer one word at an instant of time. In the N^2-parallel engagement case, there are N physical input lines, and the switch operates on word slices: it is word serial and bit parallel except for a unit time shift from one physical line to the next. Thus the first line has the first bit of each word, sequentially in time, etc. As in the systolic case, reconfiguration is rapid but updating of the state of the switches is needed even when the state does not change from one multiply to the next.

2.4 N^2-Parallel Outer Product Processor

An N^2-parallel outer product processor such as that shown in Fig. 2.4-1 performs $C=AB$ by taking outer products of column i of A and row i of B, and summing the results over i.

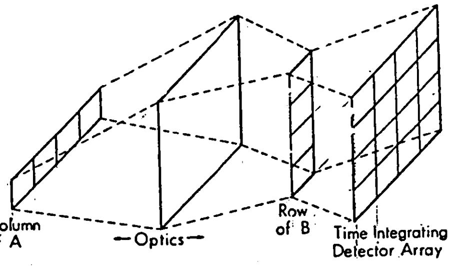

Fig. 2.4-1. N^2-parallel outer product processor.

It can perform a matrix-matrix operation in N clock cycles. However, typical acousto-optic implementations require the clock cycle to be equal to the fill time of the AO cell; this is a much longer clock cycle than the systolic and engagement cases. Thus, an acousto-optic implementation has the same speed order of magnitude as an N-parallel systolic or engagement architecture. Other implementations using electrooptic devices may avoid this difficulty. The data input is a row of B at a time, or bit parallel, word-serial. In the acousto-optic implementation discussed, the input is actually serial, first the first word of the first line (one bit at a time), then the first word of the second line, etc. The detector is a 2-D array of stationary, time-integrating detectors. With this system broadcasting can easily be done, to provide a generalized crossbar. As in the systolic and engagement cases, the data is completely synchronous. Since the A matrix is read in for each matrix multiplication, reconfiguration is rapid, although the state of the switches needs to be updated for each matrix multiply.

2.5 N^2-Parallel Inner Product AO Deflector

The system shown in Fig. 2.5-1 improves overall light efficiency by deflecting light instead of absorbing it.

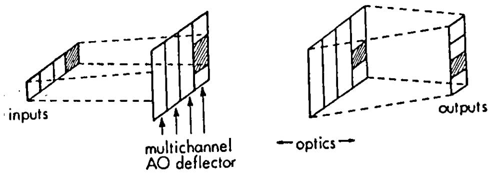

Fig. 2.5-1. N^2-parallel inner product AO deflector.

The input data to the crossbar enters through the 1-D array of sources on the left. Each source is then transferred to the corresponding cell of a multichannel AO device, used as a deflector. There is a separate channel for input line of data, or each column of A. Rather than read in the elements of A into the AO device (N elements into each channel), a single frequency-modulated signal is input into each channel; the frequency determines the amount of y-deflection desired for the corresponding input line. Broadcasting can be achieved, to a limited extent, by superimposing multiple frequencies onto the same channel of the AO cell, or by time multiplexing the different frequencies in the cell. Each channel of the AO cell in this system has just one signal on it; it is not divided into multiple (moving) resolution elements as in the previous AO systems. The light in each channel is then focused down in the x-dimension, yielding a 1-D output array.

In this system only the fill time of the AO cell limits the reconfiguration time of the switch. The bandwidth of the input data lines could be quite high; it is limited by the speed of the sources and detectors, and not by the AO cell. The time bandwidth product requirements of each cell of the AO device are modest. The reconfiguration time of the network is equal to the time window used in each cell, which is less than or equal to the maximum time window of the device; thus a reconfiguration time on the order of 1 μs can be expected.

Another advantage of this system is that, as in the N^2-parallel inner product multiplier, there are no special formatting or buffering requirements on the input or output data. The data enters in a word-serial, bit-parallel fashion; each different functional input line is a different physical input line. Also, there are N control signals instead of N^2, and they are read in in parallel. The number of input and output lines is equal to the number of cells in the AO device, which puts a limit on the number of lines that can be switched with one crossbar. The operation of the switch can be synchronous or asynchronous, and the data can be analog or digital.

2.6 N^2-Parallel Inner Product/Engagement Processor

Another type of matrix-matrix processor architecture usable as an optical crossbar is shown in Fig. 2.6-1.

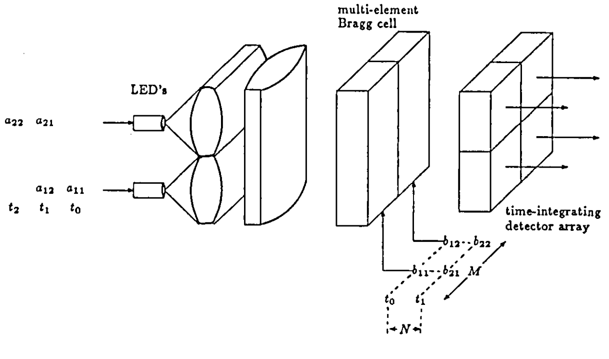

Fig. 2.6-1. N^2-parallel inner product/engagement processor.

The system is a combination of an N^2-parallel inner product processor and an N^2-parallel engagement architecture. The b 's to be multiplied in the system enter a parallel array of AO cells as shown, although the data for each row enters simultaneously instead of being staggered as in the N^2-parallel engagement processor. The input data also arrives in a time-staggered form and controls the illumination of LED's or laser diodes as shown. A set of optics similar to that in the N^2-parallel inner product processor spreads the light across the multichannel AO cell, and the final result accumulates on a time-integrating detector array. The results emerge in a time-offset fashion from a row of the detector array as shown. This system requires $3N-2$ clock cycles to complete a matrix-matrix multiplication and requires a digital synchronous data format. Broadcast operation is possible with this system, and the overall light efficiency can be as high as $1/N$.

2.7 Matrix-Vector System Performance Comparison

The systems described in these previous sections have greatly differing characteristics. For example, some of the systems provide a bandwidth that is essentially independent of the size of the system, while for others, it is an inverse function of the system size. In Table 2.7-1, we compare the six different systems of Sections 2.1-2.6 based on the six parameters of interest listed in section 1.2.

The engagement and outer-product systems with full N^2 parallelism require $N \times N$ time-integrating detectors which are operated synchronously with the data. 2-D $N \times N$ detector arrays have either N output lines or 1 output line. Thus the necessity of multiplexing at least N detector signals onto each electronic output line creates a bottleneck and limits the bandwidth of the overall system. Using N^2 parallel outputs could eliminate this bottleneck; the feasibility of such detectors is worthy of investigation. Also, the number of channels N may be limited by the time-integration of noise. The systolic architectures require a shift/add detector array to perform the summation. $N \times N$ shift/add arrays necessarily have at most N output lines; this and the use of electronics to perform the shift add limits the detector speed, in turn lowering the overall bandwidth of the system.

2.8 Other Matrix-Vector Systems

There are many other systems not described in this paper which show promise for interconnection applications. These systems include: an N^2-parallel encoded binary inner product processor; N^3-parallel matrix-matrix architectures; and an N-parallel strobed 1-D AO deflection system. These systems will be described in future papers.

3.0 Optical Sequential Logic System for Interconnection Networks

Because a computer can be used to implement an interconnection network, we can consider the use of an optical logic system. An optical logic system can be built out of gates and interconnections as shown in Fig. 3.0-1. An optical switching device can be used to implement a 2-D array of optical gates (e.g., NOR gates can be implemented since they can form a complete logic set). These gates can be interconnected with an optical system consisting of lenses and one or more computer-generated holograms [JENK 84a]. Here the interconnections between gates within this computer are fixed, and the system as a whole is used to implement a reconfigurable interconnection network. We have experimentally demonstrated a 16-gate optical circuit consisting of an oscillator and a synchronous

Method of implementation	Number of lines	Bandwidth (BW)	Reconfiguration time	Broadcast	Data format	Type of detector
N^2-parallel inner product	> 256	1 GHz (passive)	$(N)1\ \mu s$	yes	async	real time $N \times 1$ element
N^2-parallel systolic	> 100	10 MHz*	N/BW	yes	sync	$N \times N$ shift/add
N^2-parallel engagement	> 100	10 MHz* - 100 MHz	N/BW	yes	sync	$N \times N$ time-integrating
N^2-parallel outer product	>256	10 MHz* - 1 GHz	max (N/BW, $N \cdot 10$ ns)	yes	sync	$N \times N$ time-integrating
N^2-parallel inner product AO deflector	> 100	1 GHz (passive)	$1\ \mu s$	limited	async	real time $N \times 1$ element
N^2-parallel inner product/ engagement	>100	10 MHz* - 100 MHz	N/BW	yes	sync	$N \times N$ time-integrating

* Limited by output (detector array) electronics. Higher numbers (when given) apply when fibers guide light to discrete detectors or other optical components.

Table 2.7-1. Comparison of optical crossbar capabilities.

master-slave flip/flop with this system [JENK 84b]. We estimate that with current technology large numbers of gates (10^6 – 10^7) can be interconnected. The primary limitation at present is the extremely slow response time of the device (a liquid-crystal light valve) used to implement the gate array (10-100 ms). Fortunately, however, entirely different technologies can be utilized for optical switching, and current research in this area provides hope for realizing respectable speeds: individual optical (NOR) gates have been demonstrated at 82 MHz [JEWE 84a], [JEWE 84b], and research has begun on using this switching mechanism in 2-D arrays. We have investigated the possible implementation of optical interconnection networks with the optical system of Fig. 3.0-1 under the assumption that such 2-D switching arrays will become available.

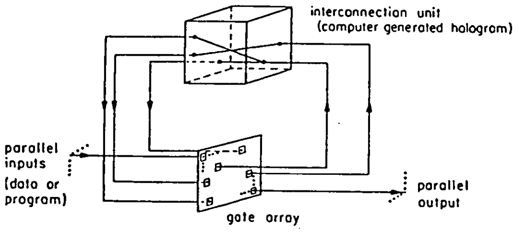

Fig. 3.0-1. Block diagram of the optical sequential logic system.

The number N of input and output nodes of a network implemented with this system is limited by the complexity of the hologram(s) and the number of gates on the device. If we assume an array of $10^3 \times 10^3$ gates on the device and currently available plotting devices for writing the hologram, we can estimate the maximum N that *one* device and *one* hologram interconnection unit can implement. Here we will assume centralized control with the control signals generated externally. A rearrangeable network consisting of a banyan followed by an inverse banyan, with all $2 \log N$ stages implemented in hardware, can be implemented with $N \approx 12{,}000$ (limited by the number of gates). In this case the data can pass through the network in a pipelined fashion. Implementing one shuffle/exchange stage also permits $N \approx 12{,}000$ (limited by hologram complexity), but the data must pass through the same hardware stage repeatedly to obtain rearrangeability. A non-blocking network can be realized by implementing a Clos network [CLOS 53] ($N \approx 650$) or a crossbar ($N \approx 500$). It should be noted that these values of N are not really limits because more than one optical system can ultimately be used in conjunction to implement much larger networks.

The optical system of Fig. 3.0-1 permits a large number of parallel input and output lines, allowing multiple optical systems to be connected to implement large interconnection networks without having to worry about careful partitioning of the network. This system differs from the optical matrix-vector inner product implementations discussed earlier: its data rate may be lower and its reconfiguration rate is higher, and the signal level of the data is regenerated as it passes through the network. The potential advantages over electronics in this case arise from the number and length of gate interconnections within each optical interconnection unit, and the number of parallel lines that can run from one optical system to another.

4.0 Conclusions and Acknowledgements

In this paper, we have reviewed the application of large crossbar interconnection networks for parallel computing systems and described several optical realizations for generalized crossbar and other networks. Several of the techniques for crossbar implementation utilize optical matrix-vector multiplier architectures, and moderately large crossbars (64×64 to 512×512) appear possible with current technology. Future work must consider additional relevant comparison factors such as light efficiency, input/output data formatting, ease of expansion, and methods for cascading small networks to make larger ones. Other difficulties that must be addressed are the relatively slow reconfiguration time of optical networks (primarily due to spatial light modulator limitations), techniques for routing and control, and methods for efficient optical-electronic signal conversion (and vice-versa). The author expresses sincere thanks to B.K. Jenkins, C.S. Raghavendra and A. Varma for their contributions to this work. This research was supported by DARPA/ARO under contract No. DAAG29-84-K-0066.

OPTICAL INTERCONNECTION TECHNOLOGY IN THE TELECOMMUNICATIONS NETWORK

Davis H. Hartman

Bell Communications Research
435 South Street
Morristown, New Jersey 07960-1961

ABSTRACT

The use of optics as an alternative method for achieving high speed (10 Gb/s $\geqslant$ B > 500 Mb/s) electronic interconnects is the subject of this paper. Particular emphasis is placed on application of optical interconnects to telecommunications technology. Optical interconnects are defined and delineated according to four separate genre. Issues and answers in the optical interconnect distribution scenario are discussed. The role of integrated optoelectronics for interconnects is stressed. Some specific recent results, theoretical and experimental, are given.

1. Introduction

Over the past fifteen years, photonics has found widespread applications in both commercial and military environments. Having its beginnings in the telecommunications field, photonics offered several clear advantages. Ultra-low loss, minimum dispersion fibers have opened doors to long-haul high speed communications hither-to unheard of. Presently, systems boasting greater than 100 km unrepeatered spans at 500 Mb/s exist. This information capacity has translated to lower cost per channel mile, leading to more profitable systems. Concurrently, other communications applications of fiber optics have emerged. Local Distributed Networks (LDN) and Local Area Networks (LAN) augment telecommunications, providing means for linking and networking remote information systems together. In fact, most recently [1] the use of light emitting diodes and single mode fibers in the local loop is being demonstrated. This application of fiber optics is attributed to new and revolutionary thought regarding the local loop architecture [2]. Recently, a fourth type of application, spinning off of the original telecom thrust, has emerged. This application is called the optical interconnect. Figure 1-1 depicts this. As shown in the figure, there are various types of optical interconnect genre, depending on the length of the interconnect (or distribution) and the switching speed employed. As one progresses to shorter interconnect lengths, higher speeds are implemented. In general, the photonic link becomes part of a signal processing (as opposed to telecommunications) structure.

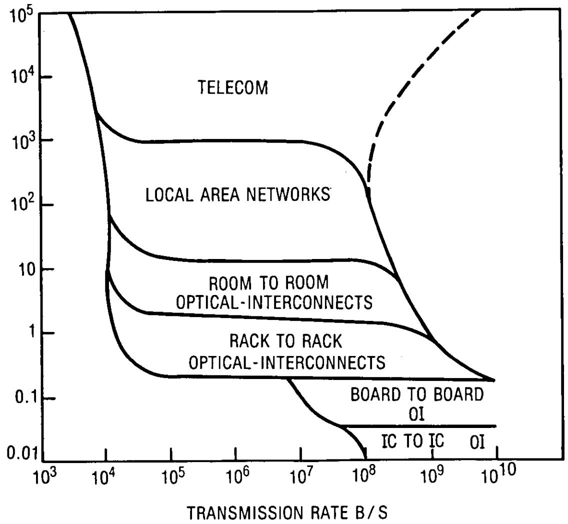

Figure 1-1. Plot of unrepeatered link lengths (in meters) versus transmission rate for photonic links; this plot shows the distinction between long haul telecommunications links, local area networks and the optical interconnect genre.

There is a threefold objective in the presentation of this paper. First, optical interconnects are to be clearly defined and partitioned. Second, it will be shown that optical interconnects are a natural consequence of the merging of telecommunications with information processing systems. Finally, optical interconnects will be presented as a viable tool for achieving high speed massively parallel digital processing.

The paper will be structured as follows; in section 2, optical interconnects will be defined. In section 3 some of the specific problems and limitations of high speed or massively parallel electronic interconnects will be discussed. Section 4 will be devoted to a discussion of various types of optical interconnect applications. Specific attention will be given to the problem of I.C.-to-I.C. interconnect. In section 5, a discussion of the use of integrated optoelectronics to perform high speed clock distribution is given. In this section, results of various specific efforts will be discussed.

2. Defining Optical Interconnects

With merging of the telecommunications and computer industries over the recent years, new technical frontiers have been opened. Global information processing and transferral systems are emerging in both commercial and military scenarios. Fiber Optics, having its beginning in long-haul telecommunications, offers significant cost per channel-mile advantage over conventional coaxial systems. As information systems technology expands, other potential solutions are offered by photonics and integrated optics.

Figure 2-1 shows the types of transmission systems in which fiber optics offers solutions. Long haul telecommunications systems are necessary to transmit large blocks of data between remote information centers. As shown, transmission lengths are typically greater than 10 kilometers, and can be thousands of kilometers. One can think of these links as analogous to interstate highways on a roadmap. Data rates are typically very high, and channel capacity is a prime consideration. For these reasons, optical wavelengths at or above 1.3 microns are used exclusively. In this wavelength region, group III-V compound materials, such as InGaAsP-InP are required for sources and detectors.

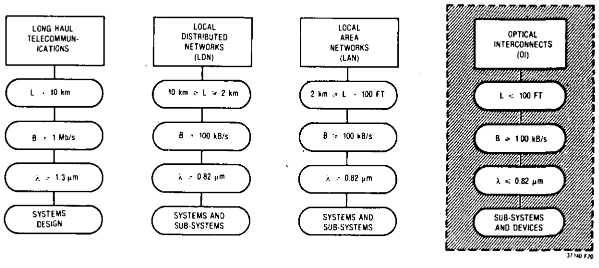

Figure 2-1. Breakdown of the types of fiber optic systems applications relevant to telecommunications.

Local distributed networks (LDN) imply the communications of two or more information centers within a 2km to 10km vicinity. Using the roadmap analogy discussed earlier, these networks serve the same purpose as intercity highways. Again, long wavelength devices are required.

Local Area Networks (LAN's) use even shorter links, and involve the networking of many computers, terminals and information processing equipment within a single information center. Ring systems, star systems, and some point to point transmission systems typify the LAN scene. On the roadmap analogy, LAN's can be thought of as intra-city streets and thoroughways. Both sub-system and system considerations are involved in LAN design.

Finally, a fourth type of application of fiber optics in information systems is called optical interconnects. Here data terminus points are linked over distances less than 100 feet. Point to point and star configurations are visualized. In the roadmap analogy optical interconnects compares with sidewalks, alleys and paths interconnecting individual structures.

The present role of optical interconnects in telecommunications can be summarized by describing the chronology of telecommunications over the recent past. Before the advent of fiber optics, telecommunications design dealt largely with the problems of bandwidth limited channels. The dominant source of transmission system degradation was the transmission line itself. Both coaxial and twisted pair transmission lines suffer from frequency dependent loss in addition to significant resistive loss. The introduction of the optical fiber radically altered this situation. Even when fiber systems were designed at 0.82 micron wavelength, significant improvements in unrepeatered transmission distance and cost per channel mile were accrued [3]. Still, systems design often dealt with dispersion limited channels [4]. The development of low loss fibers (1 to 2 db/km) and the move to 1.3 micron wavelength marked the beginning of distortionless channel transmission system design. For the first time maximum unrepeatered transmission distances were achieved in some systems without the use of equalization.

The next milestone in telecommunications evolution was set by the development of ultra-low loss single mode fibers operated at 1.55 micron wavelength. Systems operating at data rates exceeding 1Gb/s with unrepeatered spans exceeding 100 km were demonstrated in the lab [5]. With such capability the architecture of the entire local loop was rethought. The bandwidth available through the fiber made it feasible in principle to provide wideband services directly to the customer premise [6]. This concept has opened new and potentially potent market opportunities for telephone operating companies. In envisioning this objective, the local loop concept has been altered, as shown in figure 2-2. Distribution of broadband data to subscriber premises is achieved through interface with a remote hub.

At this hub complex signal processing and routing must be achieved at very high data rates (multi-Gb/s). Additionally, optical techniques such as wavelength division multiplexing may be implemented [2]. To support the bandwidth capacity of the fiber, it has become necessary to develop techniques for performing complex digital signal processing functions at multi Gb/s rates. Figure 2-3 shows an example of an interconnection network required for a high speed non-blocking switch array used in a local telephone distribution application. Inevitably, such functions are limited not by the fundamental switching capability of the I.C.'s themselves. Instead, the ability to interconnect the web of data and clock signals within a system poses the fundamental limit.

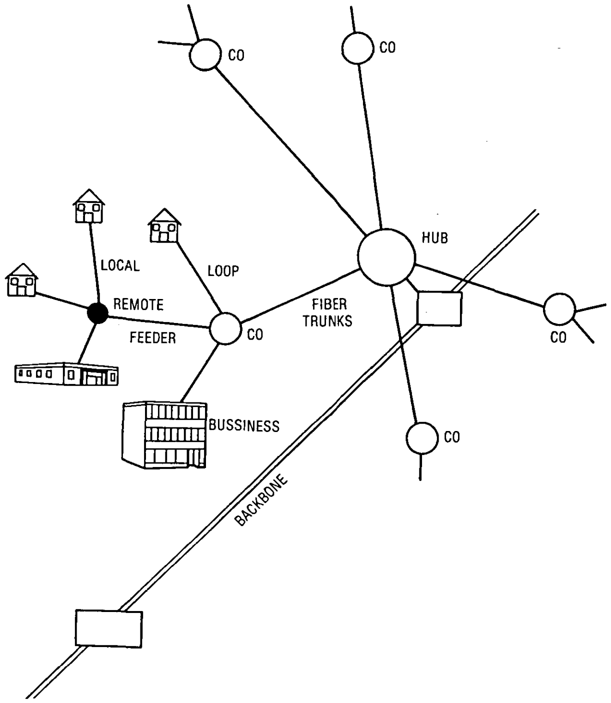

Figure 2-2. The hub exchange network concept; taken from Brackett [8].

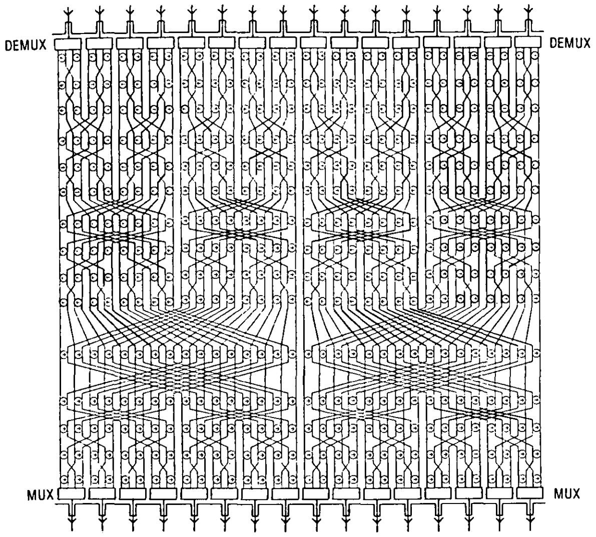

Figure 2-3. Example of a interconnection network required for a high speed non-blocking switch array.

Ironically, it appears that photonics will be an important expedient to the electronic bottleneck created by the fiber medium. Instead of offering a means of routing broadband serial data over kilometers, photonics now offer a way to distribute critical broadband signals over inches or less, on printed circuit boards.

It is possible to divide optical interconnect technology into at least four distinct genre. These genre are based on interconnection length, speed/bandwidth considerations and system application. The five types of optical interconnect scenarios cited are:

- Room-to-room interconnects
- Rack-to-rack interconnects
- Board-to-board interconnects
- I.C.-to-I.C. interconnects

Each of these genre are typified by their own set of applications, problems and solutions. The last application (I.C. to I.C. interconnects) is the primary subject of this paper. It is pointed out at the outset that this application includes various sub-genre, including intra-I.C. interconnects.

2.1 Room—to—Room Interconnects

As shown in figure 2-1, room-to-room optical interconnects are typified by point-to-point links at transmission rates as low as 10kb/s. Conceivably, transmission rates as high as several gigabits per second can exist. Link lengths are typically 100 feet or less. Longer links can occur but would then fall under the general classification of Local Area Network (LAN) links. In fact, some subjective overlap with LAN definition exists within the definition of room-to-room interconnects.

A typical application of room-to-room links is the low data rate computer link. Here issues such as EMI/EMP immunity, signal isolation or even common mode signal isolation may be important. Common mode isolation refers to situations where power and ground are defined differently in the source room and the receiver room. In this case the fiber optic link serves as a sophisticated opto-isolator.

An example of room-to-room optical interconnect situations is the remote tie-in link. Here two rooms may be isolated from each other electronically, for small signal isolation reasons. Or, the source room may be environmentally hazardous, causing EMI/EMP problems. Finally, the isolation situation may be based on security restrictions. In any of these situations, the data rates utilized may be as high as several hundred megabits per second.

2.2 Rack—to—Rack Interconnects

Rack-to-rack optical interconnects are a relatively new concept. However, specific system applications of rack-to-rack interconnects do exist in the field today. For example, AT&T ESS #5 electronic switching systems employs fiber optic rack-to-rack interconnects [7]. This system was implemented because of the reduction in size/weight achieved by replacing copper wire with glass fibers.

The optical rack-to-rack interconnect technology concept offers a fresh look at old problems. The fiber medium boasts unlimited signal bandwidth. This bandwidth is accompanied by a tenfold reduction in size and weight. Through· the proper use of signal multiplexing techniques, the bandwidth capacity of the fiber can translate to overall reduced power consumption. In complicated electronic signal processing scenarios, the rack-to-rack optical interconnect concept allows the designer to treat several networks of on-board computers and data processing equipment on a modular basis. The issues of signal processing and module interconnect/signal transmission can more easily be separated.

For the rack-to-rack interconnect application, the optical fiber is the most useful optical channel. Because fiber losses are so low at optical wavelengths exceeding 1.1 microns (particularly at 1.3 microns and at 1.55 microns), many of the backplane interconnects can be passive. That is, sufficient optical power exists to route signals entering backplane environments from outside without regenerating them. The use of mechano-optical switch matrices or even electro-optic switch matrices may augment the rack-to-rack optical interconnect concept.

2.3 Board–to–Board Interconnects

Figure 2-4 shows three examples of board-to-board optical interconnects. As shown, on much signal processing or generating equipment, there are several P.C. boards physically attached to the controller board, or backplane. Conventionally, all communication between boards is achieved by electrically interconnecting from one P.C. board, through the controller board, to another P.C. board. This practice often leads to limitations on the amount of signal isolation achievable, and on the bandwidth achievable. As shown in the figure, one method used for avoiding the use of the backplane is to communicate from board-to-board via an optical free space link. By attaching an optical transmitter and receiver module onto identical places on the P.C. board, the data link is automatically completed. Using LED's and PIN diodes, data rates up to 100 Mb/s are achievable. By replacing the LED with laser diodes, 1 Gb/s or higher may be achievable.

In situations where high speed and signal isolation requirements are both very severe, a simple fiber link can accomplish the board-to-board interconnect task. This is also shown in figure 2-4. In these situations the issues of compact design for both the transmitter and receiver module become important. Integration of the electronic and optical functions on these modules begins to take on design relevance. The combined requirements of size-weight-power limitations and high reliability/survivability dictate integration.

2.4 I.C. I.C. and Intra–I.C. Interconnects

I.C. interconnects (inter- and intra-) constitute the least mature and most important of the four types discussed. Presently, needs for high speed, parallel processing equipment constitute the largest technological bottleneck in telecommunications and computing technology. Group III-V materials (particularly GaAs and InP) are forming the basis for high speed digital I.C.'s and optoelectronics. The entirety of telephony architecture is changing to support photonics technology [8]. With this change, the much needed commercial market for GaAs digital MMIC's is rapidly emerging. Meanwhile, supercomputer architecture design is calling for advanced digital I.C. technology as well [9], [10]. Several researchers have already realized that once the high speed digital I.C. bottleneck is overcome, the problems of data distribution and interconnections at these speeds is the next bottleneck.

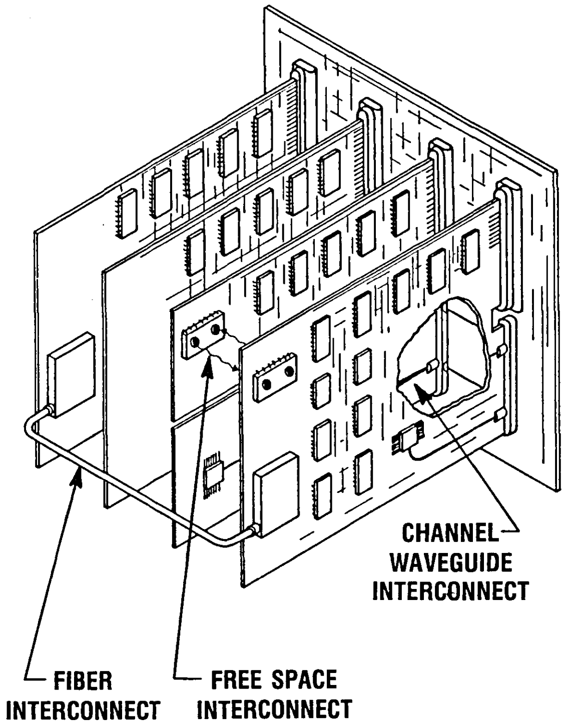

Figure 2-4. The backplane interconnect concept, showing three potentially viable techniques for achieving the interconnect.

One of the most illustrative examples of this situation is the clock distribution problem. Beyond 200 MHz, gate delays, transmission line imperfections and topology constraints pose limitations on clock distribution within a sub-system of I.C.'s. These limitations often constitute the weak link in achieving a switching speed goal. Beyond 1 Gb/s all of these problems are further exacerbated.

Photonics offers new insight into the solutions of these very serious problems. The fiber medium is a low loss, low dispersion channel. Over the short links discussed here (inches or less), the channel is virtually bandwidth unlimited. The transport of baseband information over a fiber can be accurately thought of as the modulation of a carrier oscillating at approximately 2×10^{14} Hz. For this type of modulation the carrier need not be coherent, since direct detection methods are usually employed. With a 2×10^{14} Hz carrier, even extremely wideband digital signals (for example 10 Gb/s) convert to narrowband transmission within the fiber. Even over inches of fiber, millions of carrier wavelengths are traversed. Therefore, transmission line matching becomes analogous to narrowband microwave matching. Both data and clock distribution can be achieved optically by implementing techniques common to narrowband microwave electronics.

The use of fibers constitutes only a small subset of the entire optical interconnect media. For both clock and data distribution, integrated optic transmission lines or ultimately, free space interconnects using dynamically reconfigurable holographic routing [10] may be implemented.

3. The Electrical Interconnect Problem

As a prelude to discussions on optical interconnects, this section discusses methods used in high speed broadband electrical interconnects. Also, some fundamental limits to the electrical interconnect of baseband digital signals are postulated.

3.1 Interconnects from the Device Viewpoint

When designing very high speed digital signal processing equipment, one finds that physical design and electrical design are inseparable. Because of this, high speed physical layouts are unique in appearance. First, metal flat packages are used exclusively in the design. These packages make efficient use of available space, and simplify I.C. die bonding and wire bonding. Furthermore, wire bond length is kept to a minimum; the input leads, when laid down on the printed circuit board closely resemble 50 ohm transmission lines. Second, circuit layout is planar. Circuit layout planarity and the use of ground planes has been found to be essential in high speed design. The backplane concept finds limited use as target system speeds increase beyond 1 Gb/s. Finally, the interconnects between I.C.'s are accomplished using microstrip transmission lines. Delay lines are incorporated onto the p.c. layout. Delays as long as one half a bit length ($\sim 1ns$, or 15 cm at 500 Mb/s) are often required.

Figure 3-1 depicts high speed layout topology, pointing out some of the difficulties one encounters. Impedance mismatches at bends and splits tends to appear as a capacitive load at the junction's bend, giving rise to high frequency reflections. Termination mismatches are the cause of several problems. First, it is difficult to maintain a 50 ohm transmission line impedance from one transmission line to the next. This difficulty is attributable to photolithographic variations and variations in p.c. board thickness and dielectric constant. Resistive mismatches of 10% are common. Second, the presence of parasitic capacitance at the package and the I.C. (bonding pads and wire bonds) can cause reactive impedance mismatches far exceeding 10%.

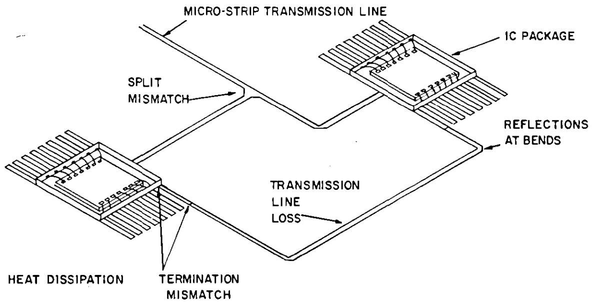

Figure 3-1. Schematic of a typical high speed electronic interconnect and distribution layout, depicting some of the problems associated with such interconnects.

Figure 3-2 shows plots of calculated loss in db/cm for microstrip transmission lines on various dielectric materials. In these calculations, both conductor loss (skin effect) and dielectric loss (for homogenous materials) are included. As shown, materials such as alumina ceramic or quartz are conductor loss limited. This situation is caused by the relatively low resistivity typical of these materials. The higher resistivity dielectric materials more commonly used in p.c. board interconnects are not as lossy as their silicon counterparts. However, the loss mechanism is proportional to $f^{1/2}$ and is most pronounced between 0.1 and 4 GHz. For a broadband high data rate digital pulse stream, the result is pulse distortion in addition to attenuation.

For comparison purposes, the loss characteristics of plastic fibers (1000 db/km or 0.01 db/cm) and glass fibers (10^{-5} db/cm) are shown. Also, reported losses for thin film plastic channel waveguides [11] are shown. It should be evident that consideration of optical waveguides for interconnects involves a trade-off between transmission loss and ultimate manufacturing simplicity. Where one avoids the deleterious effects of transmission line imperfections on microstrip lines, one must consider the extra losses incurred due to bends and optical coupling.

3.2 Interconnect from the Systems Viewpoint

A survey of existing digital switching systems and subsystems suggests a reciprocal relationship between attainable switching speeds and inherent signal processing complexity. Most existing systems switching at Gb/s rates or higher are considerably simpler in design than their lower speed (but perhaps parallel processed, high bit rate) counterparts. This concept holds at the equipment level, the board level, and even at the I.C. level. At the equipment and board level, line lengths (i.e., latency) tend to increase, quenching attempts at attaining higher complexity. Also, the limitations imposed by the interconnect medium pose fundamental problems. But, even at the I.C. level, the reciprocal relationship still holds. For example, at

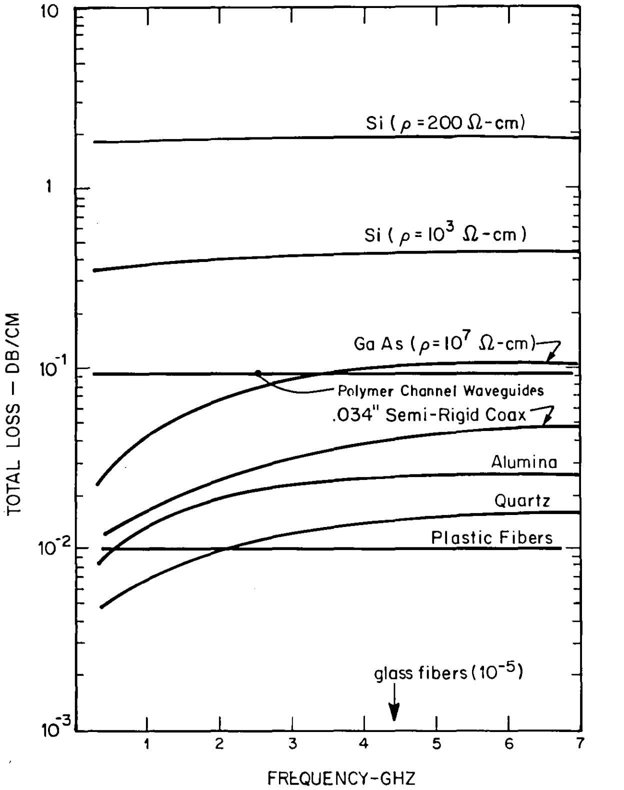

Figure 3-2. Plots of calculated loss (db/cm) for microstrip transmission lines on various dielectric materials, and for optical waveguide material.

speeds beyond 2 Gb/s, GaAs materials technology must be implemented. Because of processing constraints, most GaAs circuits are still relatively simple. Existing GaAs I.C. chips are limited in their ability to dissipate power, and also in their pinout capability. Heat dissipation in turn limits package size reduction, leading to the latency problems discussed earlier.

Using Rent's rule, it is possible to derive a semi-quantitative expression of the bandwidth/complexity relationship. This is done by relating average interconnect length, derived from Rent's rule, to the latency in signal propagation on a printed circuit board. The reader is referred to a previously published paper [12] for details of the calculations.

Figures 3-3 and 3-4 give the results of these calculations. In figure 3-4 is a plot of system switching rate vs. level of parallelism. Depicted is the point at which latency restrictions cause electrical interconnections to become prohibitively complex. It is at that point that optical interconnects can offer significant improvement over purely electrical approaches. An example of the meaning of the parameter M is that of a parallel processed system in which 8 140 Mb/s channels are multiplexed to yield a data rate, D, of 1120 Mb/s; however the actual switching rate is still 140 Mb/s. In this case, B = 140 Mb/s and M = 8. From the figure it is clear that, from a signal latency stand point, system switching rates must exceed 1 Gb/s before optical interconnects offer a viable alternative to electronic technique.

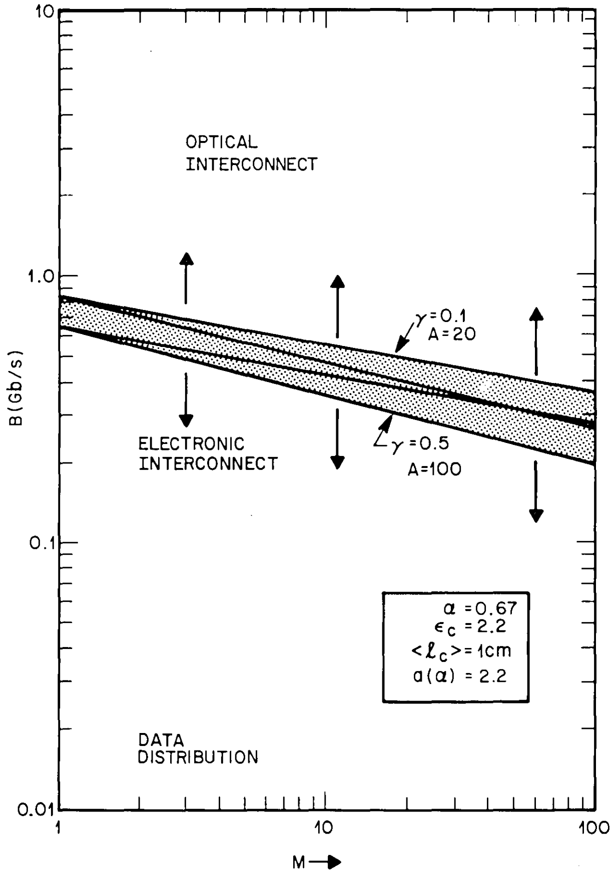

Figure 3-3. Plot of fundamental bit rate at which signal latency becomes an issue in data distribution as a function of M, the circuit level of parallelisms.

Figure 3-4 shows a similar calculation result for the case of clock distribution in synchronous digital systems. Here the system clock rate, B, is plotted vs. L, the printed circuit board size (a measure of system complexity).

As shown, clock distribution systems appear to be more sensitive to latency effects. Systems operating at 500 Mb/s and up may benefit from optical clock distribution. This is why much of the experimental accomplishments to date [13], [14], [15], have been in clock distribution.

4. Optical Interconnect Link Structure

Having discussed some of the important electronic issues in high speed digital interconnects, it is appropriate to look at the structure of an optical interconnect link. Figure 4-1 shows a functional block diagram of a generic optical interconnect link. Reference to the figure shows that both receiver and transmitter are sub-miniaturized.

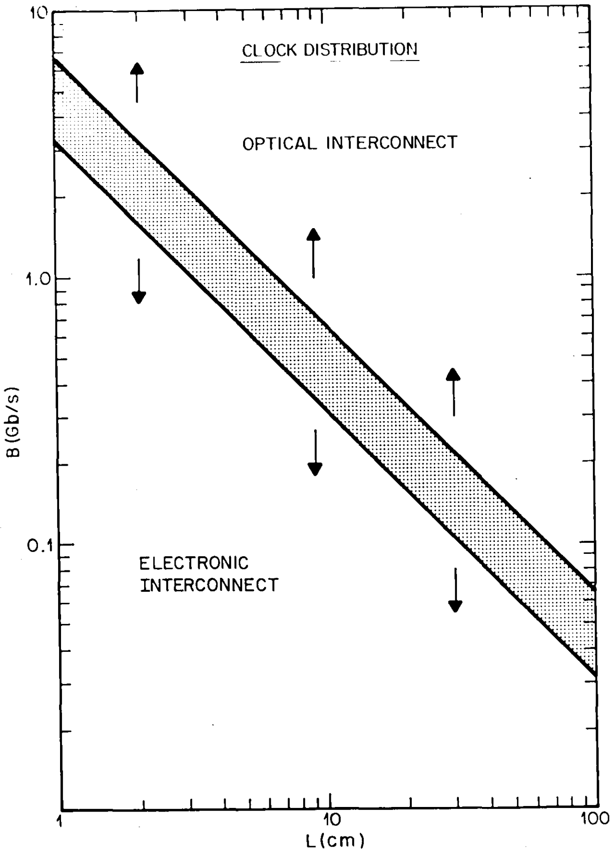

Figure 3-4. Plot of clock rate, B, at which latency becomes an issue in clock distribution, as a function of L, circuits board linear dimension.

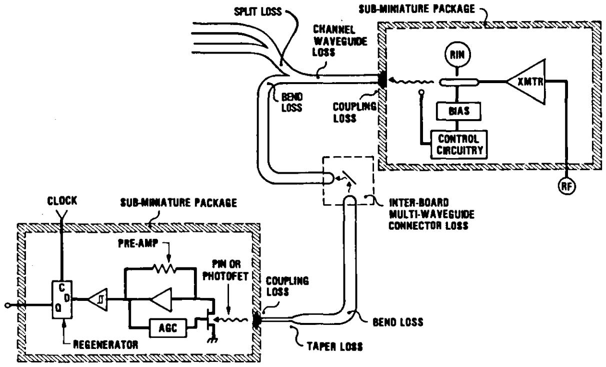

Figure 4-1. Functional block diagram of a generic optical interconnect distribution link.

The sub-miniaturization constraint eliminates standard telecommunications links from the domain of link genre. The type of optical interconnect medium is not specified in the figure (plastic fiber, glass fiber, plastic channel waveguides or even free space are possible media). Inter-board connectors are shown on the diagram, but they need not be present in many of the (intra-board) link structures considered in this paper. Other assumptions embedded in the figure include (1) the assumption of very high speed digital (baseband) links, (2) external system clocking (i.e., no timing recovery) and (3) liberal use of monolithic opto-electronic integration, especially on the receiver end.

In board-to-board and I.C.-to-I.C. interconnect design, high speed and signal isolation are often key motivating factors. To render optical interconnects useful the electro-optic and opto-electronic interfaces must take up very little space. Otherwise circuit pack real estate will be dominated by electro-optics. This situation will severely limit the space available for signal processing.

In addition to the architecturally based requirements for small size, there are also requirements based on the high speed nature of the interconnect signal. At speeds beyond a few hundred Mb/s, package design cannot be separated from electronic circuit design. The parasitic capacitances and inductances of the packages become an intimate part of the electronic circuit. These points are particularly true for broadband digital signals.

Finally, reliability considerations also drive the design of the link. Subminiaturization must be achieved with no compromise in reliability. The use of monolithic opto-electronics in these packages (particularly the receiver) offers the long term potential of enhancing system reliability through reduction of the number of physical interconnections required.

Although the optical fiber has many virtues for use in telecommunications, its use as an optical channel for optical interconnect applications is not as clear. While the optical fiber is an ultra-low loss information channel, with virtually unlimited bandwidth capacity, there are some drawbacks to the use of fibers in optical interconnect applications. Because one of the important issues in optical interconnects is packaging and sub-miniaturization, the placement of the optical channel on an electronic substrate becomes a very desirable goal. Also, the optical and mechanical coupling of the channel to the opto-electronic or electro-optic interface is a major issue. To render a very high speed system utilizing optical interconnects useful in real situations, the system must be easily and reproducibly manufacturable. If a system is largely an electrical one, with perhaps one or two point-to-point optical links, then the use of fibers constitutes a sensible choice. However, if the system requires liberal use of optical interconnects to render it tenable, then the utility of the fiber medium diminishes rapidly.

4.1 Receiver Design Considerations

Unlike a lightwave telecommunications receiver, an optical interconnect receiver is basically a high speed opto-electronic transducer. For optical interconnect applications, the main object is to receive the incoming optical data stream, transform it to electronics, amplify (and filter) it and re-digitize it. This function must be achieved with a minimum expenditure of board area with acceptable reliability. Since a fully retiming-reshaping-regenerating (R^3) receiver can take up as much space as a full printed circuit board or more, and makes use of lumped circuit elements, the R^3 approach is not feasible. Instead, it must be assumed that the system clock will be distributed separately (perhaps optically), and that pulse shaping to achieve raised cosine pulse shapes will not be performed. In spite of (and to some degree, because of) these limitations, very low bit error ratios (BER required will typically be 10^{-17}) and high signal-to-noise ratios will be required. Therefore, there is a conflict between the requirement for relative circuit simplicity and high sensitivity. The usual trade-offs between bandwidth, sensitivity, dynamic range and power consumption still exist. The monolithic opto-electronic integration of front end opto-electronic receivers can help to reduce the severity of these conflicting requirements.

The problem of optimized direct detection optical receiver design for digital applications has been treated quite comprehensively by Smith and Personick [16]. Fundamentally, for direct detection of optical binary signals, the Gaussian approximation for noise distributions constitutes a reasonably accurate assumption. Under these circumstances, the probability of incurring a detection error is given by

$$P(E) = \frac{1}{\sqrt{2\pi}} \int_Q^\infty e^{-x^2}\, dx \,. \tag{4.1}$$

The quantity Q is defined as,

$$Q = \frac{|D - a_i|}{\sigma_i} \,. \tag{4.2}$$

Here, D is the decision threshold, a_i are the mean signal levels for the 0 and 1 state, and the σ_i are the noise terms for the 0 and 1 state. With a binary digital system, then, equation 4.2 constitutes two equations, one for each state. From equations 4.2, any two of the 4 variables D, Q, a_0 and a_1 can be determined once the other two are specified. The quantities a_0 and a_1 are related to each other through the laser diode extinction ratio,

$$a_0 = r\,a_1, \qquad r \ll 1 \,. \tag{4.3}$$

These quantities can also be related to the average converted optical power $\eta \overline{P}_0$, at the photodetector through the relation,

$$\eta \overline{P}_0 = \tfrac{1}{2}(a_0 + a_1) \,. \tag{4.4}$$

Solving for a_0 and a_1 gives,

$$a_0 = 2\eta \overline{P}_0 \left[\frac{r}{1+r}\right] \; ; \; a_1 = 2\eta \overline{P}_0 \left[\frac{1}{1+r}\right] \,. \tag{4.5}$$

Using eq. (4.5) in equations (4.2) expresses the decision equations in terms of the two variables, $\overline{P}_0$, the minimum detectable optical signal for a given BER, and D, the decision threshold. These equations are,

$$D - 2\eta \overline{P}_0 \left[\frac{r}{1+r}\right] = Q\,\sigma_0 \,, \tag{4.6}$$

$$2\eta \overline{P}_0 \left[\frac{1}{1+r}\right] - D = Q\,\sigma_1 \,. \tag{4.7}$$

Equations (4.6) and (4.7) provide the fundamental starting point toward receiver sensitivity calculations. The terms σ_0 and σ_1, the variances in the signal levels in the zero and one state, are specific to the receiver design.

In optical interconnect receiver design, there are four basic types of noise. These are,

1. Signal independent receiver noise current sources.
2. Signal independent receiver noise voltage sources.
3. Signal dependent quantum noise (Poisson Distribution).
4. Signal dependent laser diode intensity fluctuation (non-Gaussian).

Types 1 and 2 contain contributions from various elements in the receiver circuit; for the most part they are thermal noise sources and shot noise sources. The voltage sources are similar, and include flicker noise at the receiver front-end, etc. Type 3 refers to the quantum limit of signal detection and any intersymbol interference terms. Type 4 is commonly disregarded. It refers to basic intensity fluctuation in the optical output of laser diode. Some contributions to these terms are more strongly signal dependent than others. They are all lumped together as relative intensity noise (RIN). The presence of signal dependent RIN significantly alters the form of sensitivity equations, and also the fundamental results in the case of high speed optical interconnects.

RIN is defined in terms of square of the optical fluctuations at the output of the device. Specifically,

$$\mathrm{RIN} = \frac{(\Delta P_0)^2}{P_0^2} \,, \tag{4.8}$$

where P_0 is the laser output power. Sato et al [17] have measured the RIN of various laser diodes as a function of laser bias-to-laser threshold voltage. These measurements, redrawn on a log-log plot, are shown on figure 4-2. The figure shows that the RIN for various structures follows an inverse power function dependence on the quantity $[I_D/I_T - 1]$, with a power index given by the quantity γ.

Typically, γ lies between 2.5 and 4.5, depending on the

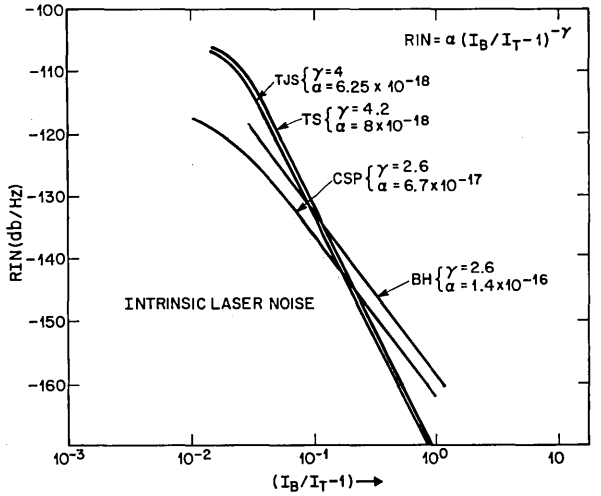

Figure 4-2. Plots of measured RIN for various laser diode structures, as a function of laser bias. The data was obtained from Sato et al [17] and redrawn in log-log fashion.

structure. Through inspection of figure 4-2, two conclusions can immediately be drawn; (1) Intrinisic RIN is strongly signal pattern dependent; S/N is much higher in the "one" state than in the "zero" state. (2) Conventional values of r (i.e. $r \simeq 0.1$ to 0.01) yield quite low S/N ratios at high data rates; this is particularly true for gain-guided devices. Therefore, a potential limit on digital signal fidelity at the source-end exists. This limit clearly depends on the digital data rate and on the system extinction ratio.

Using the equations discussed above, and a simple piecewise linear model for laser diode light output vs. bias current input, it is possible to model the mean square fluctuations in laser output as they appear at the receiver front-end. From this model one can rewrite equations 4.6 and 4.7 explicitly in terms of the signal dependent laser noise term and all of the conventional circuit noise terms normally present at the receiver front-end. Because of the inverse power functional dependence of laser noise on laser optical output, these equations represent coupled transcendental equations, whose solution must be determined numerically. Combining equations 4.6 and 4.7 and eliminating D yields a function of the form,

$$f(\eta \overline{P}_0) = 0 \, . \qquad (4.9)$$

The details of this function are presented in a separate publication [12]. Figure 4-3 shows plots of $\eta \overline{P}_0$ vs. transmission rate for various values of r. Also shown for comparison are plots of $\eta \overline{P}_0$ vs. B for an optimized telecommunications receiver (BER = 10^{-9}) for which the front-ends were hybrid (curve number 5) and monolithic (curve number 4).

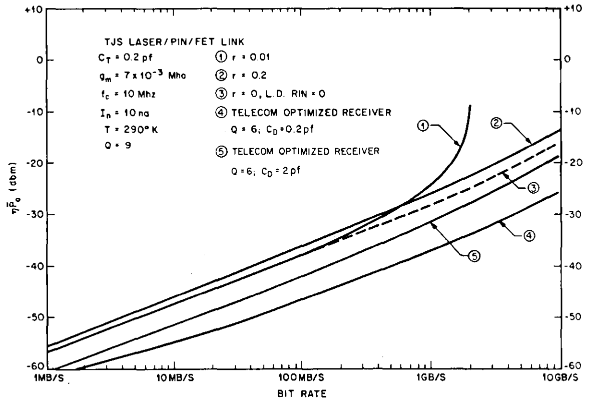

Figure 4-3. Plots of $\eta \overline{P}_0$, the minimum detectable signal for the specified bit error ratio, as a function of digital transmission rate, B, for various transmission scenarios.

Inspection of this calculated data reveals several interesting points. First, the effects of intrinsic laser noise can be dramatic at very high data rates. If r is chosen incorrectly, bit-error-ratio saturation can occur (c.f. curve number 1). In fact, even if r is chosen for optimum conditions, bit-error ratio saturation can still occur, but at a higher data rate. Secondly, there appears to be an optimum value of r. This is shown in Fig. 4-4. Here $\eta \overline{P}_0$ is plotted vs. r at B = 1.5 Gb/S. There is a clear (but fortunately wide) minimum in $\eta \overline{P}_0$ vs. r. This points to the necessity of designing control circuitry that will ensure the stability of the laser threshold current and the laser modulation current relative to each other.

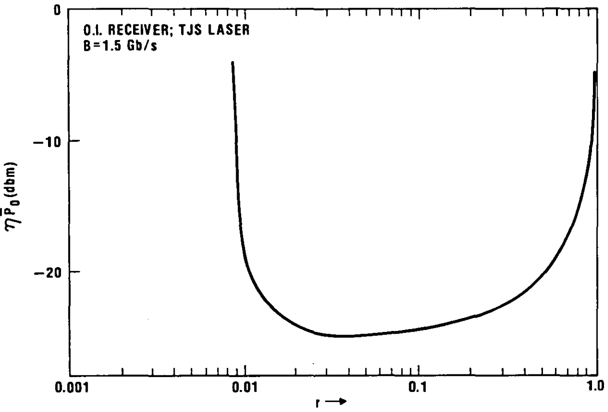

Figure 4-4. Plot of $\eta \overline{P}_0$ vs r for 1.5 Gb/s transmission, showing the existence of an optimum value of r, the laser diode extinction ratio.

Further, the sensitivity that one can expect from a receiver designed to optical interconnect constraints cannot be as high as that of an optimized telecommunications receiver. The differences can be accounted for in the higher BER objective, the wider signal bandwidths required (i.e. larger normalization integral values) and the laser noise term. Finally, and very importantly, curve number 4 in figure 4-3 shows what can be achieved through monolithic front-end integration. Clearly, the monolithic front-end design embodies the potential of making up a considerable portion of receiver sensitivity lost in complying with optical interconnect design criteria. Concurrently, the monolithic approach actually facilitates the achievement of sub-miniaturization; which has influenced the optical interconnect design so strongly. Therefore, monolithic opto-electronic integration adds an element of synergism to optical interconnect design.

4.2 Optical Interconnect Link Analysis

To complete this discussion on optical interconnects, a first-cut look at some typical optical interconnect links is now made. The instrument for looking at optical interconnects is the optical power budget. Table 4-1 shows a summary of the basic types of systems considered. As shown, laser diode and LED based links are both considered. Three different data rates are studied; these are 565 Mb/s, 2.26 Gb/s and 4.52 Gb/s. Short wavelength ($\lambda = 0.82 \mu m$) transmission is considered exclusively. This is done because of the maturity of laser diode technology, amenability of silicon technology at the receiver end and due to the low-loss characteristics of plastic channel waveguides at $\lambda = 0.82 \mu m$. Fanout, or distribution, is considered a major system issue, since point-to-point links can most easily be accomplished electronically; even at very high data rates.

	Link # 1	Link # 2	Link # 3	Link # 4	Link # 5	Link # 6
Transmission Rate (Gb/s)	0.565	2.62	4.52	0.565	2.62	4.52
Data Source	LD	LD	LD	LED	LED	LED
Link Length (cm)	25	25	25	25	25	25
Optical Wavelength (μm)	0.82	0.82	0.82	0.82	0.82	0.82
Photodetector	p–i–n $D = 150\mu m$	p–i–n $D = 100\mu m$	p–i–n $D = 100\mu m$	p–i–n $D = 150\mu m$	p–i–n $D = 100\mu m$	p–i–n $D = 100\mu m$
Front-End Electronics	GaAs FET or Si Bipolar	GaAs FET	GaAs FET	GaAs FET or Si Bipolar	GaAs FET	GaAS FET
Monolithic Front-end?	Yes	Yes	Yes	Yes	Yes	Yes
Channel Waveguides?	Yes	Yes	Yes	Yes	Yes	Yes

Table 4-1. Optical Interconnect Link Types.

Laser based optical interconnects represent the most obvious choice of links. With direct drive, the laser diode can be on full on/off modulated at multi-Gb/s rates. Peak output power of +10 dbm is comon for laser diodes. The potential for even higher peak output exists, although thermal dissipation problems become more severe.

Table 4-2 shows optical power budgets for laser based links at 565 Mb/s, 2.26 Gb/s and 4.52 Gb/s. Source power and link loss elements are tabulated in the upper portion of the table. All optical power terms are given as *average* quantities (with a 50% duty cycle, these values are 3 db below peak quantities). Using the receiver sensitivity calculations from the previous section, minimum detectable signals ($\eta \bar{P}_0$) are then given.

SYSTEM PARAMETER	B = 565 Mb/s	B = 2.26 Gb/s	B = 4.52 Gb/s
Laser Output Power (Avg)	+7 dbm	+7 dbm	+7 dbm
Laser-to-waveguide coupling loss (db)	-2	-2	-2
Distribution loss (db)	TBD	TBD	TBD
Waveguide loss (db, @ 0.2 db/cm)	-5	-5	-5
Waveguide bend loss (db)	-2	-2	-2
Waveguide-to-detector coupling loss (db)	-2	-3	-3
Total power incident at detector (not including distribution loss).	-4 dbm	-5 dbm	-5 dbm
O.I. Receiver Minimum detectable signal ($\eta \bar{P}_0$, in dbm)	-28 dbm	-22 dbm	-18 dbm
Net Optical Gain Available (db)	24 db	17 db	13 db
Margins and Degradation Factors:			
Detector d.c. Quantum Efficiency (db)	-1	-1	-1
Detector a.c. Q.E. [monolithic receiver assumed] (db)	-1	-1	-1
Power Rail Degradation (db)	-2	-3	-3
Laser diode EOL Margin (db)	-2	-2	-2
Useful Optical Gain Available (db)	18	10	3
Maximum distribution possible	64	10	4

Table 4-2. Optical Interconnect Link Budget - Laser based system.

The difference is the net optical gain available (in dbs). Next, system margins and degradation factors are subtracted from the net optical gain. The result is the useful optical gain. As presented in the table, no distribution (or fanout) is assumed. Instead, after the useful optical gain is determined, the maximum possible fanout is determined from that number. Clearly, the distribution loss must include power splitter insertion loss as well as the simple power division term. Therefore, the number derived in the calculation represents an upper bound on distribution.

Link loss terms included are source-to-waveguide coupling loss, waveguide intrinsic loss, waveguide bend loss and waveguide-to-detector coupling loss. The reader is referred to [15] for a more detailed explanation of the values assumed. From these numbers and receiver sensitivity values (c.f. figure 4-3) the net optical gain available at the receiver input is 24 db, 17 db and 13 db for 565 Mb/s, 2.26 Gb/s and 4.52 Gb/s operation, respectively.

Next, an attempt is made to include other systems margins and degradation factors. The first term allocates 1 db to photodetector d.c. quantum efficiency. An additional 1 db is allocated to account for the difficulty in producing OEIC's with sufficient photodetector photon collection depth to prevent substrate photo current production. The power rail degradation term is discussed in [12]. Finally, to account for the slow degradation of laser diodes over their lifetime, a 2 db end-of-life margin is included.

After these margin and degradation terms are included, useful optical gain at the three data rates is 18 db (565 Mb/s), 10 db (2.26 Gb/s) and 6 db (4.52 Gb/s). If all this available margin is allocated to distribution of signals to various nodes, then the maximum distribution possible is 64 (565 Mb/s), 10 (2.26 Gb/s) and 4 (4.52 Gb/s).

As already discussed, laser diodes will most likely represent the element of choice in future optical interconnect links. However because of the fact that laser diode reliability is not yet firmly established at the 10^7 hr mark or higher, (and variances are still high), alternative sources such as LED's may be attractive in some instances. Therefore we present link budgets for LED based systems as well as laser diode based links. Table 4-3 summarizes the budget for LED based links. The first, and most significant difference between LED and laser diode based links is in the output power available from an LED. Currently, edge-emitting LED's have been fabricated capable of emitting -4 dbm of optical power into free space at 565 Mb/s.

SYSTEM PARAMETER	B - 565 Mb/s	B - 2.26 Gb/s	B - 4.52 Gb/s
Laser Output Power (Avg)	-4 dbm	-11 dbm	-14 dbm
Laser-to-waveguide coupling loss (db)	-3	-3	-3
Distribution loss (db)	TBD	TBD	TBD
Waveguide loss (db, @ 0.2 db/cm)	-5	-5	-5
Waveguide bend loss (db)	-2	-2	-2
Waveguide-to-detector coupling loss (db)	-2	-3	-3
Total power incident at detector (not including distribution loss).	-16 dbm	-24 dbm	-27 dbm
O.I. Receiver Minimum detectable signal ($\eta\overline{P}_0$, in dbm)	-31 dbm	-24 dbm	-21 dbm
Net Optical Gain Available (db)	15	0	0
Margins and Degradation Factors			
Detector d.c. Quantum Efficiency (db)	-1	-1	-1
Detector a.c. Q.E. [monolithic receiver assumed] (db)	-1	-1	-1
Power Rail Degradation (db)	-2	-3	-3
Laser diode EOL Margin (db)	-1	-1	-1
Useful Optical Gain Available (db)	10	0	0
Maximum distribution possible	10	0	0

Table 4-3. Optical Interconnect Link Budget - LED based system.

Suzuki et al [18] have reported the fabrication of LED's operating at 2 Gb/s with an average output power of -11 dbm. To date no other devices have been reported with modulation capabilities beyond this. Because of the wider angular power distribution of LED's, coupling to waveguides is not as efficient as with laser diodes. However, when using large feature size channel waveguides (typically $150\mu m \times 75\mu m$), coupling losses of 3 db should be achievable. All other loss terms are expected to be similar to those for laser based links. Therefore, the total power incident at the photodetector will be approximately -16 dbm (565 Mb/s), -24 dbm (2.26 Gb/s) and -27 dbm (4.52 Gb/s). Next, it is noted that receiver sensitivity values are slightly better for the LED based system. This reflects the absence of source noise effects (c.f. curve no. 3 in figure 4-3). Combining these sensitivity values with the incident power reveals that the only data rate at which power margin exists is 565 Mb/s. Then, subtracting the same degradation factors and a 1 db end-of-life margin for the LED yields 10 db useful optical gain available at 565 Mb/s. This translates to a maximum distribution of 10.

Inspection of tables 4-2 and 4-3 reveals several interesting points. Most obvious is that as higher bit rates are approached, the available optical gain for distributing signals vanishes rapidly. This occurs because the minimum detectable signal increases monotonically with bit rate, and because the available power from optical sources is limited. Systems degradations and necessary margins cut deeply into this diminishing gain. One of the key motivations for device design in optical interconnects, then, is to find ways to remedy this situation. There are several ways to do this. The first and most obvious one is to provide more optical power at the source. In spite of the fact that high power lasers are being designed [19], they must be accompanied with low threshold currents, low noise properties and agile modulation characteristics. Even when this is accomplished, the obstacles to providing acceptable broadband performance at multi gigabit per second rates, while dissipating heat acceptably in an sub-miniaturized package, are formidable.

At the receiver end, monolithic design is clearly a necessary ingredient for optical interconnects. Monolithic OEIC receivers are the only practical means for reducing input parasitics, thereby achieving acceptable sensitivity and speed in a sub-miniaturized package design. Figure 4-5 summarizes the results of this section. Here receiver sensitivity ($\eta\overline{P}_0$) and transmitter output power are both plotted vs. data rate, B. Curves for both LED's and laser diodes are shown. Clearly the optical margin stays open longer for laser diode-based systems.

The dotted lines for laser diode transmitters beyond 5 Gb/s reflect the level of understanding regarding full on/off modulation at these data rates and at high optical powers. Clearly, at very high data rates, external modulation of laser diodes may become a necessity, in spite of the serious packaging issues. Furthermore, to achieve high power output, a shift to the longer optical wavelengths, where optically induced damage in $LiNbO_3$ is not as serious a problem, may be in order. Methods for reducing some of the systems degradations terms are also desirable.

If any of these measures are successful, the optical interconnect concept can carry viability with it beyond several Gb/s, where it will be most needed. As data rates move toward double digit gigabit rates, circuit subminiaturization will continue, and the free space

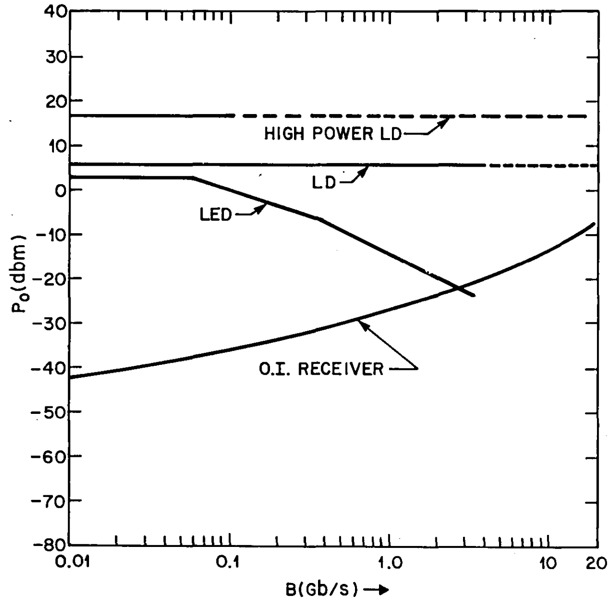

Figure 4-5. Receiver sensitivity for O.I. applications, transmitter power, both plotted as a function of B, the transmission rate. The figure depicts the closing of the optical power margin with increasing transmission rate.

implementation of optical interconnects will become more important. However, it is asserted here that many of the same constraints (e.g. receiver sensitivity, fanout limitations, thermal dissipation) will still set fundamental engineering limits to what can and cannot be done in high speed signal processing at these rates.

5. Integrated Opto–Electronics for Optical Interconnects

In board-to-board and I.C.-to-I.C. interconnect situations, high speed and signal isolation are often key motivating factors. The issues of compact design for both transmitter and receiver modules become very important. Integration of optics with electronics offers not only size/weight reduction advantage, but performance enhancement as well. Monolithic integration of optics and electronics (known as integrated opto-electronics or integrated electro-optics) represents the ultimate in device integration. Monolithic receivers offer the potential of enhanced bandwidth and sensitivity (due to reduced input parasitics). Monolithic transmitters offer fanout and signal multiplexing advantages. Used together, the two offer a means by which wire bonds and bonding pads can be eliminated at critical high speed modes. Through the reduction of interconnection nodes, packaging constraints are alleviated and reliability of the overall system benefits.

This section discusses progress made in one of these areas. In particular, monolithic integration of optical detectors with associated high speed receiver electronics is addressed. The reader is referred to previous publications ([13], [14]) for more details of the discussion to follow.

The I.C. described here was developed to demonstrate the viability of optical interconnects in the clock distribution problem. The system concept is shown in figure 5-1. An optical clock signal, generated from a laser diode, is split into many parts using a fiber optic power splitter. A number of synchronously operated I.C.'s are then clocked optically from the same source. The technique used to achieve planar optic-electronic coupling was called the lateral fiber-I.C. coupler [14].

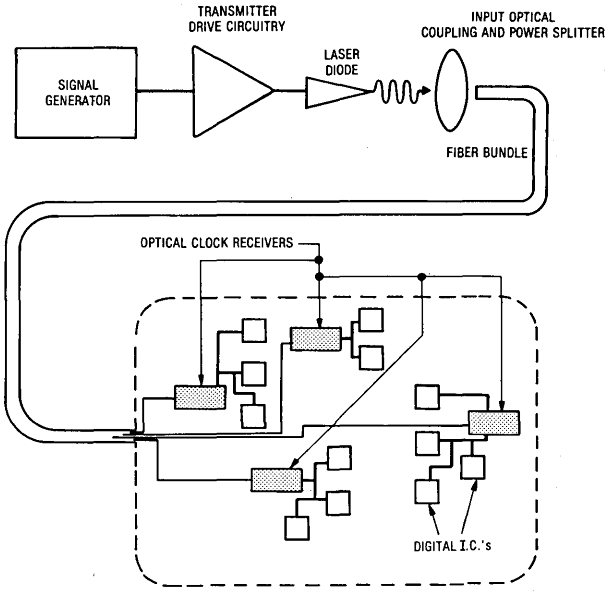

Figure 5-1. Block diagram of an optical clock distribution system that operated at 500 Mb/s and used fibers as the interconnect medium [12], [14].

The concept is shown in figure 5-2. The end surface of a fiber is lapped and polished at approximately 45°. Then a thin layer of aluminum is deposited on the surface. The result is a 45° mirror integrated onto the fiber. The fiber is then coupled laterally to the detector/amplifier I.C. The I.C. is then packaged in a miniature metal flat pack for incorporation onto the p.c. board.

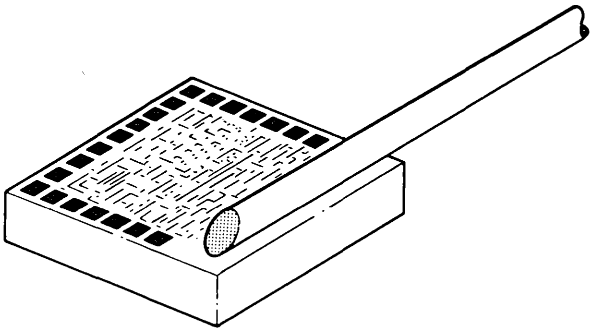

Figure 5-2. Schematic representation of the lateral fiber coupling technique.

Design of the I.C. was predicated on the requirement that an existing ECL process would be used in fabrication. An absolute minimum of modification of this process was to take place in the photodetector fabrication. The mainline process used is a very high density monolithic integrated circuit process designed specifically for high speed ECL circuits operating at subnanosecond speed. In this design, the active region of the bipolar transistors in high frequency amplifier circuits is about $1.1 \mu m$.

Since the deepest diffusion performed in the integrated circuit process is the buried layer, at approximately $3 \mu m$, and since the light penetration depth of silicon at $\lambda = 0.82 \mu m$ is approximately $10 \mu m$, it is clear that some modification or addition to the I.C. process was required to achieve acceptable photodetector performance. The solution involved a compromise between the two competing objectives of optimizing optical response and leaving the I.C. process unaffected. At the beginning of the I.C. process flow, the photodetector area was defined by a mask and a deep phosphorus implant was made into the p-type substrate. The phosphorus was then in-diffused to widen the compensated intrinsic region as much as possible. Implant was made to a depth of approximately $5 \mu m$. The resultant diffusion profile for the integrated photodetector indicated an intrinsic region width (defined here at FWHM) at zero bias of approximately $4.5 \mu m$.

Figure 5-3 shows a block diagram of the detector/amplifier circuit design. Functionally, it is composed of five sections. These are 1) the photodetector, 2) the front end transimpedance amplifier, 3) an intermediate stage amplifier, 4) an ECL limiting amplifier and 5) a D.C. bias control feedback network. Transimpedence gain was 3000 ohms. In the design, the primary goal was to obtain the highest gain-bandwidth product (at 500 Mhz) possible, with receiver sensitivity a secondary issue.

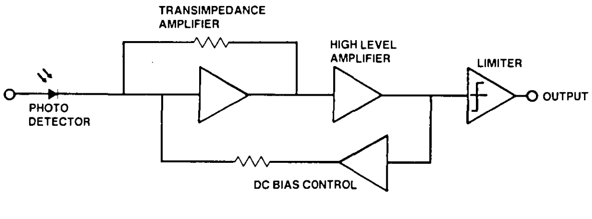

Figure 5-3. Block diagram of the 500 Mhz detector/amplifier circuit design.

5.1 Detector/Amplifier Measured Performance

The detector/amplifier I.C.s were characterized during a test and evaluation phase of the development effort. Parameters measured in these tests included optical sensitivity, frequency response, waveform reproduction, and DC stabilization. The highlights of this test effort are presented here. Data presented here is typical, not best case. Furthermore, data from several different devices is shown in the scope traces and plots. Reference [13] gives a more complete description of the device performance.

For the purposes of evaluation of the photodiode and the amplifier circuits separately, a family of I.C.s were fabricated in which the photodiode contact was separated from the amplifier input. On these I.C.s, bonding pads were placed at the photodiode output and amplifier input. The photodiode responsivity to unmodulated optical signals was measured with a test configuration involving a $0.82 \mu m$ laser diode source coupled to a communications grade $50 \mu m$ core graded index fiber. Cladding modes were eliminated with the addition of coupling gel over a 3 cm length of stripped fiber near the laser-fiber interface. The average dc responsivity for the $80 \mu m$ detector was .5A/W. Excellent linearity prevailed over the usable input power region.

Transient response of the detectors was measured by illuminating them with pulses from a laser diode excited by a HP33004 comb generator. These pulses occurred at a 500 MHz repetition rate and exhibited sharp rise and fall times, approximating a delta-function pulse. When measured using a high speed photodetector, they showed nondeconvolved pulse widths (FWHM) of 40 ps. Figure 5-4 shows a sampling scope trace of the response of our $60 \mu m$ diameter integrated silicon photodetectors to these pulses. Rise times of 60 ps and FWHM of 150 ps are measured, indicating a high frequency response (into 50 ohms) of approximately 4 to 5 GHz. The tail in the response reflects the trade-offs involved in the integrated opto-electronic design.

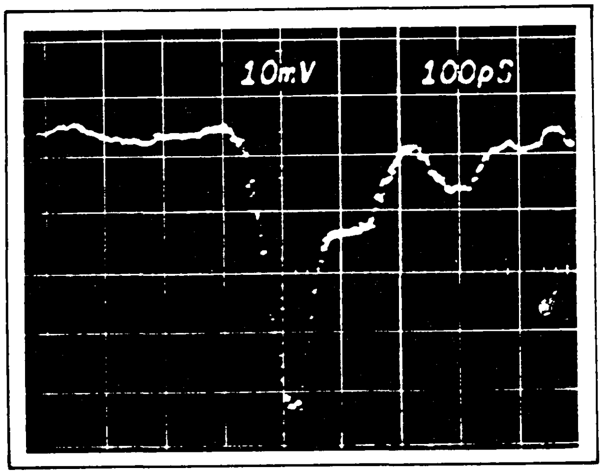

Figure 5-4. Measured impulse response of the integrated n-i-p photodiode (load impedence 50 ohms).

Many devices were tested with the optical input provided by the lateral coupling technique described earlier. Figure 5-5 shows a micro-photograph of the packaged detector/amplifier. Tests revealed that additional optical losses occurring from the use of the lateral coupler compared to direct coupling are typically 1.5 dB.

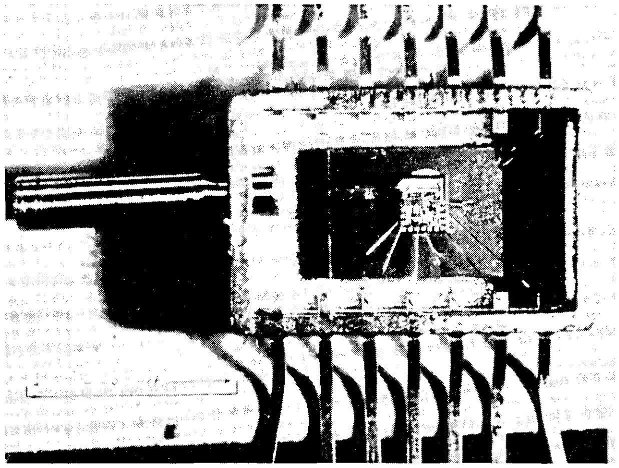

Figure 5-5. Micro-photograph of the packaged detector-amplifier I.C.

Swept frequency response of the packaged devices was measured for a detector/amplifier having a modulated optical signal input through a lateral coupler. The results are presented in figure 5-6. This figure shows the combined frequency response of the photodiode driving the amplification stages.

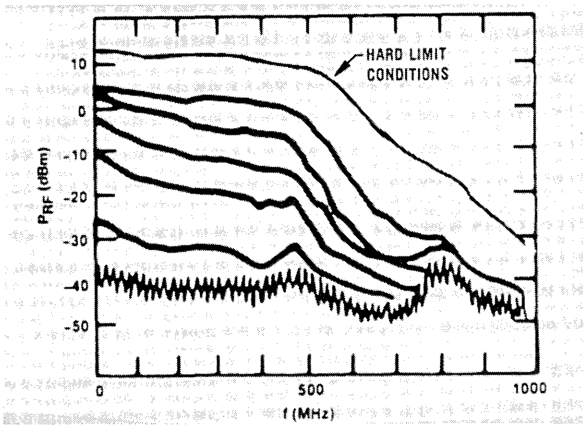

Figure 5-6. Swept frequency response of the packaged detector-amplifier I.C.'s.

The photodiode characteristic response is evident at the low frequency end of the spectrum with peaking evident at the high end (small signal region). The top trace shows the detector/amplifier output response when the input was driven by nearly 1 mW optical power. This is the maximum amount of optical power the I.C. can handle before DC bias problems occur. Also, it is more than 10 times the power required to drive the output sine wave across its full transfer curve. This is referred to in the figure as a "hard limit condition." In the lower traces the average input optical power begins at approximately 100 uW and decreases in 5 dB steps. The packaged devices were also tested for response to binary data sequences. This was done by modulating the laser diode transmitter circuit with a pseudo-random binary sequence generator output. The results are presented in figure 5-7. It is evident that the waveforms are accurately reproduced and that the risetimes are sufficient for transfer of wideband binary information. Measured output pulse jitter was less than 50 ps.

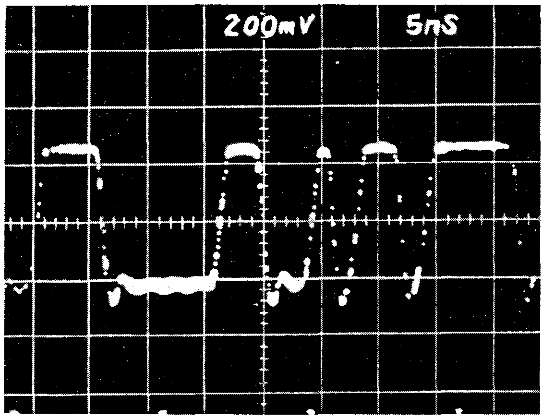

Figure 5-7. Response of the packaged detector/amplifier I.C.'s to a 500 Mb/s NRZ data input.

6. Summary

This paper has addressed the concept of high speed digital interconnects, with an eye on the use of photonics as an alternative to conventional methods. An attempt has been made to point out some of the fundamental engineering limits (as opposed to fundamental physical limits) to high speed interconnects.

The primary theme of the paper is the assertion that as target system data rates are pushed into the multi-Gb/s domain, packaging and interconnections become more and more important. This is because the interconnect media becomes transmission line-like. Under these circumstances wideband transmission forces the designer to consider the device package as part of the electronic circuit. Mechanical and electronic design are merged into one. No longer is one more important, or more simple than the other.

To illustrate this theme, the problem of receiver design for optical interconnects has been addressed. Link budgets for laser diode based and LED based optical interconnect links have been presented. Finally, a specific example of the utility of integrated optoelectronics in optical interconnects has been given.

STANDARDS AND ARCHITECTURE FOR TOKEN-RING LOCAL AREA NETWORKS

Jacalyn Winkler
Jane Munn

IBM Corporation
Research Triangle Park, North Carolina

ABSTRACT

Local area network standards have been developed by the Institute of Electrical and Electronics Engineers (IEEE) and are becoming international standards through the International Organization for Standardization (ISO). The token-ring is an approved IEEE standard and an ISO draft international standard (DIS). This paper presents the architecture for token-ring local area networks as described in the IEEE 802.5 Standard and ISO DIS 8802/5. Also included is a discussion of the logical link control sublayer as described in the IEEE 802.2 Standard and ISO DIS 8802/2.

INTRODUCTION

The IEEE Project 802 Committee has developed a family of standards for local area networks (LANs). These standards encompass the data link and physical layers of the Open Systems Interconnection (OSI) Reference Model [1] developed by the International Organization for Standardization (OSI). The data link layer for LANs is divided into two sublayers: medium access control and logical link control. The IEEE 802.5 Standard [2] defines the specifications, formats, and protocols of the physical layer and the medium access control sublayer for the token-ring local area network. The IEEE 802.2 Standard [3] defines the services and procedures of the logical link control sublayer.

The physical layer of a token-ring LAN provides data synchronization, data symbol encoding and decoding, and physical attachment to the ring. The medium access control (MAC) sublayer controls access to the ring, so that individual stations have the opportunity to transmit without interference from other stations. The logical link control (LLC) sublayer provides two distinct types of service that provide for the transfer of information between network layer entities on a LAN. (Network layer entities are entities above the data link layer that interface directly to the LLC sublayer.) One type of service, unacknowledged connectionless, provides a datagram approach to information exchange where information is simply sent and received without correlation to previous or subsequent information and with no form of acknowledgment to ensure delivery. Another type of service, connection-oriented, provides error-free, in-sequence delivery of information without duplication.

A token-ring LAN is comprised of stations connected sequentially by a series of point-to-point links. Each station acts as an active repeater and regenerator of signals on the ring. Due to the physical configuration and protocol operation of the token-ring, problem detection, isolation, and bypass are possible. The token-ring architecture also provides eight levels of priority for access to the shared transmission medium, allowing fair access to the medium within each priority level.

On a token-ring LAN, a station obtains the right to transmit data by capturing a token (a special bit pattern circulating the ring between data transmissions). The transmitting station changes the token to a frame and appends addressing information and data. Each station on the ring examines the addressing information and repeats the frame. A station recognizing the destination address as its own also copies the frame. When the frame returns to the sender, the sender removes the frame from the ring and generates a new token.

One station on the ring - called the active monitor - provides token-monitoring and other protocol monitoring functions to ensure that the ring is operating normally. The other stations - called standby monitors - monitor the health of the active monitor, and are ready to take over if the current active monitor fails. Although only one station on the ring is designated as the active monitor at any one time, the active monitor function is part of the architecture of every station on the ring.

Stations on the token-ring detect and report error conditions allowing for the isolation of errors. The errors detected by a station are divided into two categories: soft and hard errors. Soft errors are those that temporarily degrade the ring performance. Examples of soft errors detected by a station are line hits, possible duplicate addresses, and invalid symbols between starting and ending delimiters. Hard errors prevent the token-ring protocols from functioning properly. Examples of hard errors are a streaming station, and a broken wire.

CH2345-7/86/0000/0479$01.00 © 1986 IEEE

The specifications, formats, and protocols of the physical layer and the medium access control and logical link control sublayers for the token-ring LAN are discussed in more detail in the following sections.

PHYSICAL LAYER

The physical layer of the token-ring LAN synchronizes its clock with the signal received from the ring so that it can interpret received data. The data signalling rates as defined by the IEEE 802.5 Standard [2] are one and four million bits per second. Station attachment is via shielded twisted pair cable. Unshielded twisted pair attachment is under study by the IEEE 802.5 committee.

Differential Manchester Encoding

The token-ring LAN uses the differential Manchester code to convert binary data (bits) into signal elements. These signal elements:

- Contain no direct-current (DC) components, so they avoid plating or other deterioration at attachment contacts
- Allow the receiver to derive clocking pulses from the encoded signal.

For each bit of data, the code consists of two signal elements of opposite polarity. This maintains the DC balance in each bit and guarantees a transition for clocking. The value of each bit (0 or 1) is determined by comparing the first signal element of the bit with the last signal element of the previous bit. If the signal elements have the opposite polarity, the bit has a value of 0; otherwise it has a value of 1. The polarity (positive or negative) of the signal element does not affect the decoding of the 0's and 1's; only the transition, or lack of such transition, affects the decoding.

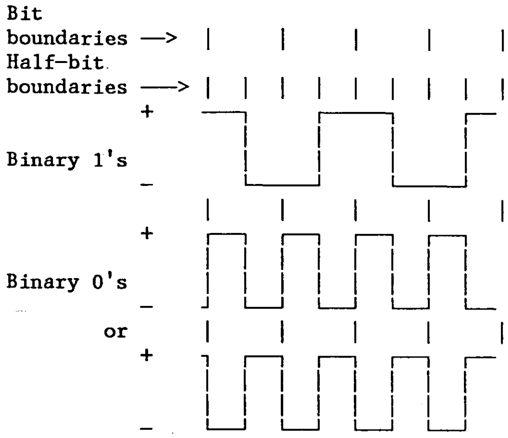

Figure 1. Differential Manchester Code

A code violation is said to occur if there is no transition (from plus to minus or minus to plus) at the bit midpoint. Frames and tokens are delimited by starting and ending delimiters that use four code violations (two positive and two negative to maintain DC balance) to guarantee uniqueness from the data stream.

MEDIUM ACCESS CONTROL SUBLAYER

The medium access control sublayer supports medium-dependent functions and uses the services of the physical layer to provide services to the logical link control sublayer. It allows a station to gain access to the ring for transmission, to detect and report error conditions, and to report configuration changes in the ring. The token-ring frame and token formats used by the MAC sublayer are provided in an appendix. The following sections describe the various functions of the MAC sublayer and the use of MAC management frames to control the operation of the token-ring LAN.

Access Priority

The access priority indicates the priority of a frame or token. The priority is contained in the first three bits of the access control field (see Appendix), allowing for eight levels of priority. Reservations for a priority token are placed in the last three bits (the reservation bits) of the same field. A station can transmit a frame using a token with a priority less than or equal to the priority of the frame. If an appropriate token is not received, the station may request a token at the required priority by placing a reservation in the access control field of a repeated frame or token.

When a station removes one of its transmitted frames from the ring and finds a non-zero value in the reservation bits, it must originate a non-zero priority token. The station determines the priority of the token based on the priority used by the station for the recently transmitted frame, the reservation bits received in the returning frame, and any stored priority (due to a previous transmission of a priority token). The priority token circles the entire ring giving every station the chance to transmit frames of a priority greater than or equal to the priority of the token. This allows for fair access at each priority level.

When the priority token returns to the originator, the station removes the token from the ring and issues a token at a priority determined by the reservation bits and the previous priority.

Active Monitor

The active monitor detects lost tokens, and frames and priority tokens that circle the ring more than once. The following sections describe the mechanisms used by the active monitor to detect and correct these error conditions.

Neighbor-Notification Process: The neighbor-notification process is initiated by the active monitor. It is used to inform stations that an active monitor is present on the ring, and of the address of their nearest active upstream neighbor (NAUN). The NAUN address is used for error isolation.

The neighbor notification process begins when the active monitor transmits an Active Monitor Present MAC frame to all stations on the ring. The first station to receive the Active Monitor Present MAC frame sees the address recognized and frame copied bits in the frame status field (see Appendix) set to zero indicating the frame was sent by its NAUN. It then sets these bits to one, saves the source address of the received frame as its NAUN address, and transmits a Standby Monitor Present MAC frame to all stations on the ring.

The next station immediately downstream copies the Active Monitor Present MAC frame, sees the address recognized and frame copied bits set to one, and disregards the frame. The station then copies its NAUN address from the Standby Monitor Present MAC frame that was transmitted by its upstream neighbor, sets the address recognized and frame copied bits in that frame to one, and transmits its own Standby Monitor Present MAC frame to all stations on the ring.

In this way neighbor-notification proceeds around the ring, with other stations transmitting their Standby Monitor Present MAC frames, until the active monitor copies the last Standby Monitor Present MAC frame, in which the address recognized and frame copied bits are set to zero. Neighbor notification thus enables a station to learn its NAUN address, and to provide its address to its downstream neighbor.

Frame and Token Control: The active monitor uses the monitor bit in the access control field to detect circulating frames or tokens with priority greater than zero. The monitor bit is set to zero in tokens and transmitted frames. When the active monitor repeats a frame or priority token with the monitor bit set to zero, it sets the monitor bit to one. If the bit has already been set to one, the active monitor assumes that the token or frame has already circulated the ring once (the station that originated the token or frame did not remove it). The active monitor purges the ring (see "Purge Process") and originates a new token.

The active monitor ensures that a token is always available on the ring by using a timer with a relatively short time-out that exceeds the time required for the longest possible frame to circle the ring. The active monitor restarts this timer each time it repeats a token or frame. If this timer expires, the active monitor assumes that the token was lost on the ring. The active monitor purges the ring (see "Purge Process") and originates a new token.

Purge Process: The active monitor purges the ring by transmitting a Ring Purge MAC frame to all stations on the ring. Receipt of the returned frame indicates to the active monitor the ring is viable. Other stations receiving a Purge MAC frame reset to repeat mode and cancel or restart appropriate timers.

Standby Monitor

The function of a standby monitor is to detect failures in the active monitor and other disruptions of the ring protocol. Each standby monitor maintains two timers to perform this function.

One timer, which has a longer duration than the active monitor's token monitoring timer, ensures that the active monitor's token monitoring function is operative. This timer is restarted when a token is repeated. If this timer expires, the standby monitor initiates token-claiming (see "Token-Claiming Process") to elect a new active monitor.

A second timer used to detect the absence or failure of the active monitor is restarted each time the standby monitor receives an Active Monitor Present MAC frame. If this timer expires, the standby monitor assumes that an active monitor is not present on the ring, or that the active monitor has malfunctioned. The standby monitor then initiates token-claiming.

Token-Claiming Process

Token-claiming is the process used to elect an active monitor. A standby monitor detecting an error, or the absence of the active monitor, initiates the token-claiming process by broadcasting Claim Token MAC frames to all stations on the ring. A station copying a Claim Token MAC frame compares its individual address to the source address of the received frame. If the source address is less than the station's individual address, the station transmits its own Claim Token MAC frames; otherwise, the station repeats received frames. If a station transmitting Claim Token MAC frames receives a frame with a source address higher than its individual address, the station stops transmitting its own Claim Token MAC frames and begins repeating received frames.

Receipt of its own Claim Token MAC frames indicates that the station has been elected as the active monitor. This station then purges the ring and originates a new token.

Beaconing Process

A station detecting a hard error broadcasts Beacon MAC frames to all stations on the ring to inform them of the detected error. The Beacon MAC frame includes the address of the nearest active upstream neighbor for use in error isolation and recovery. Upon receipt of Beacon MAC frames, the NAUN of the Beaconer removes from the ring and tests the continuity of the wire connecting it to the ring. If an error is detected, the station remains off the ring and the ring recovers. If the NAUN does not find an error when testing its lobe, the station reattaches to the ring.

After a period of time, if the ring has not recovered, the beaconing station removes and tests the continuity of the wire connecting it to the ring. Again, if an error is detected, the station remains bypassed allowing the ring to recover. If no error is detected, the station reattaches to the ring. If the error persists, manual intervention is necessary to recover the ring.

Attaching to the Ring

In order to communicate on the ring, a station must successfully go through a sequence of events during the ring insertion process. Before physically inserting in the ring, a station performs self tests to ensure the continuity of the wiring connecting it to the ring and that the station itself is functioning properly. After successfully completing these tests, the station physically attaches to the ring. The station then checks to be sure there is an active monitor on the ring by detecting a frame sent by the active monitor. If there is not an active monitor on the ring, the station initiates token-claiming.

After either detecting or establishing an active monitor, the station checks for the presence of another station on the ring with the same address by issuing a Duplicate Address Test MAC frame to its individual address. If the frame returns without being copied by another station, the station's address is assumed to be unique. The station then waits to participate in neighbor notification to learn its NAUN's address, and to provide its address to its downstream neighbor.

Lastly, the station requests parameter values from a management server on the ring. This request contains registration information for the station attaching to the network. If a management server is present on the ring, the station completes the insertion process after receiving a response from the server. If a server is not active on the ring, the station completes the insertion process and uses the default values for the ring parameters.

Soft Error Detecting and Reporting

Soft errors are intermittent faults that temporarily disrupt normal operation of the token-ring; they are normally tolerated by error recovery procedures. Soft errors are indicated by architectural inconsistencies (such as cyclic redundancy checks or timeouts) in received or repeated frames, and by a ring station's inability to process received frames. If soft errors result in degraded ring performance, the ring can be reconfigured to bypass the faulty node.

Each ring station maintains a set of counters to measure the frequency of occurrence of the most critical soft errors. At specified intervals, these errors are reported to a management server using a Report Soft Error MAC frame. The Report Soft Error MAC frame reports the number of errors detected since the last report was made. This report identifies the transmitting station's NAUN for use in error isolation and recovery.

Configuration Control

A management server may collect configuration information from stations on the ring. Configuration reports are generated when the insertion or removal of a station is detected during the neighbor notification process. A configuration report is also generated when a new active monitor is elected.

A management server may change the configuration by forcing a station off the ring. A management server may also query a station for various status information unique to that station.

LOGICAL LINK CONTROL

The IEEE 802.2 Standard [3] for logical link control defines peer-to-peer protocol procedures for the transfer of information between any pair of network layer entities on a local area network. Logical link control is not unique to the token-ring; it is intended to be used in conjunction with all the medium access control and physical layer standards defined in IEEE 802.

The formats and protocols of logical link control were derived from HDLC standards [4]. The format of the LLC protocol data unit (LPDU), the unit of information delivered from or to the MAC sublayer, differs from HDLC in that it does not include a frame check sequence or frame delimiters, and it contains two address fields. The functions of frame delimiting and frame check sequence generation and verification are provided by the medium access control sublayer; therefore, they are not necessary in the logical link control sublayer.

The two address fields contain the destination and source link service access point addresses. Link service access points (LSAPs) are the logical points at which network layer entities acquire the services of the data link layer (see Figure 2). To support the coexistence of multiple network layer entities, the LLC sublayer supports up to 127 service access points. The destination link service access point address in the LPDU is used by the receiving LLC to identify the network layer entity for which information is received. Within a network layer entity, the source link service access point address in conjunction with the MAC source address is used to determine the logical "connection" for which information is received. A network layer entity may have multiple logical "connections" active simultaneously.

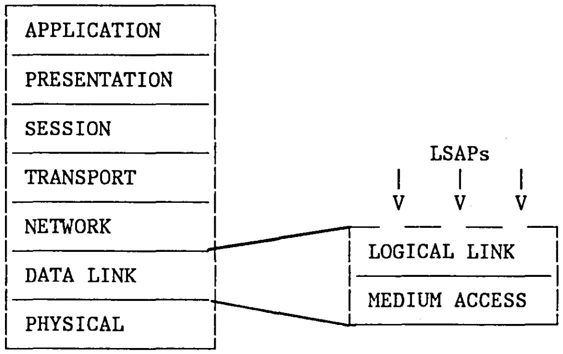

Figure 2. Link Service Access Points in the OSI Reference Model

The logical link control protocols closely resemble those defined in HDLC [4]. While basically a connection-oriented protocol, HDLC does define an optional facility for unacknowledged information transfer. LLC differs from HDLC in that it requires the support of unacknowledged information transfer and defines as optional a connection-oriented protocol.

Logical Link Control Services

Logical link control provides two types of service to the network layer: unacknowledged connectionless (type 1) and connection-oriented (type 2). The requirements of the higher layers determine which service type is applicable in a given situation. To provide a common set of minimal services, all stations are required to provide unacknowledged connectionless service.

Unacknowledged connectionless service is a datagram approach to information exchange where information is simply sent and received without correlation to previous or subsequent information and with no form of acknowledgment to ensure delivery. The LLC sublayer requires the network layer to explicitly specify the source and destination addresses in all requests for unacknowledged connectionless data transfer service. When information is received, the LLC sublayer routes the information as well as the addresses to the appropriate network layer entity as specified by the destination link service access point address. No state information is maintained by the LLC sublayer for unacknowledged connectionless data transfers. Unacknowledged connectionless service is useful when higher layers provide adequate error recovery and sequencing, or when it is not essential to guarantee the delivery of information.

Connection-oriented service provides a reliable communications path between any two network layer entities (identified by LSAP addresses) on a local area network. This service provides flow control, sequencing, and error recovery procedures. A "data link connection" is established, at the request of a network layer entity, between two LSAPs prior to any exchange of information. The connection may be reset to its initial state or terminated at any time by either network layer entity involved in the connection. Connection-oriented service is applicable when higher layer protocols require error free service.

The performance tradeoffs between using connection-oriented service and performing error recovery in the LLC sublayer, and using unacknowledged connectionless service and performing error recovery at a higher layer, is a subject of continual controversy. For an analysis, see "Performance Analysis of Error Control Alternatives in Local Area Networks" by Syed and Field [5].

Logical Link Control Protocols

The protocols defined for both unacknowledged connectionless and connection-oriented data transfer were derived from HDLC protocols. As in HDLC, the concept of "command" and "response" protocol data units is used. In the following sections, descriptions of the protocols for each type of service are provided.

Unacknowledged Connectionless Service: Unacknowledged connectionless service provides data transfer between two network layer or management entities with minimum protocol complexity. Figure 3 lists the LLC commands and responses that provide unacknowledged connectionless service.

LPDU Name	Abbr.	Command	Response
Unnumbered Information	UI	X	
Exchange Identification	XID	X	X
Test	TEST	X	X

Figure 3. LLC Commands and Responses for Connectionless Service

The UI command LPDU is used to transport data from one network layer entity to another. UI command LPDUs may be sent or received at any time. Received UI LPDUs are neither acknowledged nor verified for correct sequence. The receiver of an UI command LPDU simply passes the contents of the information field to the network layer entity designated by the destination link service access point address. UI command LPDUs can be lost if an exception (for example, a transmission error or a receiver-busy condition) occurs during transmission. Higher layer protocols are responsible for detection of lost or duplicate LPDUs, and for any required retransmissions.

The XID command LPDU is used to convey identification and characteristics of the sending station, and to cause the receiving station to respond with the XID response LPDU. The IEEE 802.2 Standard [3] defines the format for the information field of an XID LPDU. The field contains information related to the types of service provided by the station or by a specific LSAP, and for connection-oriented service, it specifies the receive window size. All stations must support the information field defined by IEEE 802.2 and must be capable of returning an XID response when an XID command is received. The logical link control standard does not exclude the exchange of user-defined XID information formats, such as, those defined by Systems Network Architecture (SNA).

The TEST LPDU is used to perform a basic test of the transmission path between two stations. The information field is supplied by the user or a management facility. All stations must have the ability to return a TEST response when a TEST command is received.

Although XID and TEST are considered part of the unacknowledged connectionless service, they provide facilities that are more likely to be invoked by management entities rather than by network layer entities. An implementation may choose to provide error recovery procedures for XID and TEST within the logical link control sublayer as long as the flow sequences remain independent from that of the connection-oriented service.

Connection-Oriented Service: The protocol procedures for connection-oriented service are similar to the HDLC asynchronous balanced mode of operation (see [4] for details). Figure 4 lists the LLC commands and responses that are used in connection-oriented service. Unlike HDLC, which allows the choice of 8 or 128 as the modulus for sequence numbering, logical link control defines the modulus to be 128.

Before information can be exchanged between two network layer entities, a data link connection must be established between two LSAPs. Connection establishment is requested by a network layer entity. Upon receiving such a request, the LLC sublayer sends a SABME command LPDU to the destination specified in the request. The receiver of the command accepts the connection by returning an UA response LPDU, or rejects the connection by returning a DM response LPDU. If the connection request is rejected, the initiating network layer entity is notified and must retry its connection request at a later time if it still desires the connection. If the connection request is accepted, the data link connection is successfully established and the two network layer entities may exchange information. The LLC sublayer provides in-sequence information transfer without loss or duplication of data.

LPDU Name	Abbr.	Command	Response
Information	I	X	X
Receive Ready	RR	X	X
Receive Not Ready	RNR	X	X
Reject	REJ	X	X
Set Asynchronous Balanced Mode Extended	SABME	X	
Disconnect	DISC	X	
Unnumbered Acknowledgment	UA		X
Disconnected Mode	DM		X
Frame Reject	FRMR		X

Figure 4. LLC Commands and Responses for Connection-Oriented Service

Information is transferred from one network layer entity to another using I command or response LPDUs. (The concept of a command or a response in a peer-to-peer environment is not meaningful in many cases; a station may use either in many situations.) Each I LPDU contains a send sequence number that allows the receiver to verify proper ordering. The sender of an I LPDU runs an acknowledgment timer and maintains a copy of the entire LPDU until an acknowledgment is received. To maximize throughput, a number of I LPDUs may be outstanding, i.e. sent but not yet acknowledged, in each direction of a data link connection before the transmitter must stop and wait for an acknowledgment. This transmit window has a maximum value of 127.

If a received I LPDU contains the next sequence number expected, the information is delivered to the network layer entity and an acknowledgment is returned to the sender. Acknowledgments are indicated by the value of the receive sequence number in I, RR, RNR, and REJ LPDUs. All I LPDUs numbered up through the receive sequence number minus one are acknowledged; hence, a single LPDU may acknowledge multiple I LPDUs. The IEEE 802.2 standard does not require an acknowledgment to an I LPDU be returned at the earliest opportunity unless the I LPDU was a command with the P bit set to "1" (see [3] for details). If an I LPDU is not available for sending, a station may delay the sending of an acknowledgment for some period of time bounded by the probability of the expiration of the remote acknowledgment timer, for either an I LPDU to become available for transmission, or to accumulate additional I LPDUs to be acknowledged in a single RR LPDU, subject to window size constraints. One method that may be used to control acknowledgment sending involves the use of a timer and a counter such that an explicit acknowledgment will be sent whenever the timer expires or the count limit is reached (see [6] for details).

If an I LPDU is received out of sequence, the information field is discarded and a REJ LPDU containing a receive sequence number equal to the expected sequence number is returned. The receiver of the REJ LPDU will retransmit the I LPDU containing the expected sequence number and any other unacknowledged I LPDUs that had been previously sent following the one that was rejected.

Lost frames that cannot be discovered by sequence number validation are detected when the acknowledgment timer expires. Upon expiration, a "checkpointing" operation is initiated. "Checkpointing" consists of sending a RR command LPDU with the P bit set to "1." The receiver of the command is obligated to respond with its expected sequence number. By interrogating this number, the initiator of the "checkpointing" operation can determine if retransmission of any I LPDUs is necessary.

If a station becomes temporarily unable to receive information frames due to resource constraints such as buffering limitations, it can notify the remote LLC by sending a RNR LPDU. The receiver of a RNR LPDU should stop sending I LPDUs until it receives further notification. A RR LPDU may be sent to notify the remote LLC that it may resume sending I LPDUs.

Either network layer entity involved in the connection may request that the connection be terminated. A DISC LPDU is sent to notify the remote LLC of the disconnection. The receiver of the DISC LPDU responds with an UA LPDU. The disconnection is not negotiable; the receiver of a DISC LPDU may not reject the disconnection request.

If a protocol error is detected, the station detecting the error sends a FRMR LPDU containing a summary of the detected error to the originating station. When a station receives a FRMR LPDU, it may attempt to reset the connection or treat the connection as being disconnected.

CONCLUSIONS

The IEEE 802.5 and 802.2 Standards have progressed to Draft International Standards within ISO. The architecture for token-ring LANs as defined in the standards provides superior fault isolation, problem determination, and recovery capabilities. The protocols allow excellent operational characteristics at high speeds and under heavy loads.

The architecture for token-ring LANs can easily be extended to include the interconnection of rings via bridges. This extension would provide improved connectivity, performance, and availability. Source routing provides a method of routing frames through a bridged network, where the source of a frame explicitly identifies the route that a frame is to follow. The appendix contains a proposed addition to the token-ring frame format to include the routing information field used in source routing.

APPENDIX: TOKEN-RING FRAME AND TOKEN FORMATS

The basic transmission unit on the token-ring LAN is the frame. Frames are composed of a number of fields of one or more bytes, as shown below:

```
┌──┬───────┬───────────┬─────────┬──────//────┬───//─────┬─────────┬──┬──┐
|S |Control|Destination|Source   |Routing     |Informa-  |Frame    |E |F |
|D |Fields |Address    |Address  |Information|  tion    |Check    |D |S |
|  |       |           |         |            |          |Sequence |  |  |
└──┴───────┴───────────┴─────────┴──────//────┴───//─────┴─────────┴──┴──┘
|<────────── Physical Header ──────────────>|            |<── Physical ->|
                                                               Trailer
```

SD = starting delimiter
ED = ending delimiter
FS = frame status field

Figure 5. Frame Format

Starting Delimiter: The starting delimiter is a single byte with the following format:

```
┌─────────────────┐
| J K 0 J K 0 0 0 |
└─────────────────┘
```

J = Code Violation
K = Code Violation

Figure 6. Starting Delimiter

All valid frames and tokens start with this byte.

The J and K indicate code violations, which identify the byte as a delimiter. Use of code violations avoids using special bit patterns of normal codes for delimiters; therefore, bit insertion, as used in HDLC, is not required.

Control Fields: The control fields are each one byte in length and are used to determine access to the ring. The control fields have the following format:

```
┌──────────────────────┬──────────────────┐
│ P P P  T  M  R R R   │ F F  Z Z Z Z Z Z │
└──────────────────────┴──────────────────┘
 Access Control        │ Frame Control

 P = Priority Bit         F = Frame Type Bit
 T = Token Bit            Z = Control Bit
 M = Monitor Bit
 R = Reservation Bit
```

Figure 7. Control Fields

The priority bits indicate the priority of a token or frame. There are eight priority levels, from zero to seven.

The token bit is used to distinguish between frames and tokens. A token is the signal used to give a station permission to transmit. The figure below shows the format of the token:

Starting Delimiter	Access Control	Ending Delimiter

Figure 8. Token Format

The monitor bit is used by the active monitor to prevent a token whose priority is greater than zero, or any frame, from continuously circling the ring.

The reservation bits allow stations with high access priorities to request, in repeated frames or tokens, the priority of the next token. There are eight reservation levels, from zero to seven.

The frame type bits indicate the type of information contained in the frame as either MAC management, or user data.

The control bits are used in the MAC management frames to determine the method for copying a frame. If the control bits equal zero, the station copies the frame using normal receive buffers and does not copy the frame if no buffers are available. If the control bits are greater than or equal to one and the normal receive buffers are full, the station copies the frame into buffers reserved for MAC protocol management to insure appropriate action is taken by the station.

Destination Address: The destination address identifies the ring stations that are to copy the frame. Destination addresses are always six bytes in length with the following format:

```
              bytes
| 1 | 2 | 3 | 4 | 5 | 6 |
┌─┬─────┬─┬──────────────┐
│ │     │ │              │
└─┴─────┴─┴──────────────┘
 ││         └─ Functional Address bit
 │└─ Universal / Local Administration bit
 └── Individual / Group Address bit
```

Figure 9. Destination Address

The individual/group address bit indicates whether the frame is addressed to a specific station or a group of stations on the ring. The universal/local administration bit indicates whether the address is administered by IEEE thereby, guaranteed to be unique across all types of LANs, or administered such that the responsibility for unique addresses is placed on the local administration. All addresses must be unique in a given network. The functional address bit indicates whether a locally administered group address is a bit mapped address (functional address) identifying a management function, or a flat six byte group address.

These indicators are an integral part of each station's address, and considered during address-recognition.

Source Address: The source address identifies the ring station that originated the frame. Source address is six bytes in length with the following format:

```
              bytes
| 1 | 2 | 3 | 4 | 5 | 6 |
┌─┬──────────────────────┐
│ │                      │
└─┴──────────────────────┘
 │└─ Universal / Local Administration bit
 └── Routing Information Indicator
```

Figure 10. Source Address

A source address is always an individual address, so the individual/group address bit distinction defined in the destination address field is not needed. Instead, this bit may be used as a routing information indicator specifying whether or not a routing information field is present in the frame.

As in the destination addresses, bit 1 of byte 0 indicates whether the address is administered by IEEE or a local authority.

Routing Information Field: Following the source address is a routing information field present only in frames leaving the source ring. The field, when present, consists of a two-byte routing control field and up to fourteen two-byte segment numbers.

bytes

2	4	6		m
Routing Control	Segment Number	Segment Number	//	Segment Number

Figure 11. Routing Information Field

Routing Control Field: The routing control field is two octets in length with the following format:

	B	r	LTH	D	r
bits	1	2	5	1	7

B = Broadcast
r = reserved
LTH = Length
D = Direction

Figure 12. Routing Control Field

The Broadcast bit indicates if the frame is destined for all segments in a network. This bit does not imply that the frame is destined for all stations on all rings. The Length bits indicate the length of the routing information field including the routing control field. The Direction bit indicates if the frame is traveling from the originating station to the target station or visa versa.

Information Field: The variable-length information field contains an integral number of bytes of MAC management or user information.

While there is no explicit restriction on the size of the data field, the values of various MAC timers limit the practical maximum frame size. In an environment where there are several rings, connected by bridges, the bridges may also be the limiting factor in determining the practical maximum frame size.

Frame Check Sequence: The frame check sequence is a four-byte cyclic redundancy check (CRC) covering the frame control field, the addresses, the routing information field, the information field, and the frame check sequence itself.

Ending Delimiter: The ending delimiter is a single byte with the following format:

J K 1 J K 1	0	E

J = Code Violation
K = Code Violation
E = Error Detected Bit

Figure 13. Ending Delimiter

As in the case with the starting delimiter, code violations (J, K) are used to denote the ending delimiter. The ending delimiter is different from the starting delimiter in that bits 2 and 5 are set to 1. Using different patterns for the starting and ending delimiters simplifies the detection of each.

The error-detected bit is used to indicate that an error was detected in the frame by a station on the ring. It also indicates to a station detecting an error in a frame or token, whether the error has been logged by another station on the ring.

Frame Status: The frame status field is a single byte with the following format:

A	C	r	r	A	C	r	r

A = Address Recognized Bits
C = Frame Copied Bits
r = reserved

Figure 14. Frame Status Field

The address recognized and frame copied bits indicate the following conditions to the sending station: no station recognized the destination address and the frame was not copied, a station recognized the destination address and copied the frame, or a station recognized the destination address but did not copy the frame.

ABSTRACT

The acceptance of the personal computer as an intelligent workstation, coupled with the increasing demand for shared access to common files and for electronic office communication, has created a need for a reliable, high-speed, local communication network. This paper is an overview of an implementation of the IEEE 802.5 token-ring network recently released by IBM. The paper covers the general architecture of the network and focuses on how this implementation achieves high reliability and the flexibility of an open system, which are essential to meet present and growing data communication needs.

1.1 INTRODUCTION

A LOCAL AREA NETWORK (or LAN) is a geographically confined communication system, generally inhabiting a shared transmission medium. The main ingredients of a LAN are:

- the transmission medium
- the access protocols, which govern the way that access to the shared medium is achieved
- the adapter, for controlling the connection of a device to the medium
- the communication protocols, once access is achieved.

A gathering of people in a room has all the ingredients of a local area network. The transmission medium is the air filling the room (a bus topology!). The access protocols may vary from meeting to meeting. In a social gathering and within the confines of social amenities, we contend with others for the right to speak. At the next lull in the discussion, we begin to speak. If someone else begins at the same time, we both politely back off for a brief moment and then re-initiate our conversation. Eventually, someone wins the contention and gains control of the transmission medium. In a lively gathering, a high percentage of the time could be spent on the access protocols. In a more structured business meeting, access may proceed in an orderly fashion around the table. In this case and even with everyone having something to contribute, very little time is spent on the access protocols. If each person's time to speak is limited, then each will have access to the medium again within a guaranteed amount of time. The adapter is our set of vocal cords and the communication protocols are the ordinary rules of language, specialized to the occasion.

In the late sixties, the ALOHA Network at the University of Hawaii was developed to apply packet radio techniques for communication between a central computer and terminals scattered about the Hawaiian Islands. This network used a contention-based access method for gaining control of the central processor. Contention methodology was enhanced in the Ethernet communication system, developed by Xerox in the early seventies. Ethernet utilizes Carrier Sense Multiple Access with Collision Detect (CSMA/CD) to control access of multiple processors to a shared bus. A station initiates transmission only if the bus is quiet. Because this access method requires backoff and retransmission whenever multiple transmissions collide on the bus, the throughput is adversely affected when high utilization of the communication bandwidth is attempted. Also, since the transmission must travel the length of the bus and return before potential collisions are detected by the transmitting station, the access method does not provide a proportional increase in throughput as the transmission rate is increased, unless the bus is shortened.

The token-ring access scheme (10) offers an alternative method for sharing a common transmission medium. Transmission is point-to-point serially around a ring, with the transmitter of one station attached to the receiver of another station. A special bit sequence called a TOKEN is passed from each station to the next downstream station. If a station wishes to transmit, then that station will capture the token (ie, not forward it) and instead transmit a frame, addressed to another individual station or a group of stations in the network. All stations monitor the destination address of frames being forwarded. The intended recipient copies the frame while forwarding it. The transmitting station has the responsibility of removing a frame when it has completed the 'round' trip. As soon as this 'stripping' process begins, the station can release the token to the next downstream station.

The ring topology would seem to be vulnerable to a break in the transmission path, but the sequential ordering of stations is the basis for effective on-ring error isolation and recovery (see below). In addition, the baseband, digital technology involved is mature and can be implemented inexpensively. The point-to-point nature of the transmission lends itself to the use of optical fiber cable. The controlled nature of the access method remains stable at very high speeds, so that token-ring access control was selected as the basis for the 100 megabit/sec Fiber Distributed Data Interface (FDDI), a local area network standard being drafted by the ANSI X3T9.5 Committee (see (13)).

Early work on IBM's token-ring architecture was carried out at the IBM/Zurich Research Laboratory. Members of the LAN Architecture and System Design Departments of IBM at the Research Triangle Park in North Carolina evolved the details of the architecture and made significant contributions to the LAN standards activities.

With the formal introduction of the IBM Token-Ring Network in 1985, software and hardware developers applied considerable energy to producing software written to the published specifications for interfaces and hardware that could co-exist on the transmission subsystem. Token-ring technology can support the local data communication needs of an establishment of almost any size. The widespread adoption of the personal computer as an intelligent workstation in the business environment, coupled with the increasing need for peer-to-peer and host-interactive connectivity, emphasize the requirement for an establishment-wide local area network.

In the following sections, IBM's implementation of a token-ring LAN is highlighted, with attention focused on the openness, reliability/availability, and standardization of the network, beginning with the transmission subsystem. Successively higher-level layers of the implementation are also discussed.

1.2 IBM CABLING SYSTEM AND COMPONENTS

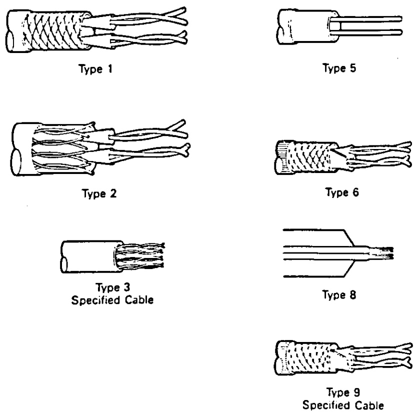
A major part of any communication system is the transmission subsystem. Standardization of communication protocols will do little to promote the acceptance of LAN technology without an equal effort to standardize the medium. Look in the ceiling or under the floors of any building that has hosted a computer and/or telephone communication system for a few years, and you will find a maze of wire, much of which has been abandoned. In 1984, IBM introduced components and specifications for a cabling system which are designed to accommodate the local communication needs of an establishment for the foreseeable future.

The IBM Cabling System has the following attributes:

- 'STANDARD' - The component and cabling specifications have been made available. Independent vendors/suppliers provide the components and the installation expertise, in addition to IBM.

- OPEN - Universal connectors and faceplates allow for easy access to the medium of a variety of communication products. IBM has announced its intention to make future devices compatible with the cabling system. Many communication products compatible with the cabling system are already available from multiple sources. A variety of communication products are accommodated by using the appropriate connector cable (or balun) in the office, without rewiring to the wiring closets.

- STRUCTURED - Instead of being a maze of point-to-point wires, the cabling is installed with a structured topology. Cable drops in offices are routed through raceways to wiring



- Type 1 — Data communication
- Type 2 — Data and voice communication (Both Type 1 & 2 can be plenum/non-plenum)
- Type 3 — data and voice communication (telephone twisted-pair)
- Type 5 — Fiber optic (Between wiring closets/network backbone)
- Type 6 — Data communication (Patch cables)
- Type 8 — Undercarpet cable (Data only)
- Type 9 — data communication

FIGURE 1: CABLE TYPES

closets, which are strategically located throughout a building. The section of cable from the office to the wiring closet is called a LOBE.

The cabling terminates in wiring racks or telephone punch-down blocks. The cabling can then be connected together at a patch panel to provide the endpoint connectivity desired. Rearrangement of the physical connectivity is easily accomplished by changing the patch-panel connections. This star-shaped wiring topology allows for a 'virtual rewiring' of the building without any of the traditional expense. Wiring closets are themselves connected together to provide structured, systematic connectivity throughout the establishment.

A new outlet in an office or a new type of cable can be difficult and expensive to provide. Ideally, a building is prewired with the cabling system during construction, with sufficient office drops and overall accessibility provided to handle future expansion.

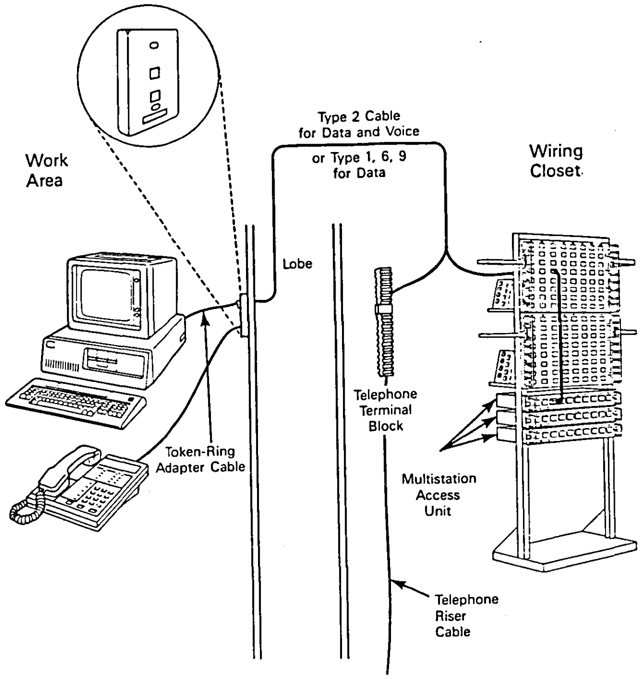


FIGURE 2 : OFFICE TO WIRING CLOSET LOBE

1.2.1 NETWORK CABLING COMPONENTS

The Token-Ring Network can be superimposed on the cabling system by adding the appropriate components in the wiring closets and in the offices.

A Multistation Access Unit allows up to 8 lobes to be combined serially in the wiring closet or (if convenient) locally within an office. The access unit is not powered. Instead, a 'phantom' current from the attaching device activates a switch in the access unit to insert the lobe into the active ring of the network or to bypass an inactive or inoperative device.

Copper repeaters can be used to extend the length of the main ring path between wiring closets beyond the specified limits. The repeater reshapes and retransmits the signal, just as does the adapter.

Optical fiber repeaters can be used in pairs to extend the length of the main ring path up to 2 kilometers by using optical fiber cable. Fiber is being increasingly used in point-to-point communication because of its high transmission rate characteristics and its immunity to electromagnetic interference.

1.3 MAC/LLC IMPLEMENTATION

The Data Link Control (DLC) layer of the communication architecture is specified in the standards that have been developed by the Institute for Electrical and Electronic Engineers (IEEE) Project 802 Committee.

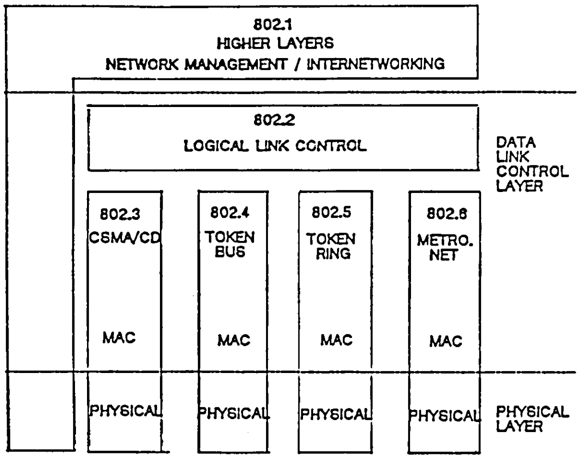

FIGURE 3: IEEE PROJECT 802 STRUCTURE

The 802.5: Medium Access Control (MAC) sublayer standard specifies the token-ring access method. The 802.2: Logical Link Control (LLC) sublayer standard specifies the remainder of the Data Link Control, independent of the particular access method. All 802 LANs have the same LLC.

The MAC sublayer handles the token protocols and the ring recovery procedures. Each ring station monitors the traffic on the network to determine if errors or interruption in the MAC layer protocols have occurred. Under normal operation, one station on the ring has special functions activated, with this active monitor capability on standby in all other stations.

The active monitor has an incremental 24-bit latency buffer to insure that a (24-bit) token will fit on the ring. The active monitor can also sense lost tokens, circulating frames, or circulating priority tokens. Additional active monitor duties include token generation in case the network has no token and activation of a 'neighbor notification' process whereby each station learns the address of its nearest active upstream neighbor (NAUN). The active monitor also provides a master timing clock for the rest of the ring, which is imbedded in the data stream through the use of Manchester encoding. The other stations are in standby mode, checking the health of the active monitor. Any station can assume the role of the active monitor, if needed. The process for 'electing' an active monitor is called 'claim token'.

The ring topology with its unidirectional flow provides a robust environment for error isolation and recovery. Since each station knows its upstream neighbor, the first station (in order around the ring) to note an error will then know the fault domain (two stations and the connecting cable) for that error. This information is reported to network management and used in automatic error recovery techniques. Error types include soft errors such as bit errors in a frame or hard errors such as loss of signal.

In the case of hard errors, a 'beaconing' protocol is used to notify all stations that error recovery is taking place and to share the fault domain information. For example, the station immediately downstream from a wire fault will repeatedly transmit a 'beacon' frame containing its own address and that of its NAUN. The other stations on the ring repeat the beacon frame. When (and if) the NAUN station sees its own address in a beacon frame, it removes itself from the ring and performs a self-test. If this test indicates normal operation, the station will re-insert into the ring. If normal ring operation has not returned in a brief period of time, the 'downstream' member of the fault domain (the beaconing station) will also go through removal and self-test. Automatic recovery and the other MAC-layer functions are handled by the processor on the adapter.

Any station that wishes to join the network goes through a five-step process to insert itself into the ring:

1. Lobe check, whereby test frames are transmitted to the bypass circuitry in the multistation access unit and wrapped back to the station for validation,
2. Active monitor present check,
3. duplicate address check,
4. participation in 'neighbor notification' protocol,
5. report to network management.

If the insertion process fails, notification is given to the attaching device.

The services of the Logical Link Control sublayer are accessed through logical, addressable points within the sublayer called Service Access Points (SAPs). Multiple logical link endpoints can exist in a single station, using SAP addressing. The services of this sublayer are of two types. TYPE 1: CONNECTIONLESS service provides for transmission (and receipt) of information without implementing link error recovery or frame acknowledgment. This type of service is also called datagram service. TYPE 2: CONNECTION-ORIENTED service requires that SAPs be extended by connection components, which serve as connection endpoints for DLC links. A DLC link consists of the two MAC/SAP address pairs, one pair in each communicating station. The connection component is responsible for processing the events which affect the particular DLC link. Frames transmitted on such links are numbered in sequence and acknowledged upon receipt. Any errors detected cause link recovery protocols to be executed. For further details, see (14).

1.4 ADAPTER DESIGN

Devices requiring attachment to the token-ring LAN must interface to an adapter that implements MAC-level protocols, regardless of the higher-layer protocols. For example, these functions are incorporated into the Front End, Protocol Handler, and Message Processor of the adapter developed to attach IBM personal computers to the ring.

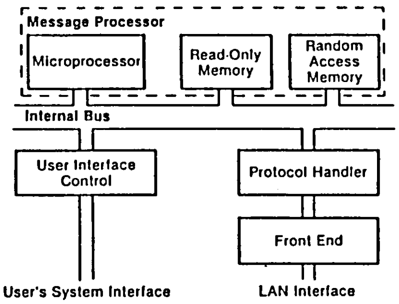

Figure4. Functional Partitioning of the Adapter

1.4.1 FRONT END

The receive/transmit functions of the adapter are implemented in the Front End. Analog circuits reshape and redrive the received signal. The 'clock' is also extracted from the received signal by means of a phase-locked loop. The Front End also supports lobe and adapter testing in addition to error monitoring of the physical attachment.

1.4.2 PROTOCOL HANDLER

Two data paths are incorporated in the Protocol Handler, which is under the control of microcode stored in the memory of the Message Handler. The serial path is used to forward received frames on the ring. The parallel path converts the serial data stream into two-byte segments, checking address fields to determine if a frame is destined for that adapter. Copied frames are stored in the random-access memory of the adapter.

1.4.3 MESSAGE PROCESSOR

Included in this segment of the adapter are a microprocessor, read-only memory for storing the operating program of the adapter, and random-access memory used to buffer messages. The Message Processor determines if a received frame requires action at the MAC layer or must be passed to the LLC layer.

1.4.4 USER INTERFACE CONTROL

The Interface Controller handles the transfer of data between the random-access memories of the adapter and the attaching device. This shared memory approach, using a memory map common to both the adapter and personal computer memories, enhances the performance of the adapter by eliminating the overhead of parameter passing, since memory address and data segment length definitions are identical between the two processors. A bidirectional interrupt capability and programmable timing facility are also provided. A permanent, adapter address (if provided) is contained in programmable, read-only memory. The standard adapter contains 8K of random-access memory. A memory-enhanced adapter with 16K of memory is also available for high-performance devices such as bridges and servers in which more data buffers are needed.

The user interface can be customized to the internal structure of the attaching device. For example, the adapter was modified to mate to the IBM 3725 Communication Controller, which then attaches high-end host machines to the network.

A joint development effort between IBM and Texas Instruments led to the TMS380 chip set (12), which implements the MAC layer protocols necessary for attachment to a token-ring LAN. This chip set is functionally equivalent to the MAC layer portion of the IBM adapters and is available for attachment of equipment from other manufacturers. Of course, LLC and higher layer protocols and a customized, device interface need to be provided as well.

1.5 BRIDGES AND SOURCE ROUTING

A bridge is a routing mechanism between two or more segments (eg, rings) of a local area network. The bridging function takes place within the Data Link Control layer, either at the MAC or LLC sublayers. The bridge is transparent to higher layer protocols. Such a relay function, existing at low levels in the communication protocols, will usually provide high throughput between the connecting segments. Contrast this with a gateway, which connects networks at levels higher than the data-link control level and therefore is involved to some extent with protocol conversion and address mapping.

The current bridge between token-ring segments uses two adapters installed in an IBM Personal Computer or Industrial Computer, and performs a relay function at the MAC sublayer. The processor of the personal computer executes a bridge program to achieve the bridging function. It is important to realize that each ring maintains its own token and MAC-level protocols. Tokens do not cross bridges. The automatic recovery techniques (if needed) are isolated to the single affected ring. Therefore the aggregate data capacity of the bridge-connected network is increased. The bridge selectively copies frames on one ring that are marked for routing and determines if the frame should be transmitted on the connecting ring.

A route through a network consists of a sequence of ring/bridge numbers, starting at the source ring and ending at the destination ring. No specific routing protocols have been recommended by the IEEE 802 Committees. The routing scheme utilized by the IBM Token-Ring Network is called SOURCE ROUTING, which means that the source station must provide the route and insert it in the frame as extended addressing. Each bridge first notes the existence of a routing information field in a frame and then scans that field to determine if its own ring/bridge/ring combination appears. If so, then the frame is forwarded. Routes can either be predefined, which is static, difficult to manage, and subject to aging, or determined dynamically when needed. In dynamic source routing, a source station wishing to determine a route to a particular adapter address, which may reside on another ring in the network, first broadcasts a special route-selection frame, which is forwarded by all bridges (subject to certain restrictions). Each bridge appends its own bridge/ring numbers to the route, thereby 'growing' the route as the frame traverses the network. The receiving adapter returns each such frame received, using the stored route in the frame in reverse order. The first such response received by the initiating station contains the 'shortest' route effectively. This route is used in further dialogue with the destination station.

Source routing does not require either the bridges or network management to have a current, global view of the network configuration. This property enhances the dynamics and robustness of network connectivity. Also, these protocols support multiple routes between source and destination rings.

1.6 PROGRAMMING INTERFACES

In order to promote the development of network software and the attachment of IBM and non-IBM equipment, documented interfaces and protocols exist at all communication levels. The Texas Instruments chip set and chip sets available from other vendors provide a MAC-level interface that can be incorporated into a custom adapter for a variety of communicating devices.

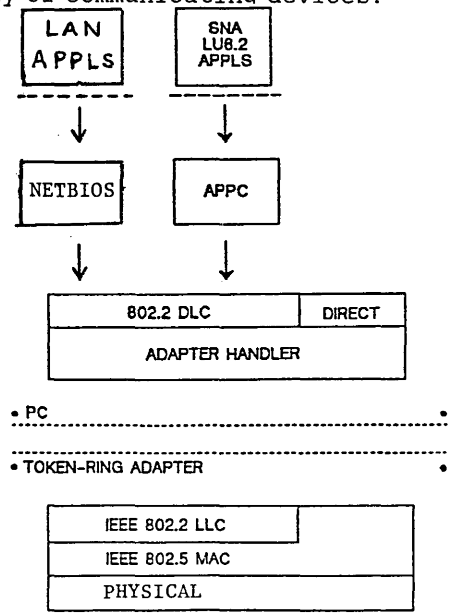

FIGURE 5: ADAPTER/SOFTWARE INTERFACES

The IBM personal computer adapters (standard and Adapter II) also provide a MAC-level interface for those users who want to write software to that interface. The DLC interface provides access to the LLC functions on the adapter. The Adapter Handler code supplied with the adapters provides a more user-friendly interface for the adapter interfaces just described.

The Network Basic Input/Output System (NETBIOS) interface is rapidly becoming a defacto-standard, programming interface for local area networks. The NETBIOS interface is provided by a program that runs in an IBM PC containing an adapter. Other networks provide the same interface, regardless of the underlying access and transmission protocols. This wide use of NETBIOS promotes the development of extensive network software that is portable across a variety of networks. Both the NETBIOS interface and the underlying protocols used to implement NETBIOS on the Token-Ring Network are documented in IBM publications.

The Advanced Program-to-Program Communication for the IBM Personal Computer (APPC/PC) program product provides a Systems Network Architecture (SNA) LU6.2 interface. This interface has also been developed for a number of other communication products, which means that software written to that interface should be directly compatible with the Token-Ring Network. Both the interface and protocols of APPC have been documented.

Other programs written to the NETBIOS interface, such as the PC LAN Program and the Asynchronous Communications Server, provide server interfaces to the network and access to the public switched network.

In contrast to the early development of communication systems in which interfaces and protocols were proprietary, the communication systems of today, integrating hardware and software from many different vendors, require an unprecedented level of openness and standardization. The IBM Token-Ring Network exemplifies these requirements.

1.7 NETWORK MANAGEMENT

The MAC-level protocols contain a number of procedures for automatic error monitoring and recovery. In the event of a network hard error, the fault domain is generated by the detecting station and transmitted on the network. A report is also generated by the first station detecting a soft error. The Ring Diagnostic provided with the adapters, when executed in an IBM Personal Computer, will retrieve these reports from the network and display them for the user. This information is a useful ingredient in the problem determination procedures provided. An extension of the Ring Diagnostic functions is also available, called the Network Manager program, which executes further ring monitoring and station control functions.

A network of bridged rings has a three-tiered management hierarchy.

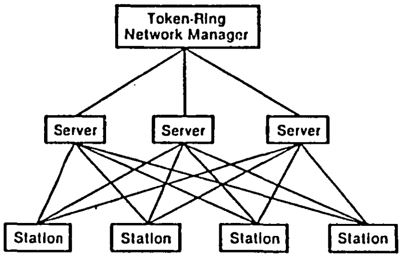

Figure 6 Management Hierarchy for Token-Ring Local Area Networks

Each separate ring has its own token protocols and ring monitoring functions, distributed across the adapters on the ring. MAC-level bridges add a second level and provide a convenient station on each attaching ring in which to house other network management functions. For example, the monitoring and reporting functions of the Ring Diagnostic are integrated into the bridge code. These server functions, residing in a bridge station or some other specially designated station on each ring, could be designed to report selective information to a network manager function residing elsewhere in the network or to perform specialized management functions.

Examples of potential management servers include:

- RING ERROR MONITOR - collects and analyzes hard- and soft-error reports from the local stations. Selected results can be reported to the network manager. These server functions are incorporated into the Ring Diagnostic and the Network Manager program product.
- CONFIGURATION MONITOR - collects configuration change reports from stations.
- RING PARAMETER SERVER - initializes and maintains a consistent set of values for operational parameters in ring stations.
- RING LAYER MANAGER - requests the status of stations, changes the values of operational parameters, and forces configuration changes.

The network manager entity on the Token-Ring Network could in turn report selected information to a higher management function whose domain is the whole establishment communication complex.

1.8 CONCLUSIONS

The IBM Token-Ring Network is an open network, utilizing the latest technology, and adhering to internationally-accepted standards for local area networks. The reliability of the components and the automatic error isolation and recovery designed into the low-level protocols provide for high availability of the network. The star-wired, ring topology promotes a systematic layout of the transmission medium in a building. The token-access protocols offer orderly, predictable access to the network, even under high utilization. Bridges and repeaters provide for network expansion, both in physical size and number of stations.

Together with the IBM Cabling System, the network offers a strategic solution to an establishment's data communication and connectivity needs for the future.

IMPLEMENTING THE IEEE 802.5 TOKEN-RING STANDARD

M.C. Hamner and J.T. Carlo

Texas Instruments Incorporated
Houston, Texas 77001

ABSTRACT

This paper will describe the methodology for implementing the 802.5 Token Ring standard with the TMS380 VLSI chipset. Critical decisions were made for the Physical and Medium Access Control (MAC) specifications to determine which functions were designed into hardware, allowed to vary using external components or controlled by software. The separation of hardware and software functions is guided by the placement of token-related processes in hardware and MAC-layer frame processing in software. Particular attention is paid to thorough testing and verification of the hardware and software to guarantee ring integrity, isolate possible failures and assure complete 802.5 compatibility.

SECTION 1 INTRODUCTION

The TMS380 token ring chipset(1) is illustrated in Figure 1.

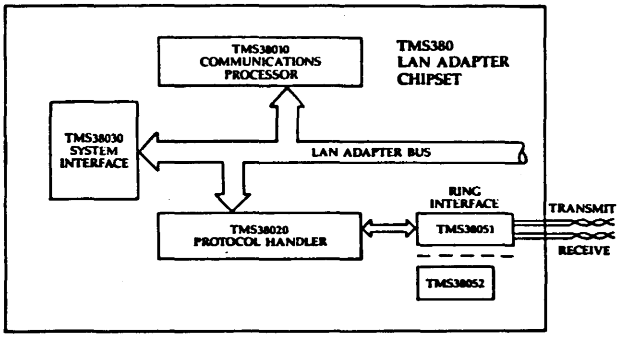

Figure 1
TMS380 Implementation of IEEE 802.5

The chipset consists of three VLSI integrated circuits and two bipolar ring interface devices. Sixteen Kbytes of ROM code, containing both MAC frame processing, diagnostics, and a high level user interface is provided in the Protocol Handler(PH). The Communication Processor(CP) contains 2.75K Bytes of RAM for data buffering and software tables. Both of these memory areas are expandable using external ROM, EPROM or RAM. The two ring interface circuits provide the data conditioning and recovered-clock function for attaching to the twisted pair medium of the token ring. The PH performs the real-time token ring protocols, such as token capture and priority control. The CP executes code which contains the Medium Access Control(2) and management protocol processes of the IEEE 802.5 and test software which ensures integrity of the station and cable attaching the station to the ring. The code also provides a command interface into the adapter for higher layer software. This interface frees the user from all MAC-level processing and isolates MAC processes from the user, protecting the integrity of the ring. The System Interface Chip (SIF) is a Direct Memory Access (DMA) controller for moving data between the host system memory to and from adapter memory.

The remaining sections of this paper describe the partitioning of the IEEE 802.5 functions in the TMS380 chipset. Section 2 describes the ring interface implementation which interfaces to the Physical Layer cabling system. Section 3 describes the Medium Access Control processes implemented in hardware and software. Finally, Section 4 describes those options which are provided to allow adapter station self-test procedures, bridges, and other products to be implemented.

SECTION 2 PHYSICAL LAYER

2.1)HARDWARE PARAMETERS

The physical layer controls the electrical connection to the medium, signal conditioning and clock regeneration. The physical layer functions are in hardware. However, different cabling considerations and network optimization are accomplished by allowing some function parameters to be controlled by variable "glue" components. Figure 2 illustrates the block diagram of the TMS380 Ring Interface.

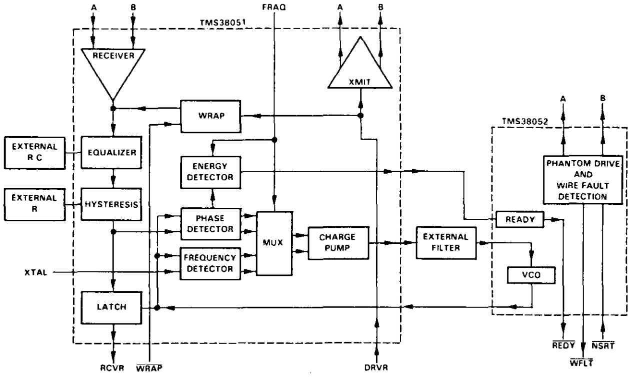

Figure 2
Ring Interface Functional Diagram

To maintain maximum flexibility during design, tradeoffs between hardware circuits on-chip and parameter setting by external glue components were considered. These parameters were varied during program development to allow optimization of system error budgets and verification of analytical models.

Referring to Figure 2, the ring interface functions are split into two separate chips to minimize electrical coupling between the Voltage Controlled Oscillator(VCO) and other clocking signals. The transmitter, receiver, and other blocks which contain data transitions are separated from the VCO to minimize clock jitter caused by crosstalk between the VCO and data.

An externally controlled adaptive EQUALIZER compensates for cable distortion and attenuation. Equalization is effective at low amplitude signals and transparent at high amplitude signals, thus matching the effects of increased frequency distortion with increased cable attenuation. This equalization can be externally modified to match the attenuation characteristics of the transmission medium by changing the external R/C circuit. This is particularly useful when changing from wire to fiber media.

A hysteresis resistor is externally connected to the HYSTERESIS block shown in Figure 2 to allow the ring interface circuit to set the noise threshold from 10mv to 30mv. IEEE 802.5 defines the minimum received signal must be no less than 50mv. Proper setting of the hysteresis resistor prevents noise from being interpreted as data. This external setting will depend on particular crosstalk characteristics of the cable and can be optimized for wire or fiber operation. Typically, a value of 10mv noise rejection threshold is recommended.

In the token ring, a single station, the monitor, provides the master clock which all other stations on the ring regenerate using a PLL. The PLL filter circuit and gain are also controlled by external components. The recommended bandwidth and damping factor of 100kHz and 25.7 respectively were determined for the IBM Token-Ring Network(3). These values determine the jitter build-up, and were set experimentally and proved analytically in order to take into account the entire system error rate budget.

2.1)RELIABILITY INDICATORS

A major feature of the TMS380 is the use of specific hardware fault indicators to monitor network availability at the physical layer. These indicators serve to isolate problems between the cabling wiring coupler and other stations on the ring. The major indicators are: wire fault, which verifies cable continuity to the trunk coupling unit; energy detection, which senses the loss of incoming signal; and frequency error which detects a difference between the regenerated Phase-Locked Loop (PLL) clock and the station's Crystal Clock.

Because cabling problems are one of the major sources of network problems, the TMS380 chipset incorporates a wire fault detection circuit to measure DC continuity of the cable to the Trunk Coupling Unit(TCU). The phantom drive current, as illustrated in Figure 3, provides for the relay switching and physical insertion into the ring.

In addition, each wire in the twisted pair, as shown by the paths (A) and (B) in Figure 3, carries a separate DC current. If the resistivity seen at the outputs PHOUTA or PHOUTB is less than 100 ohms(shorted cable) or if the resistivity is greater than 9900 ohms(open circuit), then a wire fault bit is set and indicated to the user.

An energy detection circuit is provided to monitor transitions on the received data

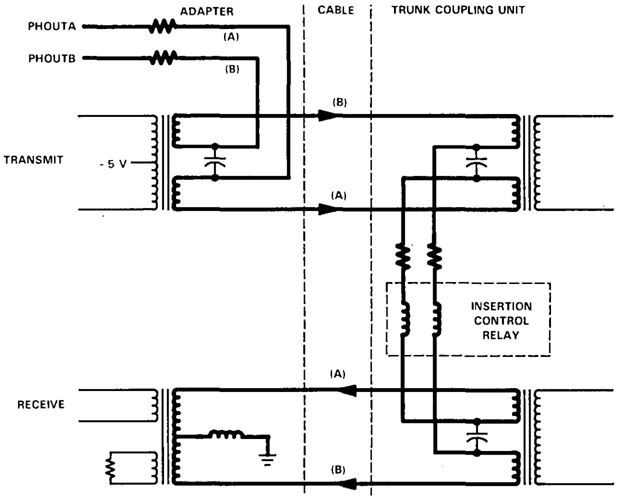

Figure 3
Phantom Drive Signal Path

signal. Under normal circumstances, the REDY- signal shown in Figure 2 is asserted and the PH deasserts FRAQ so that the VCO frequency is set by the received data transitions. If transitions are absent, then the PLL will drift off frequency, causing the PH to assert FRAQ, and the VCO frequency is synchronized to the station's own crystal oscillator clock(XTAL). Thus, in the event of loss of input signal transitions, the PLL is restored to the correct frequency range by rapid hardware intervention. In addition, a bit is set in the PH to inform the station software that a "signal loss" has occurred.

These hardware fault detectors at the Physical Layer provide indication of wiring integrity. A final key feature of the ring interface circuit is the wrap mode, which allows the capability to run diagnostics completely within a single station. In this mode the adapter is a single ring station with the full protocol set. This allows self-test diagnostics to be executed prior to insertion into the ring and can be combined with the external wrap mode (lobe test) to provide an excellent method for localizing problems at the station level.

SECTION 3 MAC LAYER

The implementation of the Medium Access Control (MAC) layer is separated between those processes which must be implemented in hardware, due to ease or speed requirements, and those which could be implemented in software. This separation is illustrated in Figure 4.

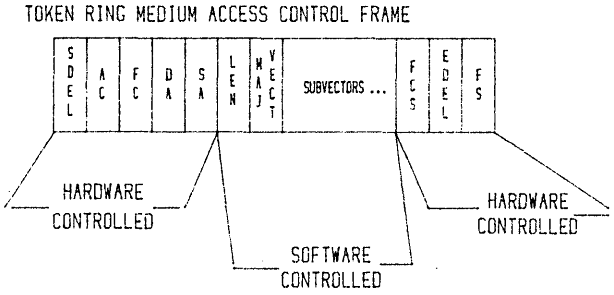

Figure 4
MAC Process Separation

While the hardware controls access to the medium, the software controls the contents of frames. Hardware is used to implement bit-level functions in order to achieve a minimum two bit delay for the repeat path through the PH. Token processing, priority control, address recognition and Frame Check Sequence(FCS) generation and checking are implemented in hardware. MAC frame processing and the MAC processes which require extensive decision tree evaluation are implemented in software. Throughout the design process, attention was paid to implementing with flexibility. Thus, hardware features and hardware operating modes can be selected by software.

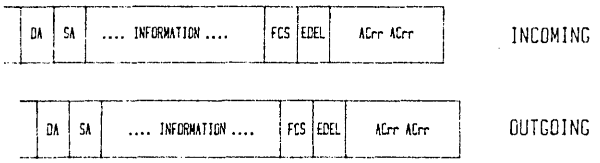
3.1) HARDWARE PROCESSES

Those processes requiring real-time bit manipulation are implemented in hardware in the PH chip. These include processes which capture and modify tokens, modify frame contents, and monitor data on the ring.

The first of these is address recognition. The address recognition feature was designed to be fast enough to recognize an address on a frame entering the station, and correctly set the Address Recognized Indicators (A) in that same frame. The PH must meet the shortest possible timing window. In the case of the A-bit setting, the shortest possible time is calculated by summing the bytes between the end of the Destination Address and the first A-bit in the Frame Status field as shown in Figure 5.

This time is equivalent to a minimum of 98 bits for a single byte information field, which is equivalent to 24.5 microseconds for a ring speed of 4 Mbps.

In addition, the PH is required to be capable of copying back-to-back frames addressed to it. The PH is capable of setting the A/C bits, recognizing a Starting Delimiter(SDEL) immediately following the FS field, and entering the address match process. At 4Mbps this is accomplished with an inter-frame spacing of eight bits. For the flexibility, the inter-frame gap size is determined by a software controlled register in the PH.



RECOGNIZE ADDRESS TIME EQUALS:

```
48 BITS - SA
 8 BITS - INFORMATION
32 BITS - FCS
 8 BITS - EDEL
 2 BITS - PH DELAY
-----------------------
98 BITS  ==>> 24.5 MICROSECONDS
```

Figure 5
Address Recognition Bit-Setting Time

For transmission, the hardware of the PH is responsible for token recognition and capture, and the digital transmission to the ring interface. The hardware synchronizes to the SDEL of a token, and then monitors the Access Control(AC) field to determine if the incoming data is a frame or a token. If it is a token, then the PH sets the token bit in the AC, inserts the user's data following the AC, and attaches the Ending Delimiter(EDEL) and Frame Status(FS) fields at the end of transmission. The PH must convert parallel data from the Adapter Bus into a serial bit stream for transmission. This process is performed entirely in hardware for speed reasons. It is, however, the responsibility of adapter software to initiate the transmission.

The transmit process of the IEEE 802.5 standard is also responsible for proper handling of priority on the ring(4). In the PH, the priority handling functions are implemented in the "fairness" process. If the priority level is increased by a station, that station must ensure that it eventually returns to the level from which it increased priority. To ensure that the "stacking" station receives a fair chance of transmitting at a given priority level, the hardware which performs the fairness process is separated from the transmit process hardware. The PH's fairness process logic is logically downstream from the transmit process hardware in the same node. If active, the fairness hardware modifies the token that was released by the transmit process to create a token of proper priority.

The IEEE 802.5 standard states that the active monitor station on the ring must periodically check for the presence of valid tokens or frames on the ring. The active monitor station uses this information to determine when a Ring Purge is necessary. To do this, a combination of hardware and software detection mechanisms are used. The PH recognizes a valid SDEL-AC sequence as "Any Token", and sets a bit readable by software. At the expiration of a 10ms timer, software checks that the bit has been set, and clears the bit. Software in the monitor station uses this feature to detect the absence of tokens, and initiate Ring Purge.

Stand-by monitors must monitor the ring for "good" tokens, every 2.6 seconds. A "good" token is defined as a priority zero token or a token of priority greater than zero followed by a frame of priority greater than zero. This process is performed in a manner similar to the "any" token check. The hardware sets a bit whenever it detects a good token, and the software checks for the bit and resets it at the expiration of a 2.6 second timer.

To implement protocol processing timers, two timers were placed in hardware. All protocol timers are based on these timers. The Return to Repeat timer indicates a lost frame to the transmit process in the PH. This timer guarantees ring integrity by automatically returning the PH to repeat mode after a frame has exceeded a certain length, independent of other hardware. The General Purpose Timer is the hardware basis for all other protocol timers. This timer is located in the Communications Processor and its duration is controlled by software through a register. A period of 10 milliseconds was chosen. This increment is small enough to handle all the timers specified by the IEEE 802.5 standard.

3.2) SOFTWARE PROCESSES

The remainder of the Medium Access Control (MAC) processes of the token ring are implemented in the TMS380 adapter software. These include neighbor notification, monitor contention, monitor functions, and MAC management support. These processes were implemented in software to keep them flexible and provide the ability to change parameters for different speed rings.

When the PH completes reception of a frame, adapter software is notified. If the received frame is a MAC frame (FC=0x), then control is passed to an adapter software task known as the "Ring Task".

The Ring Task parses the frame to first

determine if it is a ring station class MAC frame or if it is destined for the user system. If it is a ring station class frame, further parsing determines which MAC major vector has been received, and what parameters accompany the command. Depending on the value of the major vector and whether this station is the active monitor, appropriate software routines are initiated.

When the software needs to transmit a MAC frame, it queues that frame to the PH, just like any other data frame. MAC frame transmission may be caused by a timer expiration or may be in response to a received frame. To ensure that vital MAC frames are transmitted in a timely manner, the TMS380 software reserves one internal buffer for the transmission of certain MAC frames. Those MAC frames which are transmitted from this buffer are:

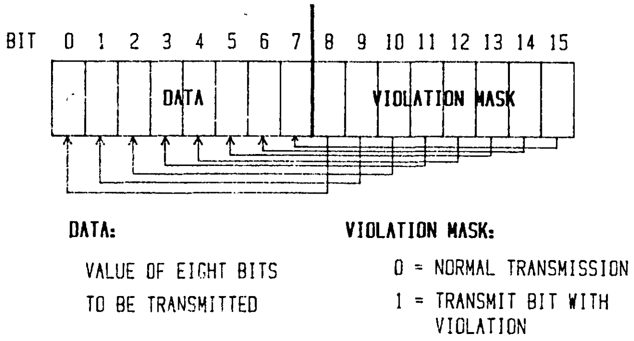
Report Error
Report Monitor Error
Report Neighbor Notification Incomplete
Report New Monitor
Active Monitor Present
Duplicate Address Test
Report SUA Change
Standby Monitor Present
Request Initialization
MAC frames which use a token are transmitted at priority 3, and are always queued ahead of user frames that are pending transmission.

SECTION 4 <u>FEATURES FOR FLEXIBILITY</u>

Though many of the Medium Access Control processes were built into hardware, the ability to override these was deemed necessary for both flexibility and for testing. In this light, various options were built into the TMS38020 Protocol Handler to allow control of hardware functions by software.

One option is that the FCS may be generated by PH hardware or transmitted directly from buffer RAM. This allows adapter software to retransmit an FCS which it received from the ring, instead of regenerating it. This feature could be used in a bridge adapter. The Transmit FCS mode is also very useful for testing the adapter. The PH's FCS detection mechanism can be tested by sending an invalid FCS with frame data. The Transmit FCS mode is selected by writing a bit in a control register so that the mode of operation can change dynamically from frame to frame.

Another option of the PH transmit process is termed "Baud Data Mode". In this mode, the PH transmitter interprets data in the adapter buffer RAM in the format shown in Figure 6.



BIT 0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15
DATA
VIOLATION MASK
DATA:
VALUE OF EIGHT BITS TO BE TRANSMITTED
VIOLATION MASK:
0 = NORMAL TRANSMISSION
1 = TRANSMIT BIT WITH VIOLATION

Figure 6
Baud Data Mode Format

This format allows the user to indicate, by bit, if the bit is to be sent as a valid Manchester encoded value or a violation pattern. In this way, software can simulate the starting and ending delimiters of a frame. Also, for testing the PH error recovery mechanisms, code can induce code violations in a transmitted frame.

To support transmit operations that do not wait for a free token, the transmit process of the PH will operate in the Transmit Immediate mode. This mode, set by software, causes the PH to transmit as soon as it is told the location of frame data in adapter memory. Monitor Contention, Beacon Process, and Ring Purge use this mode.

For debug, or for software priority control, the PH contains a Fire Token register. When this register is written to, the PH will release a token onto the ring, using the contents of this register as the AC field. This allows adapter software to release tokens at any given time onto the ring. This register is used in the diagnostic code to test adapter response to various types of tokens. It is also used in the monitor station to release a token following the Ring Purge process.

The Transmit Idle mode of the transmit process causes the PH to transmit a continuous stream of zero bits without regard to what is being received. This mode can be used for various testing modes. Transmit idles state is entered upon the detection of a BURST5 error in order to prevent downstream adapters from also detecting a BURST5 error, thus isolating the fault.

In order to maintain proper operation on the ring in case of data buffer congestion, the PH receive process provides a mode of operation known as "copy express buffer only". In this mode, the PH will only copy frames addressed to itself, if the value of the Physical Control Field (PCF) bits in the Frame Control field is greater than zero. MAC frames which are essential to ring operation are defined to have PCF bits greater than zero. The adapter reserves an internal buffer, known as the "express buffer", for use whenever it has no other buffers remaining. The IEEE 802.5 standard states that if the adapter is unable to copy a MAC frame destined for the station, it should take action based on the value of the PCF bits. In order to support this requirement , whenever the PH recognizes the address on a MAC frame with PCF bits greater than one, it issues an "attention" interrupt. With this interrupt, the value of the PCF bits is stored in a register, readable by adapter software.

The PH receive process also offers the option of copying all traffic on the ring, regardless of the destination address. The Address Recognized and Frame Copied bits on frames copied in this mode are not affected, unless the frame is addressed to the station. This feature offers the user the ability to observe all traffic on the ring. This can be useful for protocol analysis and debug, or for performance analyzers on the ring.

The PH provides the ability, with its "No-Strip" mode, to transmit frames onto the ring and immediately return to repeat mode. This capability can be used any time the adapter wants to place frames on the ring that it does not remove. For example, the TMS380 Bring-up diagnostics use this mode to test the operation of the PH fairness process.

SECTION 5 CONCLUSION

This paper has described the implementation decisions that were made in the design of the TMS380 token ring adapter. We have described the division between Physical and Medium Access Control functions. The TMS380 Ring Interface devices control most of the physical layer protocols, including insertion into the ring, transmission of valid signal, and reception of signal from the ring. The PH chip performs the remainder of the physical layer protocols, including jitter compensation and monitor clocking. The MAC layer is implemented in both the PH and in software executed by the CP. The PH handles token manipulation while the software controls the interpretation of received MAC frames and the transmission of new MAC frames.

Throughout the design process, careful attention was paid to providing flexibility in those features which were designed into hardware. In this manner, the ability to use different media types, or to fine tune MAC protocols, was maintained. All of these features for flexibility are used by today's chipset in self-test, and can be used in the laboratory environment for system test.

ABSTRACT

This paper provides an introductory overview of an emerging local area network (LAN) standard called the Fiber Distributed Data Interface (FDDI). The FDDI standard is being defined by the American National Standards Institute in its technical committee ANSC X3T9.5. FDDI is a 100 Megabits/sec optical fiber based token ring and uses a dual-ring topology for improved fault-tolerance. Some environments where FDDI may be applicable are described along with the FDDI features that make it suitable for these environments.

INTRODUCTION

The Fiber Distributed Data Interface (FDDI) is an emerging LAN standard which provides a high performance LAN solution for high-end applications such as interconnecting mainframes and their peripherals, and CAD/CAM applications.

The FDDI standard is being defined by the American National Standards Committee, ANSC X3T9.5, which is responsible for high-speed local area networks. The ANSC technical committee is a part of the American National Standards Institute (ANSI) which is the standards organization that represents the U.S. in the International Standards Organization (ISO). FDDI is a fiber-optic token-ring network which operates at a 100 megabits/sec data rate. The FDDI protocol has used the IEEE 802.5 token-ring protocol as a starting point and has made several enhancements to enable a cost-effective high-speed implementation.

There is a close working relationship between IEEE and ANSC to prevent overlaps in their activities. IEEE is defining standards at data rates below 50Mbps while ANSC is looking at speeds above 50 Mbps.

The initial FDDI specifications are better suited for data traffic as opposed to voice, and are referred to as the FDDI-1 standard. Aspects of FDDI-1 which affect hardware implementation are already frozen as a draft standard. As an enhancement to FDDI-1, the committee has begun work on a new definition called FDDI-2, which provides a better interface for both data and voice traffic.

The FDDI-1 specification consists of four documents specifying the data link layer and physical layer of the seven-layer Open Systems Interconnect model (see fig. 1). The Physical Media Dependent (PMD) document deals with the fiber optic cable, connectors and jitter specifications at the electro-optic interface. The Physical Layer (PHY) document specifies the clock recovery and encoding mechanisms. The Media Access Control (MAC) document specifies the token-passing protocol and the Station Management (SMT) document deals with network management issues.

Figure 1: Scope of FDDI Specifications

Why Optical Fiber

FDDI decided to use optical fiber as a transmission medium for a variety of reasons, including:

a. Bandwidth: Fiber cable provides a very high capacity for carrying information. The data rate can be in the range of several hundred megabits per second.

b. Attenuation: Fiber provides low attenuation, resulting in efficient communication over several kilometers without repeaters.

c. Noise Immunity: Fiber cables transmit information as light and neither generate nor are affected by electromagnetic interference.

d. Security: Since it is not easy to tap an optical fiber cable without interrupting communication, fiber is more secure then copper cable from malicious interception.

e. Cost: The cost of optical fiber cable has fallen considerably over the last two years and fiber is projected to become cheaper than co-axial cable in a year or so. Since fiber is lightweight and thinner, it is often easier to pull through overcrowded ducts, resulting in lower installation costs. In fact, the additional cost of putting a second fiber in the same cable is negligible; hence, FDDI has opted for a duplex fiber cable and provided a high-level of fault-tolerance through this added redundancy.

In the past, the cost of the laser diodes or avalanche photo diodes to interface with the fiber has been high. However, technological advances have provided low-cost LEDs and pin-diodes that can operate at the 100Mbps rate specified by FDDI.

The physical ring topology is ideally suited for use with fiber because it provides a point-to-point connection between nodes and therefore does not require taps which are harder to build with fiber.

MAJOR ENVIRONMENTS

FDDI is targeted towards four major environments: office floor, computer room, factory floor, and campus interconnections. Fig. 2 illustrates how a variety of applications could co-exist in a typical company environment.

Office Floor

A typical office environment consists of word processors, desk-top personal computers, facsimile machines, terminals, and printers. Most of these are low-cost, medium performance devices which feature direct user interfaces and require relatively slow networks for interconnection.

In addition to these applications, offices in the engineering environment will have Engineering Workstations, Computer Aided Design (CAD) equipment, graphics or imaging machines, and multi-user micro or mini-computers. The need to handle computation-intensive operations or moving large blocks of data, sets this equipment apart from PC-type devices. The performance of the network is crucial when hundreds of millions of bytes of graphics data are being moved, and as such these devices have acceptable, but higher network interface costs than terminals or PCs. Some applications will benefit from the higher data rate offered by FDDI.

Computer Room

The computer room can be visualized as a collection of very high performance mainframes or mini-computers connected over a backend network to peripheral controllers, communications controllers, file servers, and data-base machines. The peripheral controllers in turn can attach to individual disk drives or tape drives. In addition, there may be high speed laser printers on the backend network.

Usually the backend networks in a computer room do not cover a large span, but they must operate at a very high data rate and be extremely reliable and fault tolerant. In the past, proprietary networks have been used for computer room connections. Also, parallel interconnect schemes such as the Intelligent Peripheral Interface (IPI) have been used since the distance limitations are not a concern. Now FDDI is emerging as an alternative backend network offering increased performance.

Factory Floor

Networking is an essential element of the automated factory. A factory floor will typically include many kinds of controllers (for numerical, robotic and process control) as well as data acquisition and display devices and imaging and computing equipment.

Deterministic or time-bounded access to the network is a key requirement of a factory network. Process control applications, such as nuclear reactors, need periodic updating of control information within a guaranteed access time.

The first-generation factory network will be the IEEE 802.4 token-bus network, which forms a subset of the large Manufacturing Automation Protocol (MAP) being defined by several companies in the U.S. MAP networks will use a combination of baseband and broadband transmission on the cable.

FDDI would be useful in the factory environment when either higher-speed or greater noise immunity is needed.

Campus LANs

The backbone LAN can connect the different networks in various buildings on a campus spanning several miles.

The connections to the backbone network can be gateways which provide the necessary protocol conversion and buffering between two LAN's. A backbone network, however, does not have to merely connect smaller networks. It could very well have a direct interface to the mainframe computers in each building. Also, it is desirable to interconnect distributed PBXs carrying both voice and data using the same backbone. If the transmission of real-time voice is needed then the network has to be able to provide

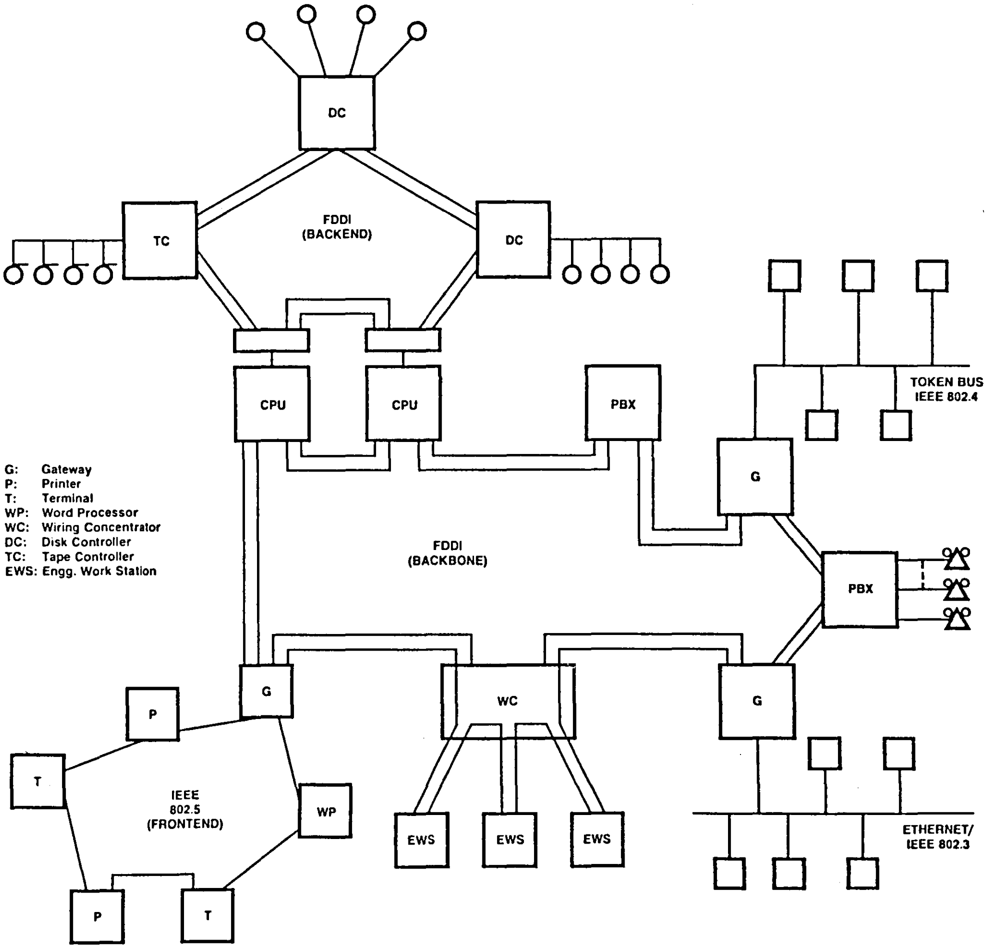

Fig. 2: A View of a Company-Wide Network

some circuit-switched capability in addition to packet-switching. Once this is possible, transmission of real-time video also is easy to provide.

Since a campus network is a backbone network, it should have a high data rate and operate over extended distances.

FDDI TOPOLOGY AND PROTOCOL

FDDI provides a considerable amount of flexibility in configuring its topology and also provides a protocol suitable for a variety of applications.

Configuration Limits

The FDDI specification places no lower limits on the number of stations and the distance between the stations. There are also no absolute upper limits. For example, for the sake of calculation of default timer values, and to keep the ring latency down to a few milliseconds, a system is assumed to include up to 1000 stations on the ring, with up to two kilometers between adjacent stations and up to 200 kilometers of total fiber cable. However, these parameters can be mutually adjusted to produce the optimum configuration for the chosen application, (for instance more stations can be allowed over shorter distances).

A Dual-Ring Approach

The FDDI ring is a combination of two independent counter-rotating rings, each running at a 100 Mbps data rate. If both rings operate simultaneously, the effective transmission rate is 200 Mbps. It is also possible to have configurations in which one ring connects all the stations, with the second counter-rotating ring connecting only a few select stations.

Figure 3 shows a possible FDDI configuration with optical fiber cables interconnecting to form the rings; the paths through which the data circulates around the ring are also depicted. The ring which reaches all the stations is termed "primary". The secondary ring carries data in the opposite direction, which is useful during ring reconfiguration. The advantage of two rings is that if one ring fails, the network can reconfigure using the other ring and still keep operating.

Class A and Class B Stations

The stations which connect to the FDDI rings are divided into two categories: Class A and Class B. A Class A station is one which connects to both rings simultaneously, and a Class B station is

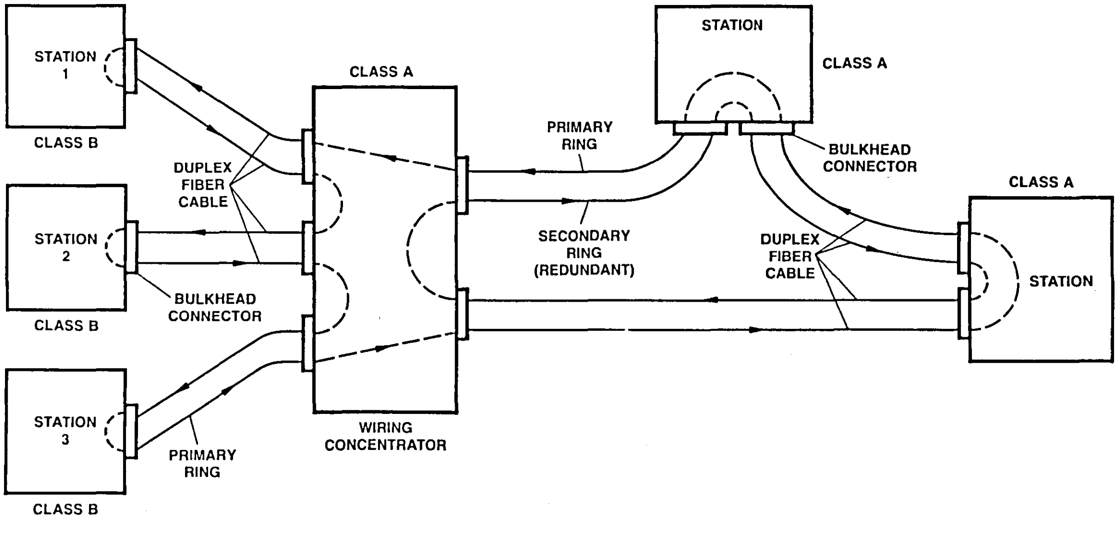

Fig. 3: FDDI Dual Ring

one which connects to only one of the rings.

The two classes help tailor the complexity of systems to meet cost objectives. Since Class B stations need to connect to only one ring, they can be implemented at lower cost. The disadvantage is that the Class B station is isolated if its connection to the wiring concentrator fails. Class A stations, on the other hand, require additional hardware to connect to dual rings, but are protected against failure. If there is a link failure they can keep operating in a reconfigured ring.

Typically those stations that need more fault tolerance will be configured as Class A. Less critical stations can be Class B. Another kind of Class A interconnect is a wiring concentrator (WC).

Wiring Concentrator

A wiring concentrator, as the name implies, is a hub node through which several other stations can be connected. A WC allows a physical ring to be easily maintained like star networks. The WC can be a service point, and several WCs can be established at various distributed locations from which shorter connections can be taken out to individual stations. A WC is always a Class A station and other Class A and B stations can connect to it.

The way the fiber cable is packaged makes the concept of WCs very attractive. The fiber cable in FDDI contains two physical fibers packaged in one jacket with a bulkhead connector on either end. The same cable is used for all class A and class B connections. For example, for the dual ring connecting the Class A stations each jacketed cable would contain one fiber for the primary and one for the secondary; for the the Class B stations the identical cable would carry the incoming and outgoing signals on the same ring for a station. Hence, when a Class B station has to be connected to a WC, only one physical cable has to be routed between the station and the WC. Because it carries two fibers, a ring path is physically established.

Fault Tolerance In FDDI

Several levels of fault tolerance are possible in FDDI. Some types of cable faults may cause the ring to reconfigure. Loss of power on certain stations may switch an optical relay in place.

Ring Configuration

Some of the faults in a network are caused by either failed components or broken cables. Even if a connection is not fully broken, there may be a substantial degradation which shows up as an increase in the bit-error rate. Figure 4 shows how

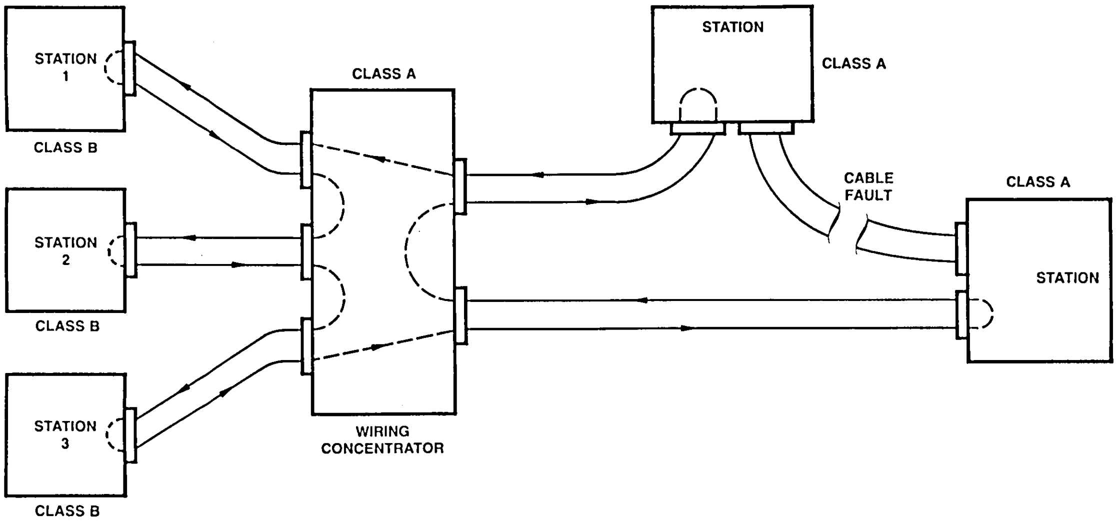

Fig. 4: Ring Reconfiguration

a ring would reconfigure its data paths if a link (or a pair of links in a cable) in the dual ring becomes inoperative. The stations would sense the breakage and use the appropriate paths on the secondary ring to keep the network running. In FDDI this reconfiguration happens automatically, within a few milliseconds. A station management interface is being defined in FDDI to facilitate this. When a broken ring is restored, the station management handshake will allow the ring to go back to its original state.

The effect of a second failure in the dual ring is interesting too. Figure 5 shows how a network can split into two smaller independent networks with both remaining operative internally.

If there is a cable fault in the cable going to a Class B station, this station is cut off from the network, and the WC can provide a bypass for the node.

Optical Bypass

Situations in which stations connected to the ring lose electrical power or are turned off can be taken care of by providing optical bypasses. A bypass provides a path for the light to bypass a station, using an electrically operated relay, such that when power is lost in the station a mirror directs the light through an alternative path.

A bypass can be provided in either Class A or Class B stations. Most Class A stations that include WCs will probably implement bypasses to get this additional level of fault tolerance. A Class A station without an optical bypass will appear as if all of its connections to adjacent stations are broken when powered off. Optical bypasses (or even electrical bypasses) may be used in WCs at their interface to Class B stations to take care of situations where the Class B stations may fail.

Encoding Scheme

Several of the low-speed standards, including the IEEE standards, use Manchester encoding for baseband transmissions. Unfortunately, Manchester encoding is only 50% efficient, and its use in FDDI's 100 Mbps data rate would have required 200 megabauds on the medium, with the LEDs and PIN receivers operating at 200 MHz.

FDDI uses a more efficient encoding scheme, called 4B/5B, to keep the baud rate down. In 4B/5B, the encoding is done on four bits at a time to create a five cell "symbol" on the medium. The

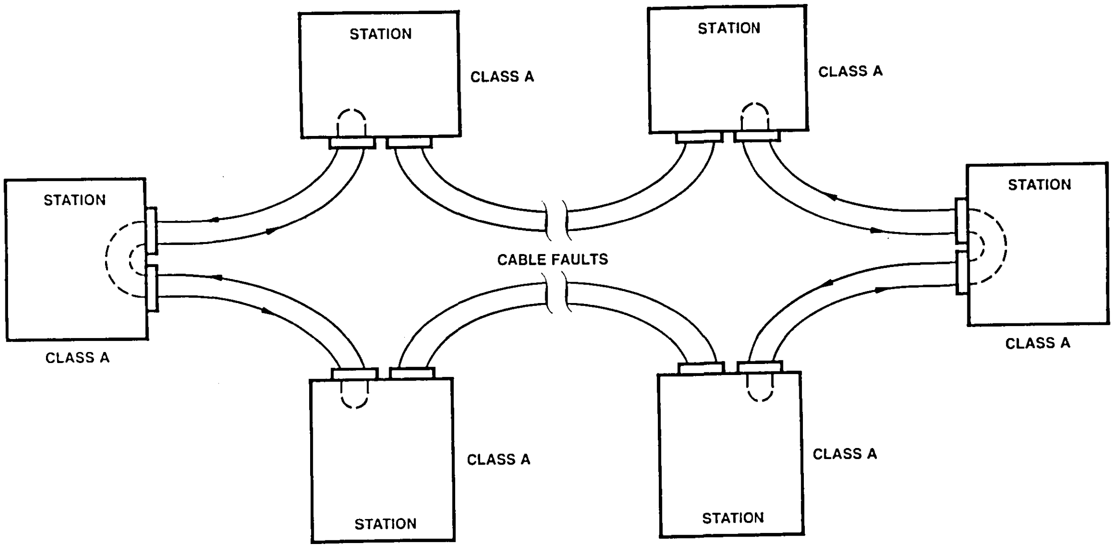

Fig. 5: A Ring with Two Cable Faults

efficiency is 80%, and at 100 Mbps the baud rate becomes 125 megabauds. The advantage is that inexpensive LEDs and PIN diode receivers, which only have to operate at 125 MHz, can be used.

TOKEN-PASSING RING

FDDI uses a token-passing ring consisting of stations serially connected by a transmission medium to form a closed loop. The packets are transmitted sequentially from one station to the next, where they are retimed and regenerated before they are passed on to the following (or "downstream") station. The idle stations can either be bypassed or function as active repeaters. The addressed station copies the packet as it passes by. Finally, the station that transmitted the packet strips the packet off the ring.

A station gains the right to transmit when it has the token, which is a special packet that circulates on the ring behind the last transmitted packet. A station wanting to transmit captures the token, puts its packet(s) on the ring, and then issues a new token, which the next station can capture for its transmission.

Access Scheme

Using an access scheme called timed-token access, FDDI allows each station a fair share of access to the network, and at the same time maintains an upper bound on the token rotation time. The token rotation time determines how often the stations get an opportunity to transmit.

In order to satisfy the requirements of various applications a station needs to know two things. One is the maximum latency before the token returns again to the given station. The other is the amount of traffic that the station can send once the token returns. The FDDI protocol allows the station to determine both these parameters through negotiation. The FDDI MAC document contains the necessary services for implementing these features. The SMT document, presently in definition, intends to formalize the precise protocol.

The total bandwidth available on the ring can be dynamically partitioned off as either synchronous or asynchronous bandwidth. Here synchronous refers to bandwidth that is guaranteed to a station for its use, every time it gets the token. The leftover bandwidth is the asynchronous bandwidth and is shared by all the stations.

Two kinds of packets can be transmitted on FDDI. Synchronous packets can be sent by the stations that have negotiated the synchronous bandwidth, every time the token is received. However, asynchronous packets can be sent only if the token is received early (i.e., within the upper bound agreed to). The asynchronous packets can be of one of eight priorities. Which priority to send is determined by a threshold time value.

FDDI also supports a special token class called restricted tokens. This is provided mainly for backend networks which have devices that need to control the network for data streaming.

BENEFITS TO VARIOUS APPLICATIONS

As shown in Figure 1, FDDI can be used as a backend, backbone, and frontend network. Different features of FDDI make it attractive for each environment.

Backend Network: For a backend network in a computer room, reliability and performance are particularly important considerations. In this environment, it is desirable for two stations to maintain unimpared operation, even if up to six intervening stations are powered-down (causing their optical bypass relays to be in the active connection path between the communication stations). FDDI is projected to meet this constraint when the total fiber length between communication stations is less than 300 meters.

The dual-ring, by reconfiguring, provides additional fault-tolerance. In a backend network most stations will be Class A nodes talking to both rings. If the 100 Mbps data rate is not sufficient in this application, an additional 100 Mbps is also available on the secondary ring as long as the ring is not reconfigured.

FDDI also supports a class of service called restricted token. This sets up a master/slave connection between the host computer and a peripheral controller, allowing the two to hog the network and stream data between them. Although the restricted token violates the deterministic access of a token ring, it is acceptable in a backend environment.

Backbone Network: A backbone network stretching over a campus may span several kilometers. The backbone can be viewed as a collection of trunk lines connecting several computer rooms or individual networks in the office environment or distributed PBXs. A high bandwidth on the backbone ensures that it is not a bottleneck during internetworking. FDDI is designed to allow links at least two kilometers in length between adjacent stations with no optical bypasses on either end. The total allowable fiber path length to satisfy the default timer values and ring latency constraints is 200 kilometers. Since duplex cable is used, the actual length of cable in the entire ring is 100 kilometers. The 100 Mbps data rate provides ample bandwidth for this application.

Another concern during internetworking is station addressing. Since FDDI permits both 16-bit and 48-bit addresses with physical and logical addressing support for both, as well as broadcast capability, the addressing translation across gateways and bridges is simplified.

For supporting distributed PBXs, a circuit-switched or time-slotted access method is desirable. The ANSC X3T9.5 committee is starting preliminary work on the FDDI-2 Specification which will implement a combination of circuit-and packet-switched traffic. This will make it easy to provide a gateway to the telephone network or ISDN.

Frontend Network: In the office floor situation, FDDI is suitable as a frontend network. The cost of connection can be minimized by having a preponderance of Class B stations. These Class B stations can be attached to wiring concentrators, which in turn will provide Class A connections to the backbone FDDI network.

Wiring concentrators in FDDI are required to be powered and as a result can be made intelligent enough so that optical bypassing will not be needed for Class B stations. Class B connections lower the cost of the connection since the duplicate physical layer logic is not needed. At the same time, they still form a part of the main ring and can transfer data at the 100 Mbps data rate.

FDDI provides for a separation of up to 500 meters between a Class B station and a wiring concentrator. When any of the Class B stations is powered down or its link is broken, the wiring concentrator can electrically bypass it very easily. The wiring concentrator also provides a convenient maintenance point.

FDDI VS IEEE 802.5 - A COMPARISON

The FDDI specification is an outgrowth of the 802.5 token-ring standard and includes the changes necessary to permit a cost-effective implementation at higher data rates. In addition it also includes new features not present in 802.5, that are necessary at the higher speeds.

Figure 6 shows the differences between the two standards. The point-to-point clocking in FDDI avoids the compounding of jitter from node to node and allows larger ring implementations. Also the 4B/5B encoding is more efficient and allows the use of 125 MHz LEDs at the 100 Mbs data rate. The restricted token feature in FDDI allows backend network nodes to "hog" the network for doing streaming operations.

The FDDI attempts to simplify hardware implementation in two ways. By allowing a half-duplex implementation only one set of FIFO buffers and CRC logic is needed. Also the protocol requires manipulation only at the byte boundaries instead of bit-boundaries, which makes it possible to put the logic in CMOS technology instead of ECL.

SUMMARY

The FDDI committee has made reasonable trade-offs to ensure that the technology needed for implementing FDDI is presently available, and that the standard will not be obsolete in the next several years. The standard has kept in mind the upgradability to higher speeds and additional services that will be necessary in the future.

The emergence of FDDI as a popular standard is spurring integrated circuits development from semiconductor vendors. The use of dedicated VLSI to support FDDI will dramatically lower the cost of an FDDI interface.

Advanced Micro Devices has a chip-set called Supernet in development which will provide the hardware required for implementing FDDI. Supernet consists of four chips: the Ram Buffer Controller (RBC), the Data Path Controller (DPC), the Fiber Optic Ring Media Access Controller (FORMAC) and the Encoder/Decoder (ENDEC). The RBC and DPC chips perform the buffer management functions, the FORMAC implements the token passing protocol and the ENDEC does the encoding, decoding and clock recovery.

#	FEATURE	IEEE 802.5	FDDI
1.	Data Rate	4 Mbs or 16 Mbs	100 Mbs
2.	Medium	Twisted Pair, Fiber	Fiber
3.	Configuration	Single Ring	Dual Ring
4.	Management	Centralized: Requires ring monitor	Distributed: No ring monitor needed
5.	Clocking	Synchronous: Transmit clock is derived from recovered clock.	Point-to-Point: each node transmits using its own crystal.
6.	Encoding	Differential Manchester: 50% efficient.	4B/5B Group Code: 80% efficient.
7.	Addressing	48 bit individual and group	16 or 48 bit individual and group.
8.	Access Protocol	Token Passing	Timed-Token Access: Stations can negotiate token rotation time.
9.	Miscellaneous	-	- Synchronous & asynchronous packets. - Restricted token for DASD devices.
10.	Implementation	Requires full-duplex hardware	Half-duplex hardware adequate.

PHASED STATE SPACE SEARCH

T.A. MARSLAND and N. SRIMANI

Computing Science Department, University of Alberta, Edmonton, Canada T6G 2H1.

ABSTRACT

PS*, a new sequential tree searching algorithm based on the State Space Search (SSS*), is presented. PS*(k) divides each MAX node of a game tree into k partitions, which are then searched in sequence. By this means two major disadvantages of SSS*, storage demand and maintenance overhead, are significantly reduced, and yet the corresponding increase in nodes visited is not so great even in the random tree case. The performance and requirements of PS* are compared on both theoretical and experimental grounds to the well known $\alpha\beta$ and SSS* algorithms. The basis of the comparison is the storage needs and the average count of the bottom positions visited.

INTRODUCTION

Phased search is a new variation on a method for traversing minimax game trees. Although based on SSS*[9], phased search has a range of performance which represents a continuum of algorithms from SSS* to $\alpha\beta$[2]. The $\alpha\beta$ algorithm was the first minimax search method to incorporate pruning into game-playing programs, and modified versions of it still predominate, even though more efficient pruning methods exist. For example, SSS* never visits more terminal nodes than $\alpha\beta$, achieving better pruning at the expense of a larger storage requirement. Here better pruning implies fewer terminal node (bottom position) visits, although other measures of performance, such as execution time and storage needs, may be more important. Even so, the number of bottom positions (NBP) visited is particularly relevant, because in any game-playing program the evaluation function spends significant time in assessing these nodes. For this reason, SSS* has the potential to reduce the search time significantly by the virtue of its better pruning. However, for uniform trees with a constant width of w branches and a fixed depth of d ply, SSS* must maintain an ordered list (called OPEN) of $O(w^{d/2})$ entries. Because of this abnormally high memory demand and the considerable time spent in maintaining the OPEN list, SSS* is not widely used, despite its known pruning dominance over $\alpha\beta$.

In its general form, the phased search algorithm, denoted here by PS*, has lower storage requirements than SSS*, but at the same time consistently outperforms $\alpha\beta$ for trees of practical importance[8]. The Phased Search algorithm with k phases, PS*(k), partitions the set of all immediate successors of MAX nodes into k groups (each of maximum size $\lceil w/k \rceil$) and limits its search to one partition per phase. It does not generate all the solution trees simultaneously as does SSS*, generating instead only a subset of them. The algorithm searches the partitions from left to right one at a time. Like SSS*, the search strategy within each phase of PS* is non-directional, but with a recursively sequential partitioning of the MAX nodes. Note that the storage requirement of PS*(k) is $O((\frac{w}{k})^{d/2})$, because PS*(k) searches only w/k successors at alternate levels of the game tree (i.e., at the MAX nodes).

GAME TREES

To provide a formal footing the following definitions are introduced. In a *uniform tree*, T(w,d), every interior node has exactly w immediate successors and all terminal nodes are at the same distance d from the root. The term *random tree* will be applied to those uniform trees whose terminal nodes are assigned *random* values from a uniform distribution. Such trees are commonly used for simulation as well as asymptotic studies of search algorithm performance, because they are regular in structure and are simple to analyze. In *ordered trees* the best branch at any node is one of the first w/R successors. Such a tree is said to be of order R. The higher the value of R the stronger the order. For random trees R = 1, while R = w corresponds to a *minimal tree*, that is, a tree in which the first successor is everywhere best. More useful are ***probabilistically ordered trees*** with parameter (p,R). Here it is only with probability p that the best subtree is among the first w/R successors. These definitions are useful since game tree searching algorithms have been compared on a basis of their effectiveness on random uniform trees[5,7] and on probabilistically ordered trees[3,6].

After generating the list of moves (a set of successor positions), most game playing programs use some knowledge of desirable features to sort the moves in order of merit. Often, the knowledge is quite accurate so the best successor will be found among the first few considered. Thus real game trees are not random, but have been approximated by ***strongly ordered trees***[3]. These in turn are similar to probabilistically ordered trees with p=0.7 and R=w. The experimental results reported here have been obtained from searches of both ordered and random trees, so that the effectiveness of search algorithms can be observed under different conditions. More detailed results are to be found in Srimani's thesis[8].

PHASED SEARCH (PS*) ALGORITHM

Let PS* with k partitions be denoted by PS*(k). For simplicity, it is assumed that the partitions are of equal size. That is, the width w of the uniform search tree is a multiple of the number of partitions. This is not a restriction, since PS*(k) generalizes easily to encompass arbitrary partition sizes.

Let P(n) be the Dewey-decimal identifier of the parent of a node n, let PSIZE be the size of each partition and let V(n) be the static evaluation at a terminal node, n. We will show that PS*(1) has identical performance to SSS*, and PS*(w) is equivalent to $\alpha\beta$. PS* is based on SSS*, but maintains two lists: one is like the OPEN list in SSS*, and the other is a BACKUP list to keep track of partially expanded MAX nodes. OPEN consists of triples (n,s,hi), where *n* is the node identifier, *s* is the status (an element in the set {LIVE, SOLVED}), and *hi* is a bound on the merit of that state (a real number in $[-oo,+oo]$). As in SSS*, the OPEN list is maintained as an ordered list of triples with non-increasing value of hi. The BACKUP list consists of vectors of the form (n,last,low,high), where *n* is the identifier of a MAX node, *last* is the node identifier of the last

CH2345-7/86/0000/0514$01.00 © 1986 IEEE

son of n included in OPEN, and *low* and *high* are the current lower and upper bounds on the value of node n. Whenever a MAX node in the OPEN list is solved or pruned, the corresponding vector is deleted from BACKUP.

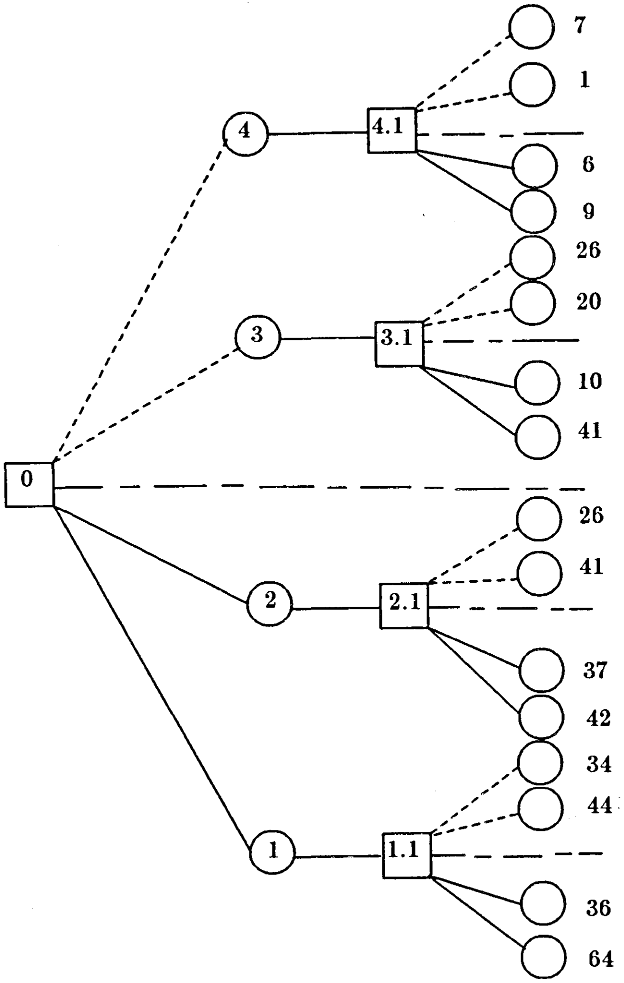

Figure 1: How PS*(2) Partitions a Tree.

The operation of phased search is seen most easily by an example. Figure 1 shows the search of a tree T(4,3) by PS*(2). Note that the successors of MAX nodes are divided into two partitions of equal size, as shown by broken lines in Figure 1. This partitioning is done recursively at each MAX node in the tree, so that the successors of a MAX node in two different partitions are never added to the OPEN list in the same phase of the PS* algorithm. Note also that, as with SSS*, at every MIN node only one successor at a time is included in the search tree. Thus for the example in Figure 1, at any instant no more than four terminal nodes are present in the OPEN list for PS*(2), while in contrast SSS* would have sixteen nodes present in OPEN simultaneously at some points in the search. Finally, note that PS*(2) will always work well if the best successor occurs in the first half of the subtrees at nodes which must be fully expanded (i.e., to use Knuth and Moore's terminology[2], at the type 1 and type 3 nodes).

Description of the Algorithm

Following the lines of Stockman's SSS* algorithm, and using his *GAMMA* operator terminology[9], PS*(k) is formed as follows:

(1) For simplicity, assume that w is a multiple of k and set PSIZE = w/k.

(2) Place the initial state (n=root, s=LIVE, hi=+oo) on the OPEN list.

(3) Repeatedly retrieve the next state (n,s,hi) from OPEN (this node has the currently highest merit, hi) and invoke the *GAMMA* operator, described in Table 1, until the termination condition is reached.

In Table 1, case 1 corresponds to the retrieval of a LIVE interior MAX or MIN node. If a MAX node is found the first partition is added to OPEN, otherwise (for a MIN node) only the first successor is taken. In the case of a MAX node, an entry is also added to the BACKUP list. For a LIVE terminal node, *GAMMA* either inserts n into OPEN with SOLVED status, or inserts the parent of n, P(n), into OPEN with SOLVED status. The choice is made in alternatives 2a & 2b and depends on how V(n), the evaluation of node n, compares to the low bound. For a SOLVED MAX node, n, *GAMMA* purges the successors of P(n) from the BACKUP list, and either adds the next successor of P(n) onto OPEN or prunes by pushing the solved parent node onto the OPEN list, cases 3b & 3c respectively. Similarly for SOLVED MIN nodes, *GAMMA* either adds another partition to OPEN or purges the pruned successor partitions. Here case 4(b) is especially complex, since it must deal with the situation when the parent MAX node has another partition to process. More than any other, it is the actions in case 4 which distinguish PS* from SSS*.

Correctness of PS*

To make it clear that the PS* algorithm always returns the minimax value, the following theorem is provided.

Theorem.
PS*(k), with its state operator *GAMMA*, computes the minimax value of the root for all trees.

Proof: It is necessary to show that

(1) PS* always terminates, and

(2) PS* does not terminate with an inferior solution.

The aim of a game tree search is to find the best solution tree. Each solution tree is a unique subtree of the game tree and is made up of all successors of each MIN node, but only one successor of each MAX node it contains. The minimax value of a game tree is the value of the best solution tree. Hence following the notation of Stockman[9], g(root) $\geq f(T_{root})$, where $f(T_{root})$ is the value of a solution tree and g(root) is the minimax value. Also, if $T0_{root}$ is the best solution tree then g(root) = $f(T0_{root})$. It follows that the algorithm always terminates after a finite number of steps, since there are only a finite number of solution trees, and any subtree once solved or discarded is not searched again.

PS* manipulates its search among different solution trees, in order to find the best one as easily as possible. Within a solution tree it carries out a minimax search, and uses the upper bound stored in the BACKUP list to help prune the search of redundant subtrees. For any solution tree, T_{root}, $f(T_{root})$ also represents the minimax value returned by PS*, provided PS* has searched that solution tree completely. All that remains is to show that PS* finds the best solution tree $T0_{root}$. By contradiction, suppose that, for some k $\geq$ 1, PS*(k) terminates with a solution tree $T1$ which is inferior to $T0$, that is, $f(T1_{root})$ $< f(T0_{root})$. This cannot happen if $T0$ and $T1$ occur in the same partition, since PS* will select the best for the same reason that SSS* does. If $T0$ is in a previous partition, then $T0$ would be SOLVED before $T1$ is encountered, and there would be a triple (n,s,hl_0) for the solution tree $T0$ such that, $hl_0 = f(T0_{root}) \geq$

$f(T1_{root})$. The value hl_0 is held as a lower bound in the BACKUP list, and so prevents $T1$ from being fully expanded and selected. Otherwise, if $T1$ is SOLVED and $T0$ occurs in one of the later partitions, the corresponding state (n,s,hl_0) would appear at the front of OPEN before the root node can be declared SOLVED. When $T0$ appears, the corresponding solution tree would be evaluated fully and found to be better than $T1$. since as the best solution tree, $T0$, cannot be pruned.

From the theorem it follows naturally that if the number of phases in PS* is k, then

for k=1, PS*(k) is equivalent to SSS* and
for k=w, PS*(k) is equivalent to $\alpha\beta$,

as far as nodes visited is concerned, since PS*(w) reduces to a depth-first left to right (directional) search. Also, for k > 1, the space requirement for OPEN is less than the $w^{d/2}$ needed for SSS*, since

the maximum size of OPEN for PS* with k partitions is at most $(\frac{w}{k})^{d/2}$ entries.

Finally the BACKUP list, for partially expanded MAX nodes, requires

$\sum_{j=0}^{\lfloor \frac{d-1}{2} \rfloor} (\frac{w}{k})^j$ entries, which is about $(\frac{w}{k})^{\lfloor \frac{d-1}{2} \rfloor}$ entries.

Thus for PS*(k) the size of BACKUP is about k/w of the size of OPEN, and the two lists together occupy significantly less space than the single OPEN list used by SSS*. Consequently, if S(A) denotes the space needed by an algorithm A, then S(PS*(k)) ≤ S(SSS*) for any k > 1 and for any depth and width of the search tree.

Comparison with other Methods

Let R be the order of the tree being searched, and let PS*(k) denote the Phased Search algorithm with k phases. Using the notation of Roizen and Pearl[7], let I(A) represent the number of bottom positions visited by algorithm A.

(1) For minimal trees (optimally ordered game trees), I(SSS*) = I(PS*(k)) = I($\alpha\beta$), because all algorithms traverse the best branch first and so achieve maximal cut-offs.

(2) For ordered trees, when p = 1 and R ≥ k, I(PS*(k)) ≤ I(SSS*) ≤ I(AB), since the best solution is always among the first w/R branches at every node in the solution tree. Although there may not be many cases where strict inequality holds, PS*(k) is at least as good as SSS* as long as R ≥ k, because the best solution is always found in the first partition. Figure 2 provides an example where I(PS*(2)) < I(SSS*), for a tree of depth 5 and width 4. Only that part of the tree which is enough to demonstrate the point has been presented. Assume that node 2.1 is solved with value 64, so the value of node 2.2 has an upper bound of 64. Consequently, 2.2.1.1.1 and 2.2.1.1.2 are solved with values 18 and 21 respectively. Then 2.2.2.1, 2.2.2.2, 2.2.2.3 and 2.2.2.4 are included in OPEN and solved with values ≥ 64, hence node 2.2.2 is solved. Note that nodes crossed in Figure 2 are visited by SSS* but not by PS*(2).

Push (i,SOLVED,low(i)) onto the front of OPEN.</td></tr>
</table>

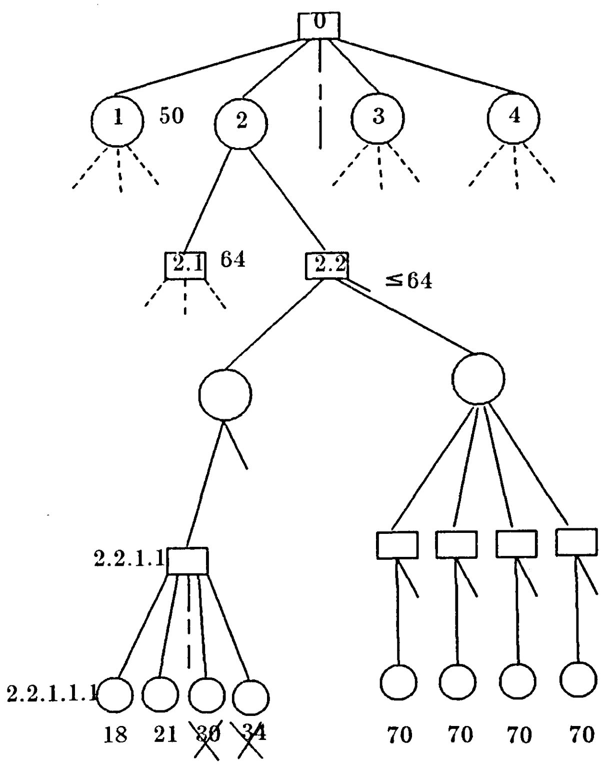

Figure 2: Tree T(4,5) in which PS*(2) is better than SSS*.

(3) For ordered trees, if p = 1 and R < k, I(PS*) can be greater than I(SSS*). Similarly, if the tree is random, then PS*(k) will occasionally evaluate some extra nodes. However, our experimental results show that even when R < k, in most of the cases (including random trees) PS*(k) is still better than the $\alpha\beta$ algorithm[8].

(4) There are trees which are unfavorable for PS*, so that I(PS*(k)) > I($\alpha\beta$). Such trees are statistically insignificant, and are uncommon in typical applications, because they represent a worst first ordering within every partition.

PERFORMANCE COMPARISON

The search algorithms PS*(k), SSS*, and $\alpha\beta$ have been implemented on a VAX 11/780 using the C language. Experimental investigations were carried out with both ordered and random trees, using different combinations of depth, width and tree ordering. Some of the results on minimal, random, and ordered versions of the uniform trees T(8,4), T(16,4), T(24,4), T(32,4) and T(8,6) are presented. For the trees of width 8, 16 and 24, orders R = 2 and 4 were searched and for trees of width 32, order 8 was also studied. For each combination, 100 different trees were generated using a modified version of the scheme developed by Campbell[1], and the average NBP visited by each algorithm are presented in the tables. The maximum amount of space needed is also given in terms of list entries.

Based on the search of 100 different trees, the following observations about the average performance of PS*(k) are possible:

(1) Data in Tables 2 through 6 show that on random trees (R = 1), the average NBP for PS*(2) is much less than for $\alpha\beta$, but more than for SSS*. For trees of order R = 2 and higher, PS*(2) and SSS* have the same performance, but it is clear that PS*(2) needs much less space.

(2) SSS* is always better than $\alpha\beta$ and is statistically better than PS* for both random and probabilistically ordered trees, Table 4. For perfectly ordered trees, each algorithm visits minimum bottom positions.

(3) Table 4 shows the results on both ordered and probabilistic trees of depth=4, width=24 and of orders R=2 and 4. In the probabilistic case, the average NBP are slightly greater, as we would expect, because at every MAX node there is some nonzero probability that the best branch is not found in the first partition searched by PS*.

(4) For most of the trees, I(PS*(i)) < I(PS*(j)), for 1 ≤ i < j ≤ w. That is, PS*(k) visits terminal nodes in increasing number with increasing k. There are some trees for which this is not true[8]. It is also known that the above relation marginally fails to hold for ordered trees (probability p=1), see for example Tables 5 and 6 where PS*(2) and PS*(4) often have statistically insignificant better performance than SSS* (i.e., PS*(1)) on order R = 4 trees.

Choice of Partition Count

From the previous discussions, it is clear that selection of the partition count, k, is important if PS*(k) is to achieve its maximum benefit. If from some previous knowledge we know that the tree is of order R, we can choose k = R. Then I(PS*(k)) would be the same as I(SSS*), but the storage requirement of PS*(k) would be about $1/(k^{d/2})$ of that of SSS*. Clearly, there is a trade-off between space and bottom positions visited. If k=w, minimum space is required, but NBP will increase to that of an $\alpha\beta$ search. On the other hand, if k=1 the NBP would be low but space needed would be as much as for SSS*. Thus PS* forms a continuum of alternatives between SSS* and $\alpha\beta$. PS* can be made effective by using information about the ordering properties of game trees, since one can choose the parameter k both on the basis of the tree ordering and on the memory space available. Different ordering schemes must be considered, since ordered trees often are more typical of those appearing in applications than are random trees.

Storage needs are also significant. For example, SSS* needs 1024 entries in the OPEN list to search a tree of depth=4 and width=32, whereas PS*(4) requires 64+9 = 73, and PS*(8) needs only 16+5 = 21 for both the OPEN and BACKUP lists. Note that although PS* maintains two ordered lists, the total size of the two lists is much less than that of the single list of SSS*. Also, an ordered list of size 64 or 16 is much cheaper to maintain than a list of 1024 elements. Hence, the time spent by PS* manipulating these overhead lists may be less than that needed by SSS*.

CONCLUSION

The new algorithm PS*(k) can be viewed as a continuum between SSS* and $\alpha\beta$, as it attempts to make use of the best characteristics of both. The $\alpha\beta$ algorithm processes nodes in a game tree much faster than SSS*, but SSS*, making more use of the knowledge gained at earlier steps, prunes better than $\alpha\beta$ and as a result visits fewer bottom positions. SSS* achieves this better pruning at the expense of extra bookkeeping which needs more storage and considerable time for the update process. The phased search algorithm PS* also does some bookkeeping and achieves much better pruning than $\alpha\beta$ in a statistical sense. Since PS* concentrates only on a subset of the solution trees in each phase, it consequently needs smaller storage and may even require less execution time than SSS*. Thus PS*(k) can be comparable to SSS* in performance, especially on *bushy* trees (i.e., trees with w > 20), and yet at the same time has significantly lower storage overhead than SSS*. Because of the built-in flexibility provided by phasing and the possibility for choosing the partition size parameter (PSIZE), PS* is expected to be useful in practice. PS* becomes most efficient if parameter selection can be done using some a priori knowledge of the expected location of the solution.

Experimental results reported here are based on a game tree model, and the algorithm remains to be tested with a typical game-playing program. However, experience with other alternatives to $\alpha\beta$[6] shows that performance on probabilistic uniform trees is a good indicator of performance in a typical application[4]. In the work reported here, the successors of a MAX node in the PS*(k) algorithm are divided into partitions of equal sizes. This is not a restriction, but further work is necessary to determine if unequal partition sizes offer a performance advantage in practice. Certainly for probabilistically ordered trees increasing partition sizes could be useful.

Acknowledgements

Financial support in the form of Canadian Natural Sciences and Engineering Research Council Grant A7902 made the experimental work possible. Discussions with Liwu Li on theoretical points and the independent implementation of PS* by Erik Altmann helped and were appreciated.

IMPROVED PARALLEL ALPHA-BETA SEARCH

Jonathan Schaeffer

Computing Science Department,
University of Alberta,
Edmonton,
Canada T6G 2H1

ABSTRACT

Conventional parallelizations of the alpha-beta algorithm have met with limited success. This paper describes a parallel alpha-beta searching program that achieves a high degree of parallelism through the use of four different types of processes: Controllers, Searchers, Table Managers, and Scouts. Improved performance is achieved through decreased synchronization overhead, increased distribution of information, and increased awareness by "scouting" ahead in the tree looking for interesting features. Experimental data is presented showing a 5.7-fold speedup with 9 processors.

1. Introduction

Attempts to parallelize the *alpha–beta* tree search algorithm have been less than successful. Simulation results have been published for several inventive parallel approaches showing tremendous speedups ([1,2] for example). However, there exists a large gulf between theory and practice; actual implementations have shown only modest speedups [3-5]. Parallel programs suffer from efficiency losses for a variety of reasons. For the alpha-beta algorithm, synchronization overhead, the cost incurred by processors becoming idle, and search overhead, the consequence of building a larger tree, appear to be the biggest obstacles to improved performance.

This paper introduces some new ideas for enhancing the performance of a parallel alpha-beta searcher. The ideas are discussed in the context of a computer chess program operating in an environment of a network of loosely coupled processors.

One way of reducing the synchronization cost is to re-assign idle processors to help out busy ones. This paper gives some experimental results of such a scheme and shows that synchronization is reduced at the cost of increasing search overhead. With the aim of reducing the search overhead, increased flow of information between processes is experimented with. Two different means of sharing information were tried: a table manager process to share results among processors (used for the transposition table [6]), and periodic merging of local tables and distributing the combined result (used for the history tables [7]). Search overhead is decreased but at the cost of increased synchronization and communication. The result is a 5.7-fold speedup with 9 processors.

Despite these improvements, beyond a handful of processors, parallel alpha-beta performance rapidly degrades. Fishburn has shown that for N processors, under certain conditions, the possible speedups are $O(\sqrt{N})$ [8]. The speedup achievable with 100 processors may not be much greater than that attained by 10, and may even be less! Accordingly, a different means is required to use profitably additional computing resources. The idea of a Scout process is introduced; a process that searches ahead of the main program in the tree "scouting" for interesting lines. The Scouts are small, fast, stripped-down chess alpha-beta searchers. They look for wins and losses of material and communicate this information back to the main program. Thus while a chess program may only see 7 half-moves (or 7-ply) deep in the tree, the Scouts can often search an extra 2-3 ply deeper. This helps increase the tactical awareness of the program and reduce the horizon effect [9] by allowing a chess program to find wins (and avoid losses) not normally possible within its search horizon.

These ideas have been implemented in the computer chess program *Phoenix* †. Experimental data is presented on the effectiveness of the schemes.

2. Parallel Alpha-Beta

Many different approaches have been discussed in the literature for parallelizing the alpha-beta algorithm. They include parallel aspiration search (limited to a 5-6-fold speedup) [10], tree-splitting (too simple, limited performance) [11], mandatory work first (too much overhead) [2] and principle variation splitting (PVSplit) [12].

The *PVSplit* algorithm applies a recursive form of *tree-splitting* [8] to achieve parallelism. The w sub-trees originating at the root of the tree are in turn assigned to a process to search. However, the searching of the first sub-tree from the root is usually more expensive than the others, perhaps comprising 50% of the work. Accordingly, *PVSplit* applies tree-splitting recursively at interior nodes along the first path from the root to terminal node (i.e. along the *principal variation*). At each point where tree-splitting occurs, the processes must synchronize before continuing. The search is conducted in iterations, searching all moves from the root 2-ply deep, then 3-ply, then 4-ply etc. After each iteration, further synchronization is necessary. The communication structure of the N processes used can be viewed as a process tree of depth 1 and width N. The process distributing the work is called the *Controller*, while the N processes actually doing the work are known as *Searchers*.

The losses in performance of this algorithm are primarily two-fold. First, synchronization is required at several places in the algorithm. At these points, processors become idle waiting for others to complete their work. Experiments have shown that as the number of computers increases, this overhead quickly becomes dominant [3]. The second loss is extra searching as a result of incomplete information. On a loosely coupled network of processors, results computed on one processor are not globally available to others and hence may be re-computed. The search overhead increases steadily but appears to level off eventually [3].

To help reduce the synchronization costs, the *PVSplit* algorithm was modified to allow idle processes to help other processes complete their tasks. This is done by changing each Searcher to maintain a list of its sub-trees that have yet to be searched. When a process becomes available to help out, work can be taken from the top of the list and off-loaded to that process. Thus at any time, any Searcher could be working for any other. The initial process communication structure is a tree of depth 1 and width N (Figure 1a). The Controller process at the root assigns sub-trees for evaluation to the N Searchers. When the Controller has no more work for a Searcher to do, that process is re-assigned to work for another that is still busy. In this way, the tree-like configuration of processes is retained; the tree just changes its shape dynamically. Figure 1 illustrates a sample scenario with

slave 3 becomes idle

slave 2 becomes idle

slave 1 becomes idle

slave 1 becomes idle

slave 3 becomes idle

slave 1 becomes idle

Figure 1. Re-Assigning Idle Processes

a Controller and 4 Searcher processes; successive diagrams illustrate the effect as a process becomes idle.

Note that synchronization is not eliminated by this approach; it is only reduced. At points where work becomes divided, the process distributing the work ("employer") must wait until all the work handed out has been completed before moving onto other tasks. In such cases, it is usually only one process, the employer, that must remain idle. For example, in Figure 1c, when process 1 finishes its work, it cannot be re-assigned until process 3 is done. The worst case scenario occurs on the last piece of work. As in Figure 1g, only one process may be busy with the others waiting for its completion. In *PVSplit*, at all synchronization points, $N-1$ processes remain idle waiting for the return of the last result.

This attempt to reduce synchronization is not without problems. First, the amount of communication is increased. Second, the search overhead would be expected to increase. Whereas formerly a subtree would be entirely searched by one processor with all the relevant information locally available, by splitting it up over several processors, not all of this information is available and extra work is performed. Third, the complexity of the program is increased. Although this effect is difficult to quantify, it not only affects the implementation and debugging time, but the execution time of the program as well.

Nodes in a chess tree are not necessarily unique. Transpositions occur, whereby two different sequences of moves can result in the same position. Transposition tables are used by chess programs to remember subtrees that have been searched [6]. On reaching a new position, the program can interrogate the table before doing the search in the hope that the sub-tree has been seen before. Unfortunately, in a multi-processor environment the transposition table information is distributed over all the processors. To facilitate sharing of this information, a Table Manager process has been added that reduces the searching each process does by making the results of other Searchers available. The Table Manager receives table entries from the Searchers and responds to their queries for information from the table.

This attempt to reduce search overhead is not without problems. First, it is achieved at the cost of increased communication in the program. Second, synchronization overhead is increased because table queries are performed synchronously; a process must wait until it gets the result before it can continue. Allowing a process to proceed and eventually be interrupted when the result is available would complicate the implementation and has not yet been tried.

The *history heuristic* is a simple means of accumulating information about a search tree that can be used for deciding the order in which sub-trees should be examined at interior nodes. For sequential chess programs, the algorithm has been successful [7]. In a parallel environment, some of its effectiveness is lost because each processor has only part of the history information. This suggests that processors should share this information. After each iteration, all processors could communicate their history tables to the Controller who accumulates them and then replies to each with the updated global table. In this way search overhead may be reduced at a cost of increased communication.

The above three ideas (re-using idle processors, table managers, and shared history heuristic information) individually can improve the performance of a parallel alpha-beta searcher. However, as the preceding discussion has shown. these enhancements can run counter to each other.

3. Scouts

Whatever depth an alpha-beta search is performed to, there is always the possibility that by searching deeper, a better result may be found. In chess programs this is particularly acute; a program may make a move that, for example, within a 5-ply search looks good, but a 6-ply search may reveal its deficiencies. Considerations such as this have motivated chess programmers to acquire the fastest possible hardware. It is not a coincidence that the best chess programs today can also search the deepest.

To overcome this problem, the idea of a Scout is introduced. Scouts are stripped down versions of Searchers. They are designed to be as fast as possible, scouting ahead in the tree looking for wins and losses of material at a depth beyond what Phoenix could usually search. All the chess expertise that allows Phoenix to play a good game of chess has been removed. It evaluates positions solely on the net material balance of the position.

Because of its simplicity a Scout can execute at twice the speed of a Searcher process. This is not enough; on average, a factor of 3-8 is required to search an extra ply. Since Scouts are only interested in finding tactically interesting lines, some heuristics are added to the search algorithm to eliminate uninteresting lines of play. For example, a line in which a series of moves are made without any threat is classified as uninteresting and ignored. These heuristics introduce error into the search in that some tactically interesting lines may be overlooked. It turns out that these type of positions occur infrequently in practice, whereas the reduction in tree size and resulting deeper searches are significant.

Scouts can be easily implemented in parallel by using the same routines used to parallelize Phoenix. They have their own Controller process to distribute the work and accumulate the results. A set of Scouts with a Controller process is called *Minix* (Mini-Phoenix).

Phoenix and Minix communicate through their Controller processes. Minix searches all the moves to find out which ones are in the set of tactically best moves, those moves that result in the best material advantage for the program. When Phoenix has decided on its move, it tells Minix who checks to see if the choice is tactically good. If so, it gives permission to Phoenix to make the move. Otherwise, Minix will veto Phoenix and order it to make a move that, from Minix's point-of-view, is tactically better.

4. Environment

A collection of workstations, with its network and communications software, may be viewed as a *multi-computer* capable of running distributed and parallel algorithms. The software facility used to implement Phoenix is a multi-computer called the Virtual Tree Machine (VTM) [13]. It is implemented on a network of autonomous VAX-11/780s, SUN-2, and SUN-3 processors each running the 4.2BSD Unix operating system [14]. The user's view of the facility is a collection of processing elements - each with its own local memory and peripherals. The VTM name is a misnomer in that arbitrary interconnects are possible, not just trees. In reality, the VTM consists of ordinary Unix processes with communication paths implemented as virtual connections between processes over a local area network. The user's interface to the machine is a set of procedures, callable from application programs, and a collection of servers that create the nodes in the virtual machine according to a description provided by the user. This description specifies the mapping between virtual processing elements (nodes) and physical processors as well as the interconnections between nodes.

Figure 2 illustrates the process/processor structure on a sample network. Each box represents a machine and each circle, a process running on that machine. Note that for illustrative purposes, both the Controller and User Interface processes reside on separate processors. In fact, they consume few resources and so can share the same processor as the Table Manager.

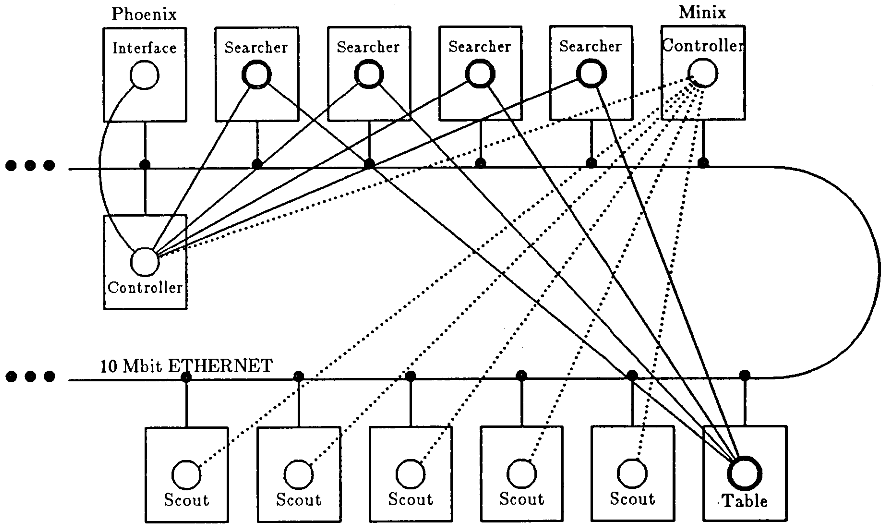

Figure 2. Phoenix and Minix

5. Results

Phoenix's PVSplit algorithm has been enhanced to reduce processor idle time and share history and transposition information. Figure 3 presents some experimental results showing speedups using 1 to 9 processors. The data was obtained by searching a standard set of 24 positions [15] to 7-ply. The *B* line is for PVSplit enhanced by the re-assigning of idle processors, *BH* is *B* with the addition of shared history information, and *BHT*, *BH* with a transposition table manager. *BHT* is able to achieve a speedup of 5.7 using 9 processors.

Previous implementations of PVSplit show the performance of the algorithm tapering off as the number of processors are increased, to a point where additional processors actually *degrade* performance. In [3], their experiments suggested performance stopped improving at 8 processors with a speedup of 4.4. Newborn's results [4] are slightly higher, but also appear to tail off quickly.

The data in Figure 3 shows that through 9 processors, performance is still increasing. The effect of sharing history and transposition information increases the performance of the algorithm without, however, eliminating the decreasing returns for additional computing power. Transposition table managers clearly provide a significant improvement in performance.

Figure 4 shows the total, search, and synchronization overheads for both the *B* and *BHT* variants. Communication overhead was experimentally small enough to be considered negligible. The addition of shared history and transposition table information has reduced the search overhead by more than 50%. Experiments have shown that the re-assigning of idle processors to help out busy ones does reduce synchronization overhead, but increases search

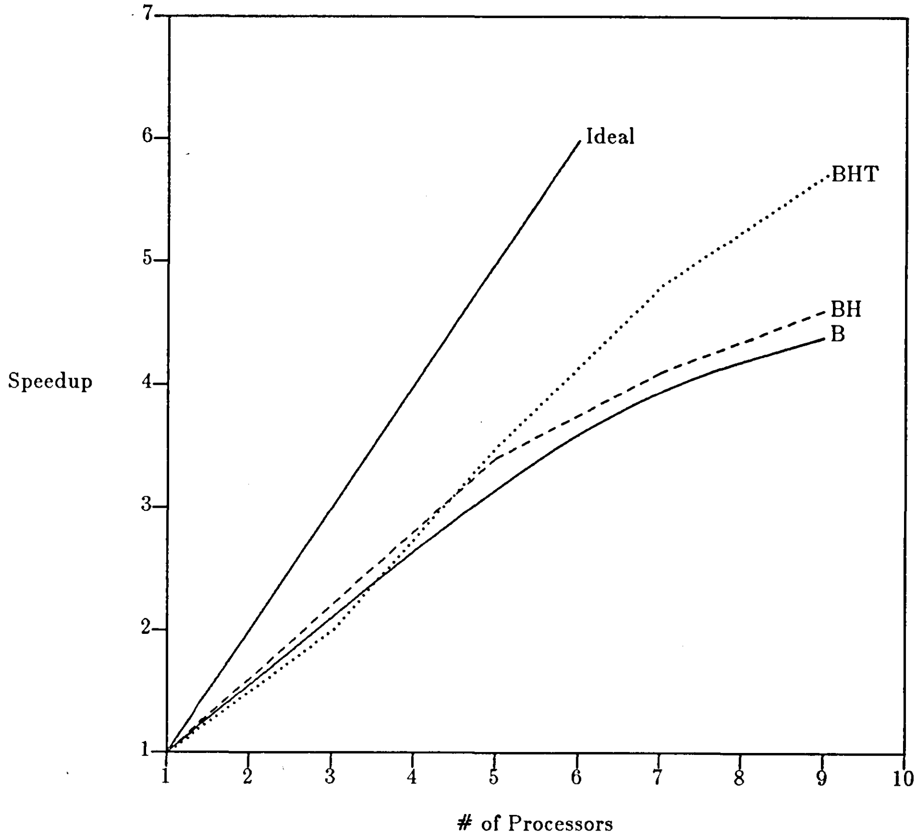

Figure 3. 7-Ply Speedups

overhead almost to the point where it offsets all the gains. Using a Table Manager at the cost of an additional Searcher helps offset this.

An anomaly appears on the graph for the *BHT* overheads with 2-4 processors. For few processors, devoting resources for a Table Manager instead of a Searcher does not pay-off in performance. Instead, with 2-4 processors one does better to use as many Searchers as possible, and for 5 or more, add a Table Manager.

Limited data is available for more than 9 processors. Experiments with 19 processors show a 7.7-fold speedup, with additional processors still providing some benefits. Overhead analysis shows that search overhead levels off, while synchronization increases dramatically. This suggests that the Table Manager process is becoming over-loaded and processors wait increasing amounts of time for response. A possible solution is the addition of a second Table Manager.

Scout processes are new and there is not a lot of experience using them. In quiet positions with few tactical possibilities, Minix can easily out-search Phoenix by 10-ply or more. In more complicated positions, it is usually 1-2-ply ahead. Unfortunately, Minix's performance is difficult to quantify. Many standard sets of chess problems contain a large number of tactical positions and on these Minix performs exceptionally well, finding a many winning moves not found by Phoenix. However, in real tournament games, the number of times that an extra one or two ply of tactical searching makes a difference in the move selected is infrequent. Since these situations do not occur often, one might argue that the computing resources are not well used. On the other hand, these winning and losing moves can be the decisive difference in a tournament game. Given that the use of Scouts results in improving even one move in a game, then they have

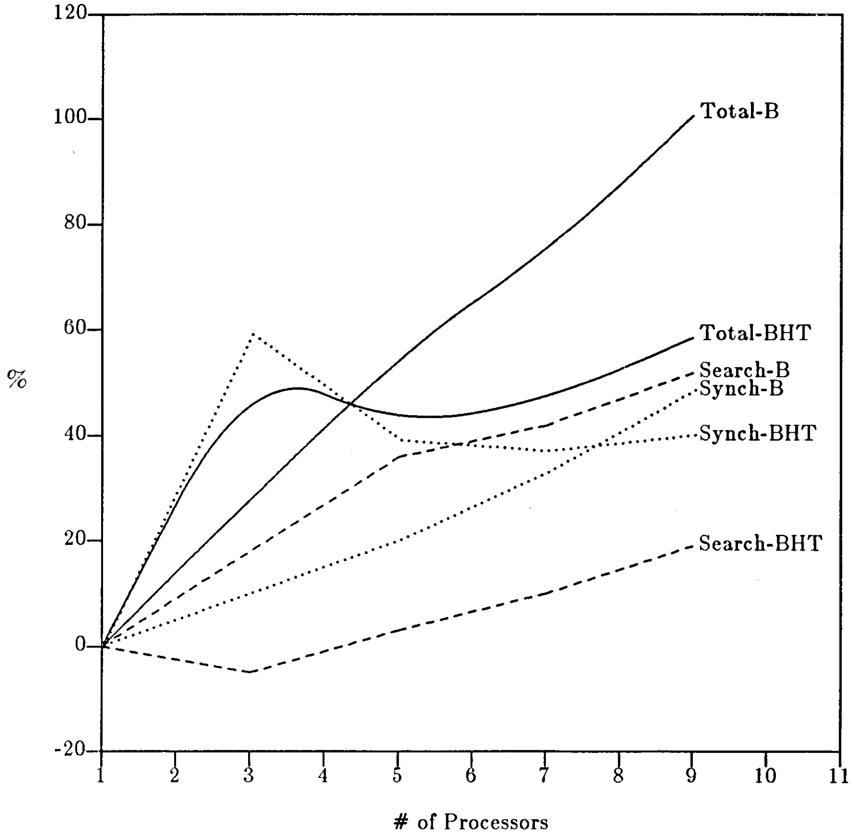

Figure 4. 7-Ply Overheads

made a significant improvement in the program's play.

At the time of this writing, Phoenix has competed in four tournament games with Minix. In only one game did Minix make a difference, and that on a move that did not alter the course of the game. In one practice game played, Minix prevented Phoenix from making a losing move. However, this data is insufficient to draw any conclusions.

6. Conclusions

Parallelizing tree search algorithms for a small number of processors is just a prelude to tackling the problems posed by having 100's or even 1000's of processors. Although no claims can yet be made on the suitability of re-assigning idle processors for reducing synchronization overhead, and globally accessible tables for decreasing search overhead, they both clearly addresses major problems posed by such a hardware configuration. Unfortunately the reduction of one overhead (synchronization for example) can result in the increase of others (communication and search). Improving on this remains an open research question. Given that existing parallelizations of alpha-beta are limited to a few processors, Scouts may provide an alternate means of using available resources profitably.

Acknowledgements

Many of the ideas used in the Scout processes evolved from discussions with Don Beal. The suggestions and help of Marius Olafsson is greatly appreciated.

NEW ADI MODEL PROBLEM APPLICATIONS

Nancy S. Ellner and Eugene L. Wachspress

Department of Mathematics
University of Tennessee
Knoxville, TN 37996-1300

Abstract

Peaceman and Rachford introduced ADI iteration to solve parabolic and elliptic linear systems. Recent generalizations enhance use of the model ADI problem as a preconditioner for solving nonseparable systems discretized by either five-point difference or nine-point finite element techniques. The theory also yields parameters for a new iterative procedure for solving the Lyapunov matrix equation. This application is well suited for parallel computation. Classical Chebyshev minimax theory is restricted to real approximation. Rouche's theorem provides a basis for generalization to the complex field. This is essential for application to systems involving matrices with complex eigenvalues. The particular application which motivated this generalization was computation of impedance boundary conditions for finite element computations by the method of "Infinitesimal Scaling" introduced by H. Hurwitz.

2. INTRODUCTION: THE ADI MODEL PROBLEM

Alternating-Direction-Implicit (ADI) model problem theory arises in diverse areas. It was developed by Zolotareff (1877) and applied by Cauer (1934) to an electrial filter design problem. In 1955 Peaceman and Rachford[9] introduced an alternating-direction-implicit (ADI) iteration for solving elliptic systems arising from five-point discretization of boundary-value problems governed by the differential equation $-\mathrm{div}[D(x,y)\mathrm{grad}u(x,y)] = f(x,y)$. The real, SPD (symmetric, positive-definite) coefficient matrix A is split into H and V where H is the discretization of the x-derivatives and V of the y-derivatives. The two-step iteration

$$(H+w_jI)u_{j-1/2} = -(V-w_jI)u_{j-1} + b$$

$$(V+w_jI)u_j = -(H-w_jI)u_{j-1/2} + b \qquad (1)$$

for $j = 1,2,\ldots,t$ and u_0 prescribed

is now known as Peaceman-Rachford iteration.

A rigorous theoretical analysis of convergence and methods for computing optimum w_j are known for the "model-problem" where H and V commute. In a series of papers published in the sixties, Chebyshev minimax theory was applied to establish existence and uniqueness of optimum parameters as a function of the eigenvalue spectra of H and V[14-18]. A convenient algorithm was devised for computing optimum parameters for the special case of $t = 2^n$. This algorithm is based on a folding technique having certain features not dissimilar to the FFT. W.B. Jordan[18] demonstrated how optimum parameters could be found for any t in terms of elliptic functions and gave simple formulas which yield values quite close to optimum. This solution in terms of elliptic functions had been discovered for the same minimax problem by Zolotareff and used by Cauer to design electrical filters.

Two significant generalizations of the Peaceman-Rachford iteration were introduced during the sixties. First, it was noted that one could replace w_jI by w_jF in Eqs. 1, where F is a diagonal matrix. The model-problem condition is then that $HF^{-1}V - VF^{-1}H = 0$. This is equivalent to a renormalization of H and V in Eq 1. A model-problem is obtained with variable mesh increments and $D(x,y) = 1$ when the difference equations are derived by the box-intergration method and matrix F has as its elements the mesh-box areas. This is true in both Cartesian and cylindrical coordinates[16] .

The second significant generalization was choice of a different value for the iteration parameter in the two sweeps. In the seminal work by Peaceman, Rachford and Douglas, it was noted that this can lead to divergence while convergence is assured with Eqs 1. The crucial point is that the two parameters for each double-sweep are related in a special way. This generalization

*This work was partially supported by General Electric Corporate Research and Development, Electromechanics Branch, Contract #P.O. G0076000.

yields optimum parameters as a function of the distinct spectral intervals of H and V (or of HF^{-1} and VF^{-1} when the parameters are multiplied by F.) This is sometimes a great improvement over parameters based on a single interval encompassing both spectra. Indeed, H or V may be singular or even have negative eigenvalues as long as A is positive definite. The analysis and examples were first given by Wachspress[15] and may now be found in many texts. Let the parameter w_j in Eqs. 1 be replaced by p_j in the first sweep and q_j in the second sweep. Let the spectral bounds be $a \leq s(H) \leq b$ and $c \leq t(V) \leq d$ with $a + c > 0$. The ADI minimax problem is then to find the parameters p_j and q_j to minimize

$$R(J) = \underset{\substack{a < s < b \\ c < t < d}}{\text{maximum}} \quad \prod_{j=1}^{J} \left| \frac{(q_j - s)(p_j - t)}{(p_j + s)(q_j + t)} \right| \qquad (2)$$

Model problems are not often encountered in practice. Nevertheless, model-problem ADI serves an important function as a preconditioner for compound iteration.

Two recent generalizations of ADI model-problem application were described by Wachspress.[18] First, one notes that the eigenfunctions of the diffusion equation are separable when the diffusion coefficient is a separable function of x and y . This generalization of the ADI model problem was described by Young[19]. The five-point difference equations derived by the box-integration method for such separable problems yield a model problem for ADI iteration. Theory relating to approximation of a nonseparable function by a separable one[2] is described by Light and Cheney[7]. Applying this to a non-separable diffusion coefficient leads to an ADI model problem as a preconditioner for a conjugate gradient or Chebyshev iteration which is often a great improvement over a Laplacian preconditioner. Schatz (in prep.) has used such generalized model problems with FPS and FFT preconditioners. Second, in solving finite element problems over rectangular grids one encounters nine-point rather than five-point equations, and no ADI model problem had been known for these nine-point equations. A transformation of variables was discovered that provided a nine-point ADI model problem. A third new application for ADI model-problem theory arises in an entirely different situation which will now be described.

3. THE LYAPUNOV MATRIX PROBLEM

3.1. The Problem and Some Solution Techniques

A recurring problem in linear algebra is the Lyapunov matrix problem where one is given the mxm matrix A , the nxn matrix B , the mxn matrix C and seeks the mxn matrix X for which

$$AX + XB = C \ . \qquad (3)$$

A unique solution is easily demonstrated for the case where s + q = 0 is not satisfied for any eigenvalue s of A and q of B . The ADI application arises when A and B are N-stable (i.e., the real parts of their eigenvalues are positive) and in the slightly more general case where the real part of s + q is positive for any eigenvalues s and q of A and B , respectively. A good survey of alternatives for solving Eq. 3 in use prior to 1972 is given by Rothschild Jameson[11]. Let N be the larger of m and n . Then the number of arithmetic operations for the four techniques they describe varies from $O(N^6)$ for the Geiss "brute-force" direct solution[3] to $O(N^4)$ for Jameson's iterative method[11]. For m = n , a more recent $O(N^4)$ direct method of Bartels and Stewart[1] with modifications introduced by Golub, Nash and vanLoan[4] appears more efficient and robust than the methods considered by Rothschild and Jameson. The bulk of the computation occurs in simultaneous reduction of A to triangular and B to upper Hessenberg form.

The new iterative method for solving the Lyapunov equation described in this paper requires $O(N^3)$ operations and is partucularly well suited for array computation. It is a generalized form of a procedure introduced by R.A. Smith in 1968[12]. Smith considered the case where A and B are N-stable. A concise summary of pertinent parts of Smith's analysis follows. Let E be the unit mxm matrix and I the unit nxn matrix. For any positive scalar q , the identity

$$(qE+A)X(qI+B) - (qE-A)X(qI-B) = 2qC \qquad (4)$$

is easily verified. Premultiply Eq. 4 by $(qE + A)^{-1}$ and postmultiply by $(qI + B)^{-1}$ to get

$$X - UXV = W \qquad (5)$$

where $U = (qE+A)^{-1}(qE-A)$, $V = (qI+B)^{-1}(qI-B)$,

and $W = 2q(qE+A)^{-1}C(qI+B)^{-1}$. By inspection,

$$X = \sum_{k=1}^{\infty} U^{k-1}WV^{k-1} \qquad (6)$$

is a formal solution to Eq. 5. The spectral radii of U and V are less than unity. It follows that the series in Eq. 6 is convergent. Define the matrix sequence Y_r by

$$Y_0 = W , \qquad Y_{r+1} = U^{2^r} Y_r V^{2^r} \ . \qquad (7)$$

It is seen that Y_r approaches X rapidly. Moreover, U^{2^r} and V^{2^r} are obtained by squaring $U^{2^{r-1}}$ and $V^{2^{r-1}}$, respectively. Each step thus requires four matrix multiplications and one matrix addition. This is a quadratically convergent iteration. Computation arithmetic is $\bar{O}(N^3)$.

3.2. A Generalization of R.A. Smith's Iteration

The generalization of Smith's iterative solution to be developed here has several advantages. The number of arithmetic operations remains of $O(N^3)$ but a parallelism not shared by Smith's algorithm is introduced for efficient use of an array computer. The restriction that both A and B be N-stable is relaxed to the condition that the sum of the real parts of eigenvalue p_j of A and eigenvalue q_j of B be positive for all i, j pairs. Fewer iterations are required with the generalization.

A crucial observation is that the identity in Eq. 4 may be generalized to

$$(pE+A)X(qI+B) - (qE-A)X(pI-B) = (p+q)C \ . \qquad (8)$$

Multiply Eq. 8 on the left by $(pE+A)^{-1}$ and on the right by $(qI+B)^{-1}$ to get

$$X - U(p,q)XV(p,q) = W(p,q) \qquad (9)$$

where

$$U(p,q) = (pE+A)^{-1}(A-qE) \qquad (10)$$

$$V(p,q) = (B-pI)(B+qI)^{-1} \qquad (11)$$

$$W(p,q) = (p+q)(pE+A)^{-1}C(qI+B)^{-1} \ . \qquad (12)$$

Then the Smith iteration in Eq. 7 yields

$$Y_0(p,q) = W(p,q) \ ,$$

$$Y_{r+1}(p,q) = U(p,q)^{2^r} Y_r(p,q)V(p,q)^{2^r} \ . \qquad (13)$$

Now note that Y_r is related to the solution X by

$$Y_r(p,q) = X - U(p,q)^{2^r} XV(p,q)^{2^r} \ . \qquad (14)$$

The procedure is convergent if the spectral radii of U and V are less than unity. It is obvious that one should choose p and q to minimize the spectral radii of $U(p,q)$ and $V(p,q)$. This is precisely the ADI minimax problem for $t = 1$.

The ADI model-problem was encountered in solving the linear system $Au = b$ when it was possible to split A into a sum of commuting matrices H and V. The case for which extensive theory was developed was for real spectra of H and V. The analysis is valid for any commuting linear operators H and V which sum to A. Prof. G.J. Habetler (R.P.I.) observed that one may define $H(X) = AX$ and $V(X) = XB$ to obtain $HV = VH = AXB$. It is no coincidence, therefore, that $AX + XB = C$ is a "model problem" for ADI iteration. It is seen that the ADI model-problem theory applies to this iterative solution of the Lyapunov matrix equation even when A and B do not commute! Moreover, the condition that $a + c > 0$ guarantees a unique solution. This is more general than the requirement that A and B both be N-stable.

3.3. An Algorithm for Parallel Computation

Smith's quadratic convergence is obtainable only with a constant p, q doublet. Moreover, two matrix inversions are required to obtain $U(p,q)$ and $V(p,q)$ for each doublet. For computation on a serial computer, it is questionable that one can improve efficiency with variable p and q. The situation is somewhat different in application to parallel processing. It will now be shown that one can iterate simultaneously with a different p,q couplet on each of several arithmetic units and then combine the results to derive some of the benefits of variable parameters.

Let $Y(r,j) = Y_r(p_j, q_j)$ as defined by Eq. 13. Parallel computation may be performed on J arithmetic units. The results may then be combined to yield the same estimate to X as would have been obtained by 2^{r-1} applications with optimum parameters for a cycle of length J. The combining algorithm is as follows:

$$X(r,1) = Y(r,1) \quad , \text{ and for } j > 1 \qquad (15)$$

$$X(r,j) = Y(r,j) + U(j)^{2^r} X(r,j-1)V(j)^{2^r} \ .$$

Each step in Eq. 15 requires four matrix multiplications and one addition. Although this is the same work as each step of the base Smith algorithm, this part of the calculation cannot be done in full parallel mode. One may replace Eq. 15 by a folding algorithm to retain some parallelism at this stage of the computation. The iterates in Eq. 15 satisfy

$$X(r,j) = X - \prod_{j'=1}^{j} U(j')^{2^r} \ X \prod_{j'=1}^{j} V(j')^{2^r} \ . \qquad (16)$$

This may be demonstrated inductively with the aid of Eq. 13. The value of $R(J)^2$ is an upper bound on the relative error $|X(r,J) - X| / |X|$, where $|\ |$ denotes the usual spectral norm.

3.4. Application To "Infinitesimal Scaling"

The Lyapunov matrix equation arises in a scheme devised by H. Hurwitz to compute an impedance boundary condition for finite element problems [6]. Hurwitz calls his method "infinitesimal scaling." An SPD matrix C is found as an impedance boundary condition by solving the nonlinear matrix equation

$$(C + Q)N^{-1}(C + Q^T) = M \qquad (17)$$

when given the real SPD matrices M and N and the real antisymmetric matrix Q .

Let $A_n = (C_n + Q)N^{-1}$. (18)

Then a quadratically convergent Newton-type iteration to solve this equation for C is

$$A_nC_{n+1} + C_{n+1}A_n = M - QN^{-1}Q^T + C_nN^{-1}C_n . \qquad (19)$$

This is the Lyapunov equation with $B = A^T$. Moreover, A is N-stable since its symmetric part is SPD.

Another property of the system is that Q is very small in norm compared to C . This yields a spectrum restricted to lie in a rectangle in the positive-real half-plane centered on the real axis and of height much smaller than its width. This is precisely the kind of spectra where ADI iteration can be expected to be very efficient. It was this problem which motivated generalization of the ADI model-problem theory to the complex domain.

4. ADI MODEL-PROBLEM THEORY FOR COMPLEX SPECTRA

4.1. Polynomial Approximation and Backward Spectrum Analysis

Chebyshev minimax theory for polynomial approximation over the reals has been extended to the complex domain. The alternating extremes property in the real case is replaced by constant absolute value of the error function on the spectrum boundary in the complex domain. Rouche's Theorem relating to the number of zeros and poles inside the boundary is then used to establish the minimax property.[9]

Analysis of the minimax problem for the eigenvalue domain $z = 1 + vi$ with v varying between -1 and 1 reveals some of the subtleties of the problem in the complex domain[5]. The transformation $w = i(1 - z)$ yields an interval of $[-1, 1]$ for w . One may examine the Chebyshev polynomial appropriate for this domain with normalization to unity at $z = 0$ or $w = i$. As observed by Opfer and Schober[9], this does not yeild the optimum polynomial in z . The Chebyshev theory establishing the de la Vallee property of alternating extremes of equal magnitude does not hold for complex-valued functions. However, as the degree of the approximation is increased, the Chebyshev polynomial attains its maximum absolute value on a curve that includes the eigenvalue spectrum and collapses in on this spectrum rapidly. As observed by Trefethen[13], this is an essential property of the optimum polynomial. Determining the optimum polynomial is not a simple task. Fortunately, in practice a prescribed error reduction is achieved only after the polynomial degree is sufficiently large that the Chebyshev polynomial is close to optimum. This theory also applies to the ADI rational approximation in which elliptic functions replace trigonometric functions in the analysis.

One of the more prevalent spectrum domains considered for Chebyshev polynomial approximation is an ellipse with major diameter along the real axis. The zeros of the Chebyshev polynomial are spread out along the real axis when the minor diameter is small compared to the major diameter. As the relative magnitude of the minor axis increases, the zeros coallesce toward the center. When the domain is a circle, the optimum polynomial has a single root at the center of multiplicity equal to the degree of the polynomial.

Rather than seeking optimum functions for a given spectrum, we choose a class of approximating functions and investigate the regions on which these functions are optimal. We consider the "lemniscates" described by Opfer and Schober[9]:

Definition: The G-lemniscate of $F(z)$ continuous on region W in the complex plane C is

$$L = \{z \in W: |F(z)| \le G\} \qquad (20)$$

Consider first polynomial approximation to zero over a complex region. Let u be a fixed value greater than unity at which a polynomial approximation to zero over the real interval $[-1, 1]$ of maximal degree t is normalized. The polynomial which has the least maximum absolute value over $[-1, 1]$ is the Chebyshev polynomial

$P_t(z) = \cos[t \arccos(z)]/\cos[t \arccos(u)]$.

Let $P_t(1) = H$. The H-lemniscate of P in the complex plane identifies an extended spectrum for which this polynomial is optimal. The application of Rouche's Theorem to the minimax problem over the lemniscate is as follows: P has absolute value of H on the H-lemniscate and t roots within the lemniscate. Let R be a "better" polynomial for approximation over this region in the sense that $|R| < H$ over the closed region bounded by the lemniscate. It is easily demonstrated that the winding number of $P - R$ is the same as that of P as one traces a path around the lemniscate. Hence, P and $P-R$ have the same number of roots in this region. P is known to have t roots within the lemniscate. Both P and R are normalized to unity at u outside this region. Therefore, $P - R$, a polynomial of degree at most t , has at least $t + 1$ roots. This is impossible. Hence, P is optimal.

The lemniscate oscillates between the degenerate ellipse which is the line segment $-1 \leq z \leq 1$ and the ellipse centered at the origin with semi-major axis endpoints $\pm$ cosh v and semi-minor axis endpoints $\pm i \sinh v$, where $v = \text{arcsinh}(1)/t$. Now consider the G-lemniscate for any G in the interval (H, 1). As G increases toward unity, the lemniscate expands to become a circle of radius u. The Chebyshev polynomial is optimal for this entire set of lemniscate spectra. Let $v^* = \text{arccosh}(G)/t$ and let $v' = \text{arcsinh}(G)/t$. The G-lemniscate oscillates between the ellipses

$$[\text{Re}(z)/\cosh v^*]^2 + [\text{Im}(z)/\sinh v^*]^2 = 1 \quad (21)$$

and

$$[\text{Re}(z)/\cosh v']^2 + [\text{Im}(z)/\sinh v']^2 = 1. \quad (22)$$

Let the ellipse of Eq. 21 be denoted by E(G). This ellipse is contained in the G-lemniscate. The Chebyshev polynomial has been used for many years to approximate zero over this elliptic spectral region[15]. Manteuffel[8] has shown that it is optimal. As t increases for a fixed eigenvalue spectrum, v^* and v' approach a common value. The G-lemniscate approaches the E(G)-ellipse. This is related to fundamental theorems developed by Trefethen[13] in a more general approximation theory setting.

This theory is applied to polynomial extrapolation in iterative solution of large systems of equations. Let the spectrum z of a base iteration be within the ellipse with major axis between a and b on the real axis (where $b < 1$) and semi-minor axis of length c. One then defines $v^* = \text{arctanh}[2c/(b-a)]$ and $z'(z) = (\cosh v^*)(2z - a - b)/(b - a)$. The optimal polynomial is then $P_t(z')$ with $u = z'(1)$. Let $\cos B = \tanh v^*$. Then the maximum absolute value of P over the ellipse is:

$$G = [\tan^t(B/2) + \tan^{-1}(B/2)]/\cosh[t \,\text{arccosh}(u/\sin B)]. \quad (23)$$

One of the problems arising in polynomial approximation is to find the ellipse containing a given spectrum and normalization point which minimizes G. This problem has been investigated by Manteuffel[8] and others.

4.2. The ADI Minimax Problem With Complex Spectra.

ADI theory has been generalized to complex spectra. Now, the appropriate domain for analysis is still an ellipse but for the logarithm of the spectrum rather than the spectrum itself. The spectrum is first normalized so that the ellipse is centered at the origin. (If the real part of the spectrum varies from a to b, the spectrum is divided by the square root of ab to yield this ellipse. The parameters determined for this problem are then multiplied by the square root of ab. Minimax analysis is invariant to multiplicative but not additive normalization.) Just as for polynomial approximation, as the ratio of the minor to major axis of the ellipse increases, the optimum parameters coallesce toward the origin which corresponds to a normalized eigenvalue of unity. When the spectra of H and V are real, ADI convergence is greatly enhanced by use of variable p and q. This is especially true when H and V have very large condition numbers (more precisely, when the eigenvalue bounds b and d are much greater than a + c.) Just as in polynomial approximation, this enhancement through use of variable parameters diminishes as the imaginary components of the spectrum increase.

W.B. Jordan's bilinear transformation[15] reduces the two-variable ADI minimax problem of Eq. 2 to a problem in one variable (say x) over the real interval [k', 1] with k' determined from the eigenvalues a, b, c and d. When $a + c > 0$, k' is in (0, 1). The variable u is defined by $x = \text{dn}(Ku, k)$, where dn is the elliptic function which varies from 1 to k' as u varies from 0 to 1. The optimum rational function for this problem is

$$Q_t(x) = k_2^{1/2} \text{sn}[(2tu+1)K_2, k_2] \quad (24)$$

where k_2 is a function of t and k'. In most applications, k' is close to zero. Choice of t sufficiently large to attain a significant error reduction yields a value of k_2 close to zero also. The error reduction after t ADI iterations is equal to k_2 (the square of maximum absolute value of Q_t in the interval [k', 1].)

Just as for the polynomial approximation previously discussed, one may generalize to the complex plane by considering the family of $G\sqrt{k_2}$-lemniscates for the function $Q_t(z) = \sqrt{k_2}\,\text{sn}[(2t(u+iv)+1)K_2, k_2]$. A value of $G = 1$ yields a lemniscate which cuts the real axis at the extremes which are the alternating points for the real problem. A $G\sqrt{k_2}$ - lemniscate for $1 < G < 1/\sqrt{k_2}$ and $0 \leq u \leq 1$ identifies an extended spectrum for which the $Q_t(z)$ function is the optimal rational polynomial of that form by an application of Rouche's theorem. The function $Q_t(z)$ has absolute value $G\sqrt{k_2}$ on its $G\sqrt{k_2}$ - lemniscate and is a rational function of the form $q_t(-z)/q_t(z)$. Suppose there exists a better approximation of this form to zero over the lemniscate region. The difference between these two functions is a ratio of polynomials of maximal degree 2t-1 which has t roots between k' and 1, and (by symmetry) t roots which are the negatives of these as well. This difference function also vanishes at the origin, which is a contradiction since this function of maximal degree 2t-1 then has 2t+1 roots.

As in the case of Chebyshev extrapolation, as the degree of approximation increases for a fixed eigenvalue spectrum, the $G\sqrt{k_2}$-lemniscate of $Q_t(z)$ collapses rapidly on its largest interior convex region, which contains the spectrum. However, the largest convex region here is not elliptical. It becomes approximately elliptical under the 'log-symmetric' transformation $z' = \ln(z/\sqrt{k'})$. The approximating ellipse has semiminor axis endpoints $\pm bi = iv^*\ln(4/k')$ and semimajor axis endpoints $\pm a = \ln[\sqrt{k'} \cos b]$. Then for efficient application of ADI iteration, the log-symmetric transformed spectrum must be embedded in an ellipse with the least value of effective spectral radius G^2k_2 of the iteration. The effective spectral radius of the ADI iteration is bounded by $\exp(\pi^2/\ln(k'/4))$ when the spectrum is real[16] and by $\exp(\pi^2/\ln(k'/4) + 2\pi v^*)$ when the spectrum is complex.

4.3. Numerical Results

Suppose the spectrum lies in a rectangle such that the real part of the spectrum lies between a and b , and the imaginary part lies between -c and c , where $0 < a << 1$ and $c < a << b - a$. Then optimum ADI iteration parameters will be obtained from the approximating ellipse (section 4.2) with maximum possible value of $(\pi/\ln(4/k'))-2v^*$ of all those ellipses containing the log-symmetric transformed spectrum. This will occur for some ellipse with boundary containing at least one of the left or right sets of corners of the log-symmetric transformed rectangle. This is a constrained maximization problem in the one variable $w = \ln(4/k')v^*$ which can be shown to have a solution for spectra with a, b, and c as described above. Numerical trials suggest that the solution is unique.

The Lyapunov problem

$$A^TX+XA = W \qquad (25)$$

was solved according to the complex-spectrum ADI method outlined above, and by the ADI method assuming a real spectrum between a and b for comparison. The matrix A was chosen to be a 20X20 block diagonal matrix with eigenvalues equally spaced along the upper and lower sides of

Table 1: Numerical results for two test matrices A using complex-spectrum method parameters and real-spectrum method parameters. Errors measured are $||X_n-X||/||X||$ with the Eucliden norm, where X_n is the nth iterate.

the rectangular spectrum boundary. The results for two different matrices with the same real spectral ranges are given in Table 1. The results of the iterations for the real-spectrum and complex-spectrum ADI parameters were very comparable. However, there is generally a slight improvement when using the complex-spectrum method parameters. Also, the associated theoretical error bounds are more accurate at higher numbers of iterations and larger imaginary eigenvalue components. Errors nearly identical to those in Table 1 were obtained from matrices with four eigenvalues defining a rectangular spectral bound and the remaining eigenvalues distributed randomly within the rectangle. This suggests that, as expected, the corner eigenvalues are determining the actual convergence rate.

An analagous method can be used if the spectrum is known to lie in a convex polygonal region within a rectangle, defined by the real and complex spectral ranges, which satisfies the conditions on a, b, and c stated above. In this case, the tighter bounds on the spectrum should give more rapid convergence. Numerical studies of this case are in progress.

FINITE ELEMENT ANALYSIS USING ADVANCED PROCESSORS

Graham F. Carey and E. Barragy

The University of Texas at Austin
Austin, Texas 78712

Abstract

The evolution of advanced scientific processors is briefly summarized and the impact of the microelectronics revolution on vector and parallel scientific computation is examined. These radical changes in computer architectures are having a profound influence on numerical algorithm development and the implementation of numerical approximation techniques. We consider specifically the finite element method for solution of boundary-value and initial-value problems in engineering and science. The main steps of mesh generation, solution, and post-processing in a finite element analysis are outlined for implementation in a concurrent processing environment. We also give a specific example for parallel processing with a residual-based iterative method on a partition of subdomains.

Advanced Processors

Since the earliest attempt by Babbage in 1822 to develop a mechanical 'analytical engine,' the need to solve scientific and engineering problems has naturally been a dominant factor in the evolution of computers and calculating methods. However, modern scientific computation dates from the introduction of electronic computers, such as the ENIAC in 1946. Phenomenal advances in electronics since that time have led to the emergence of succeeding generations of advanced computers such as the IBM 7090, ILLIAC, CDC 6600 and CRAY 2. Although the term 'supercomputer' has been applied only recently to the current generation vector computers, the term generally describes the leading scientific computers of a given generation. Thus, today's supercomputer will, in due course, be superceded by the advanced processors of the next generation. The revolution in microelectronics has been at the center of technological advances in computing. Large-scale integrated circuits on a tiny chip now have more computing power than the mainframe computers of the 1960's. These advances are all the more impressive when we consider the short period over which they have occurred. One is tempted to imagine that this development can continue unabated at the same rate and in the same manner through miniaturization. However, at the present sub-micron level at which chip research is being conducted, the distances are so small that fabrication difficulties are formidable. Moreover, the speed of light becomes a very real constraint at this scale. The prevailing wisdom is that a major scientific breakthrough using, perhaps, ideas related to "quantum tunneling" will be necessary for the current rate of progress in chip design to be maintained.

There is another aspect of the microelectronics industry that has a very direct bearing on current trends in advanced computers. This is the fact that computer chips can be manufactured in large quantities at very low cost. As a result, the familiar desk-top personal computer has more computing power than an IBM 7090 at a minute fraction of the cost. In fact, a processor for the recently announced ETA 10 supercomputer would fit on a desk top. The mass production of chips has led not only to processors for desk-top computers but also to the development of systems in which processors may be used concurrently in parallel, either independently or jointly on a given task. The ideas of exploiting parallelism are not new, and various forms of parallelism exist to differing degrees in all computers at the arithmetic and storage levels. Historically, parallelism at the processor level was an integral part of the early ILLIAC design but was obviated by progress in microelectronics. The difficulties confronting smaller chip design and the economy of mass production of chips has led to a renaissance in parallel processing.

Current generation supercomputers are configured with a few vector processors in parallel. Examples are the CRAY XMP (2 or 4 processors), CRAY 2 (8 processors) and ETA 10 (8 processors). Much of the scientific calculation performed using these computers is still in serial mode with the processors used independently on different problems to increase throughput. Opportunities to multitask (or microtask) a single large-scale problem exist, and this is a topic of current study. Rather than use a few very sophisticated processors, one can also consider linking many simpler processors into a highly parallel distributed network. Each individual processor costs little but is far slower than the parallel supercomputers mentioned above. The essential idea is to partition the calculation among many processors uniformly to achieve high computation speeds.
The hypercube design has been developed as an

CH2345-7/86/0000/0535$01.00 © 1986 IEEE

effective means of linking processors in a parallel computing system. For example, the INTEL IPSC Hypercube became available in 1985, and is presently configured in 32, 64 and 128 processor versions. In April 1986, the FPS-T series appeared, also configured using the hypercube concept, but involving more advanced vector processing units. Other parallel computers, such as the Balance 8000, are also in research use.

The introduction of vector processors and now of parallel processing has led us to re-examine numerical methods and algorithms that were previously developed and refined for sequential scalar calculations. Features of a numerical method and the associated algorithm, that proved inefficient for sequential scalar calculations, may now be quite attractive (and vice versa; see, e.g., Fox and Otto [1984], Voigt [1985]). In the next section, we examine this issue further in the context of finite element methods and algorithms.

Finite Elements

The finite element method grew out of the need to solve accurately structural analysis problems in the aerospace industry during the late 1950's. Although the mathematical ideas had been outlined earlier in the appendix of a paper by Courant [1943], it was not until advanced electronic computers were widely available that the method could be effectively applied for routine engineering computations. Since this period, finite element techniques have evolved rapidly and are now established as a basic method for solving boundary and evolution problems in science and engineering. In a finite element analysis, the problem is formulated in a weighted integral sense and a piecewise-polynomial approximation sought on a discretization of the domain composed of 'elements' of simple shapes. Contributions of each element to the associated discrete system are computed independently and the resulting numerical linear algebraic problem solved using sparse matrix methods.

Point iterative methods were used initially for finite element system solution due to the limited fast memory available. Since engineering design problems in structural analysis frequently involve many right-hand side vectors, factorization of the system matrix followed by repeated substitution sweeps was preferable. This has become the prevalent approach for system solution and is used widely with such sparse solution schemes as simple banded solvers, envelope (or profile) solvers and frontal solvers. For problems with few right-hand sides, iterative techniques may be a viable alternative, particularly when very large-scale problems are considered and memory limitations again become a significant constraint. On the other hand, iterative methods are most effective when the matrix is symmetric positive definite. While iterative methods may also be successful for other matrices, special preconditioning strategies are frequently required; in certain important classes of problems including, for instance, convection-dominated transport the methods fail or may not be practical.

In finite element analysis of time-dependent problems using implicit integration or of nonlinear problems, sparse linear system solution is still required, and the above considerations again apply. The availability of very large fast memory on the CRAY 2 permits sparse elimination solution of very large three-dimensional problems, but this is generally not feasible with other existing single or parallel systems.

There are several levels at which one can identify parallelism, ranging from concurrent physical processes through the choice of mathematical model to the selected algorithms for numerical solution. These ideas and several strategies for concurrent processing are discussed in a previous study (Carey [1986]) and detailed studies presented by several contributors to the same special journal issue on "PDE's and Algorithms on Advanced Processors." (See, for instance, the articles by Seager [1986] on conjugate gradient multitasking, Rodrigue [1986] on subdomain splitting, Adams [1986] on multicolor iterative methods, Kincaid et al. [1986] on vectorized iterative methods and McBryan and Van de Velde [1985] on elliptic methods, among others. The earlier ASME monograph, edited by Noor [1983], gives a broad overview of other developments in this area.

In the present study, we will focus specifically on the inherent structure of the finite element method as derived from the integral statement of the problem and the independence of element calculations. This philosophy can also be successfully incorporated in the solution procedure, by re-designing the solution algorithms appropriately.

Let us consider the three main steps in a finite element scheme:

(i) Preprocessor - Here, we define the domain, problem data, control variables and then generate the mesh. The significant computation is the mesh generation, and various strategies may be used to this end. These range from interpolatory mapping using the element basis to solution of Laplace-type problems for the nodal coordinates. Since the latter procedure can itself be posed as a finite element problem on a rectangular domain, the arguments in (ii) for vector and parallel calculations also apply to this subsidiary problem.

An effective procedure that lends itself to concurrent computing is the block method of generating a mesh: The global domain is partitioned to a number of major subdomains 1, 2, ..., NS where NS is related to the number of processors NP available (e.g., NS = m NP , integer m). The partition topology of the mesh is resident in each processor (or in a control processor). Subdomain meshes are generated by each respective processor to yield the desired nodal coordinate data and element data. Across the interface between adjacent blocks, shared nodal point information and element connectivity information is "exchanged." Hence, communication is proportional to the number of interfaces in the partition and processing time to the density of the mesh in each subdomain, as well as the number of subdomains NS and number of processors available NP .

(ii) Processor - In the processor, the main element computations and system solution are carried out. Recall that in standard practice the element matrix and vector contributions are calculated sequentially for each element and "assembled" to the global finite element algebraic system. Since the element calculations are independent, they may be made concurrently in parallel. There are two main choices. First, elements can be processed NP at a time until the element list is exhausted. (The elements are dealt out to the processors in any order.) Alternatively, we can retain the subdomain format and again assign processors to specific subdomains: Processor 1 computes all element contributions associated with subdomain 1, and so on.

The assembly step must also be considered. If each processor has sufficient local memory, then the element contributions can be assembled locally, independently and concurrently. Following this, global communication across the interfaces between subdomains can be introduced to complete the assembly of the interface equations. This yields a global sparse matrix problem which can be partitioned in various ways for efficient parallel elimination or iterative solution.

Rather than assemble to the global system and solve as indicated, one can instead retain the original subdomain-processor format. Using, for instance, the idea of substructure analysis, we can pre-eleminate the interior unknowns in each subdomain to construct, in essence, subdomain "super-elements." These super-elements can be assembled in the standard way to give a reduced system corresponding to the unknowns on the interface. Assembly again requires exchange of information at the common interfaces and accumulation of nodal equations, with some overlap of communication and computation.

Iterative methods can also be combined with the above strategy as, for instance, in block iteration for each of the subdomain blocks. Here, all the internal degrees of freedom are retained in each block matrix. For a residual-based iterative method, the block matrix operations can be made concurrently, with exchange of information concerning residual vectors at the interfaces only. We discuss this scheme in more detail later.

(iii) Post-Processing - The finite element vector of nodal unknowns (displacements, potentials, temperature, etc.) may be used to determine subsidiary results (stresses, velocities, fluxes, respectively) of engineering interest. Furthermore, in adaptive refinement procedures, the finite element solution on a given mesh is post-processed to compute the error indicator of each element for the refinement algorithm (see, e.g., Carey and Oden [1984]). Both the indicator calculation and the refinement procedure can be carried out by different processors on separate subdomains. However, some caution must be exercised again at the interfaces to ensure compatible refinements here between adjacent subdomains and the problem complexity is significantly increased. Energy integrals on the entire domain and similar global scalar quantities must be accumulated and, hence, requires communication among processors.

Summarizing, one variant of the parallel finite element scheme proceeds as follows:

(1) The domain is partitioned to major blocks;
(2) Mesh generation is carried out concurrently on blocks (subdomains);
(3) Element matrix calculations are carried out sequentially within blocks but in parallel between blocks;
(4) (a) Pre-eliminate internally within blocks, concurrently, or
    (b) Block matrix-vector products for iteration concurrently;
(5) (a) Solve reduced system by parallel-vector elimination, or
    (b) Update residuals at interfaces during iteration;
(6) Post-process within blocks for element derivatives, integrals, error indicators, etc.

Remarks: (1) For "massively parallel" architectures, the subdomain size will be relatively small and, hence, the amount of computation on each processor proportionally less. For some of the steps above, e.g., (3), (4) and (6), little or no processor communication is involved. Step (5), however, requires exchange of data between processors at the block interface and communication considerations become more significant (see also Gannon and von Rosendale [1984).

(2) As indicated previously, the scheme above can be extended to treat nonlinear problems and time-dependent problems. For instance, in a successive approximation or Newton scheme, the coefficient matrix and right-side vector of a linear algebraic system are recomputed element by element within subdomains in each step of the nonlinear iteration. Hence, steps (3)-(5) above are then simply embedded within the outer nonlinear iteration. In the time-dependent case, if an

implicit scheme (e.g., Crank-Nicolson) is used, we again have a linear (or nonlinear) system to solve at each time step, so steps (3)-(5) are carried out in each time step. Adaptive stepsize control based on, say, truncation error estimates will require minimal communication between processors. Explicit time integration is, of course, simpler to implement and vectorize within subdomains. Using differing time steps in different subdomains increases the complexity and communication an order of magnitude.

Example: Subdomain Block Iteration. As an illustrative example, we consider the use of a block iterative solution scheme 4(b) and 5(b) for system solution. Let the domain be partitioned into NS = NP subdomains where NP is the number of processors. The subdomain and processor interconnection topology are common. Let $e_1, e_2, \ldots, e_{NS}$ be the number of elements generated in each subdomain.

The main calculation in a residual-based iterative solution (e.g., conjugate gradient solution) of the linear system

$$\utilde{A}\utilde{u} = \utilde{b} \qquad (1)$$

is the matrix vector product in the residual calculation for iterate k

$$\utilde{r}_k = \utilde{A}\utilde{u}_k - \utilde{b} \qquad (2)$$

Let us consider the product $\utilde{A}\utilde{v}$ for $\utilde{v} = \utilde{u}_k$ with our block partition. We can write

$$\utilde{A}\utilde{v} = \left(\sum_{s=1}^{NS} \hat{\utilde{A}}_s\right)\utilde{v} = \sum_{s=1}^{NS} \left(\hat{\utilde{A}}_s \hat{v}_s\right) \qquad (3)$$

where $\hat{\utilde{A}}_s$ is the "expanded" matrix obtained by accumulating all element contributions to subdomain s with all other entries of $\hat{A}_s$ (corresponding to the other blocks) zero. Similarly, $\hat{\utilde{v}}_s$ is an "expanded" vector of nodal values associated with the nodes of block s and with all other components zero. Clearly, the product in (3) can be obtained by computing only the block matrix product $\bar{\utilde{A}}_s \bar{\utilde{v}}_s$ where $\bar{\utilde{A}}_s, \bar{\utilde{v}}_s$ are the restrictions of $\hat{\utilde{A}}_s, \hat{\utilde{v}}_s$ to block s .

Hence, the main steps in the algorithm involve:

(1) the sequential calculation of the element contributions $\utilde{A}_e$, $\utilde{b}_e$ for element e = 1, 2, ..., e_s with accumulation to $\bar{\utilde{A}}_s$, $\bar{\utilde{b}}_s$ in each block s ;

(2) the sparse vectorized block matrix products $\bar{\utilde{A}}_s \bar{\utilde{v}}_s = \bar{\utilde{w}}_s$ in each block s to obtain the block residual $\bar{\utilde{r}}_s = \bar{\utilde{b}}_s - \bar{\utilde{A}}_s \bar{\utilde{v}}_s$;

(3) accumulation of the residual component r_{is} for nodes i on the interface of subdomain s , requiring communication between "adjacent" processors. (Fetch and add r_{is} from subregions s adjacent to node i , $r_i = \sum r_{is}$, then send r_i back to r_{is} for adjacent subregions);

(4) update solution vector $\utilde{u}_s$ on each subdomain s , accumulate solution components u_{is} for nodes i on the interface of subdomain s and send the revised interface values back to the subdomains;

(5) Repeat steps (2)-(4).

Remark: Several variants of this scheme are possible, including, in particular, element-by-element accumulation of residuals within each subdomain using the strategy of Carey and Jiang [1986]. This necessitates slightly more computation on each processor, but storage is now negligible so the approach is suitable for architectures with small, fast local memory.

PARALLELISM IN SOLVING PDES

John R. Rice*

Department of Computer Science, Purdue University
West Lafayette, IN, 47907

ABSTRACT

This paper examines the potential of parallel computation methods for partial differential equations (PDEs). We first observe that linear algebra does not give the best data structures for exploiting parallelism in solving PDEs, the data structures should be based on the physical geometry. There is a naturally high level of parallelism in the physical world to be exploited and we show there is a natural level of granularity or degree of parallelism which depends on the accuracy needed and the complexity of the PDE problem. We discuss the inherent complexity of parallel methods and parallel machines and conclude that dramatically increased software support is needed for the general scientific and engineering community to exploit the power of highly parallel machines.

I. INTRODUCTION AND SUMMARY

This paper examines the potential for the use of parallelism in the solution of partial differential equations (PDEs). There are six principal points made as follows:

1. Linear algebra is not the right model for developing methods for PDEs and it is particularly inappropriate for parallel methods.
2. The best data structures for PDE methods are based on the physical geometry of the problem.
3. Physical phenomena have large components that inherently parallel, local and asynchronous. Parallel methods can be found to reflect and exploit this fact.
4. There is a natural granualarity associated with parallel methods for PDEs. The best number of "pieces" and processors depends on the complexity of the physical problem, the accuracy desired and properties of the iteration used.
5. Parallel machines are very messy and it is essential for most users that one have very high level PDE systems to hide this mess.
6. There is much to be gained to using regularity in parallel methods, but one should not carry this to extremes.

II. LINEAR ALGEBRA DOES NOT GIVE THE BEST DATA STRUCTURES

In recent years there have been numerous papers written about linear algebra on parallel/vector machines (see Hwang[2], Sameh[5] and Ortega and Voight[3] for surveys and further references). Many machines have been designed to provide very high performance for linear algebra computations (see Hwang and Briggs[1] and Hwang[2] for surveys and further references). Most of this work is motivated or justified in some part by applications to solving PDEs. Solving large linear problems is an inherent step in solving PDEs and it is usually the most expensive step, yet the thesis of this section is that most linear algebra approaches can be misleading for exploiting parallelism in solving PDEs.

A case in point is *nested dissection*. This was a breakthrough in solving PDEs, one that many people (including myself) had searched for over a period of decades. The original presentation by Alan George of nested dissection was inscrutable. If one starts (as everyone did) with the linear algebra problem $Ax = b$, then to discover nested dissection, one had to see that a matrix rearrangement such as shown in Figure 1 was the "right" way to eliminate the unknowns. However, if one expresses the reordering in terms of the underlying geometry of the PDE, one sees that nested discretion is a natural divide and conquer algorithm. It is then easy to understand why the method works so well, to see how to extend it to nonrectangular domains or to 3 dimensions or to finite element methods.

If one starts with a conventional matrix/vector representation of a PDE computation it is much harder to find efficient methods because the inherent structure of the PDE problem is so distorted by conventional matrix/vector representations. This is further illustrated in Figure 3 which shows the conventional matrix structure obtained by discretizing a second order PDE with derivative boundary conditions on the domain shown there. It is a computational tour-de-force to recover from Figure 3 the information that is superficially apparent in the domain picture.

* This work supported in part by Air Force Office of Scientific Research grant AFOSR-84-0385.

The shortcomming of the conventional linear algebra approach is that the right data structure is not used, instead one should base the data structure on the underlying physical geometry. Figure 4 shows a domain which has been "exploded" to group "like-kinds" of elements together in a PDE problem. A method that is really successful in exploiting parallelism in this problem must "know" this structure, the most practical way to know it is to have it given explicitly in the data structure. More complex problems have other structure (interfaces, singular points, etc.) that can be incorporated in a similar way. It is not just parallelism in the computation that needs information such as seen in Figure 4, the control of numerical methods also need it. Numerical models need to be more accurate (e.g., grids need refining) near special locations. The partitioning of the computations for rapid convergence in iterative methods is strongly influenced by this information.

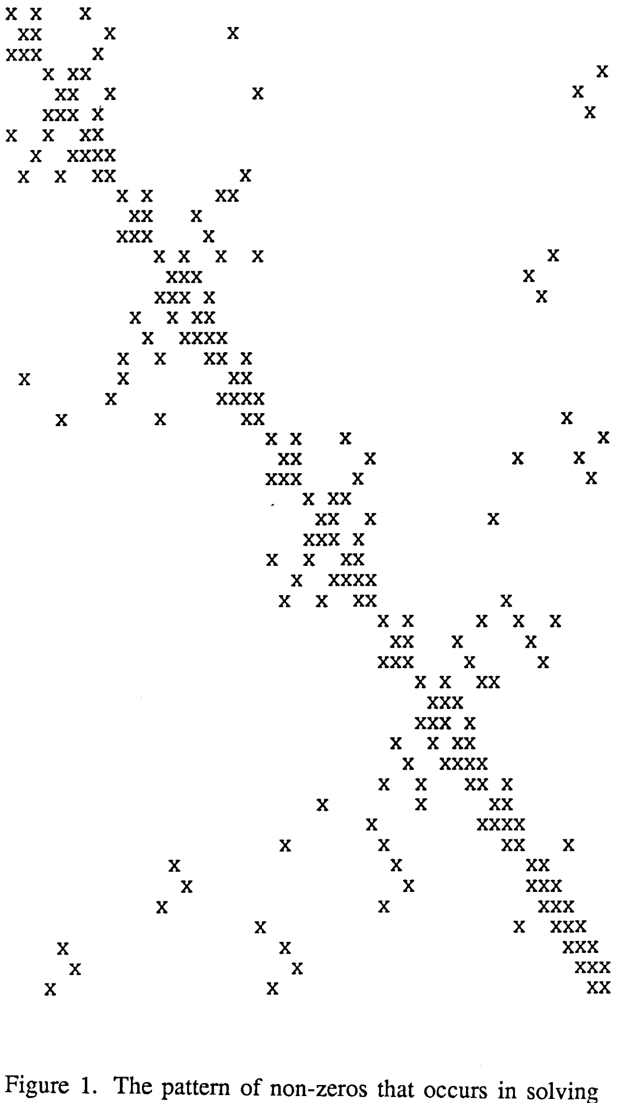

Figure 1. The pattern of non-zeros that occurs in solving Laplace's equation using the nested dissection ordering of the conventional matrix formulation using finite differences.

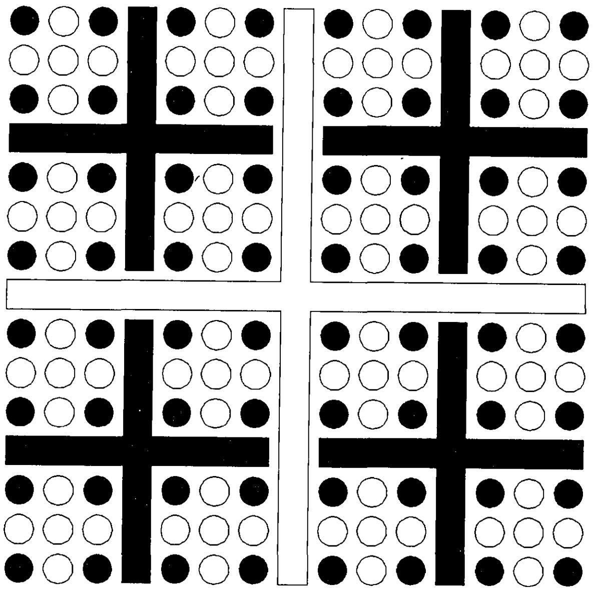

Figure 2. A visualization of the nested dissection ordering shown on a two dimension grid. Points are grouped in isolated blocks, one point per block at the first level, then 9, then 49, then 225 and so on.

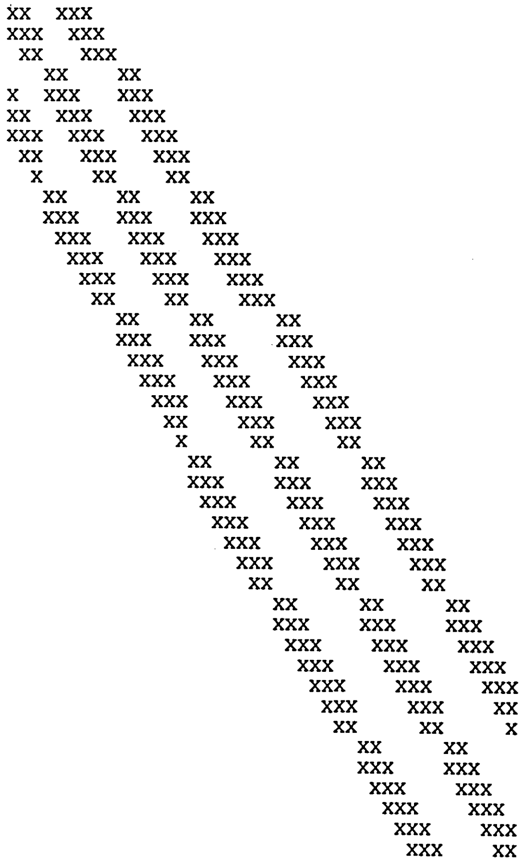

Figure 3. The conventional matrix structure obtained from a 9-point finite difference discretization on the domain of Figure 4.

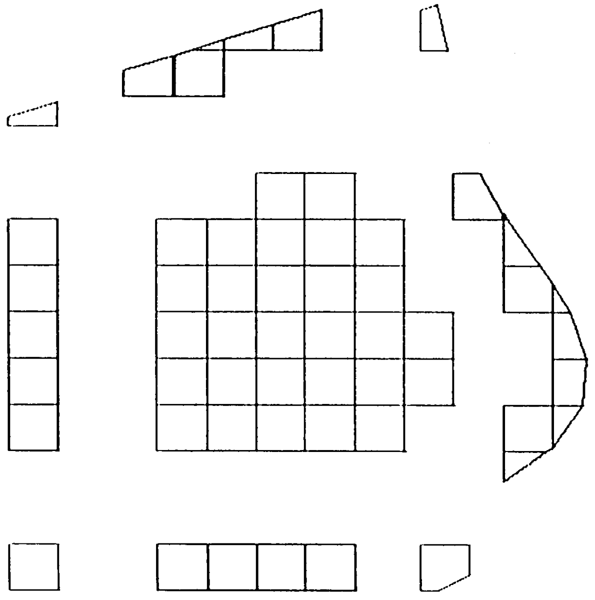

Figure 4. An exploded view of a physical domain which shows the elements of a "like" nature grouped together. The groupings are the first step in determining an appropriate structure in the problem of an efficient parallel method.

III. PARALLELISM IS (ALMOST) UNLIMITED IN SOLVING PDEs

We claim that the physical phenomena that PDEs model are inherently local in space and asynchronous. Locality means that the phenomena are inherently amenable to parallel methods, the computation done at point A does not depend on anything being done at the physically distant point B. There are logical limits to the potential parallelism, we do not foresee much parallelism in time (as opposed to space) except for very special situations. There is also some sequentiality in local computations, one must compute values of coefficient functions in an equation before one can use the equation. For specific applications one can often reduce the sequential work dramatically by preprocessing computations (i.e., computing everything possible as soon as possible).

The preceding observations are based on asymptotic considerations, i.e., if the physical domain is big enough and the accuracy required is high enough then any fixed number N of processors can be used profitably. We argue, however, that there is natural optimal or appropriate granularity and number N of processors associated with any particular PDE computations. We measure granularity in terms the number N of *elements* of the computation or model of the physical object. For simplicity we ignore any cases where computational elements do not correspond naturally with physical elements. The two extremes are:

(i) $N = 1$ processor gives 1 element which gives a sequential computation which gives very limited speed.

(ii) N very large (one Cray 2 per atom in a river?) gives a huge number of elements which gives very high parallelism which gives almost unlimited speed.

There are four considerations (at least) besides cost which lead to the existence of an optimal granularity, they are

1. Every problem has an *acceptable solve time* beyond which solving it faster does not matter.
2. Every problem has an *acceptable accuracy* beyond which more accuracy does not matter.
3. For a fixed physical problem, the number of interfaces between elements grows with the number of elements, thereby increasing the complexity and communication requirements of the computation. This growth might be very slow.
4. For a fixed problem and method, the total work might eventually grow faster with N than parallelism reduces it because of slower convergence of iterative methods, etc.

Having identified granularity with N, we see that the independent variables in an application design are N, the desired elapsed time T and the required accuracy ε. Assume now that ε behaves in a known way, that it is fixed and we only consider choosing N to achieve a specified T value. Figure 5 shows an idealized plot of cost versus time to solve a particular problem using a fixed number N of processors. The key points are that there is a lower limit on time (because processors can go only so fast) and that cost quickly reaches a plateau as the time increases. Figure 6 shows a different view of the situation, cost versus N for a fixed time to solve a particular problem. Again there is a lower limit because processors can go only so fast, but there is also an optimum. As N increases the cost starts to increase because of idle processors and/or increased communication (overhead) costs.

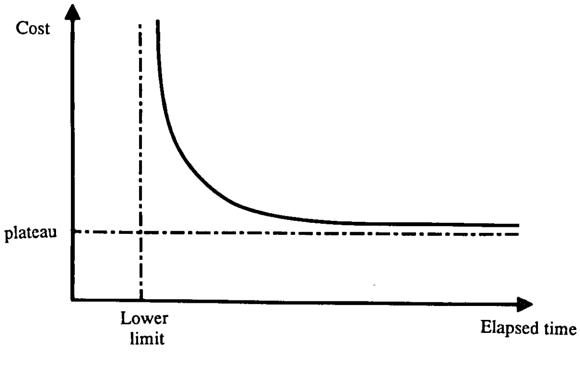

Figure 5. Cost versus elapsed time to solve a particular problem using N processors.

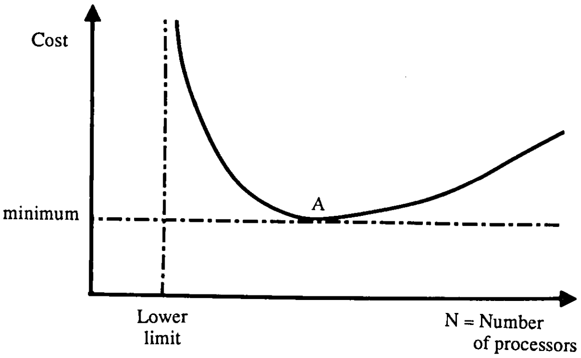

Figure 6. Cost versus the number of processors N used to solve a particular problem in a fixed elapsed time. The point A gives the minimum cost using an optimal number of processors.

We can replot the information of Figures 5 and 6 in the (N, T) plane and show two curves: the limiting curve of what is possible and the curve of optimal combinations of T and N. This is shown in Figure 7, the shapes are purely conjectural, one does not know what they are. It is true that cost decreases monotonically from point C to D.

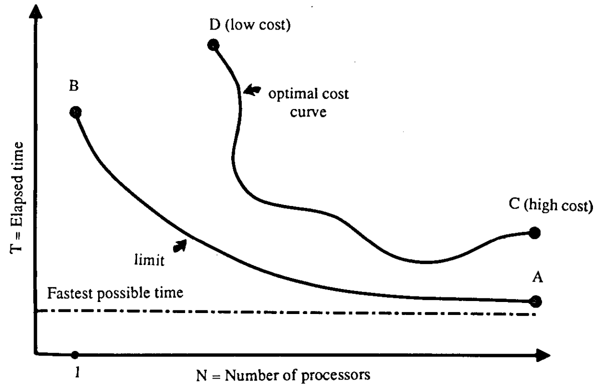

Figure 7. The (N, T) plane showing the limiting curve (A to B) of what is possible and the locus (C to D) of optimal cost combinations of N and T.

Thus we see that while in principle there might be no limit on the amount of parallelism that can be used in solving PDEs, there is definitely such a limit for any fixed application. Very little is known about actual values for real problems. I believe we are very far from the methods that give optimal time or cost in solving PDEs. On the other hand, I find it very convincing to argue that many real problems are very complex and that to achieve ''engineering'' accuracy and ''reasonable'' elapsed time with even a low cost method (never mind optimal cost) will use thousands of processors.

IV. PARALLEL METHODS REQUIRE NEW SOFTWARE SYSTEMS

Parallel machines are already rather complex, much more so than previous computers. They will become even more complex as it is discovered that a mixed set of capabilities provides more efficient computing. There will be variety is everything: processors (integer, floating point, graphics, vector, FFT, ...), memory (local, global, cache, archival, read only, ...), I/O (keyed, text, graphics, movies, acoustical, analog, ...), communication (message passing, packets, buses, synchronous/asynchronous, hypercubes, high/low speed, long haul, ...). The difficulty in managing (programming) this complexity is easily an order of magnitude higher than for present machines. The difficulty is compounded by the fact that changes in the capabilities available will become much more frequent.

The current programming methodology for solving PDEs is that of Fortran. One has a fairly intelligible language where one can exert fairly direct control of the machines resources. Each Fortran statement is typically implemental by 5-10 machines instructions. There must, I believe, always be such a language and I believe that Fortran will be expanded to handle the greater complexity of the machines. It might also be replaced by another moderate level language with such capabilities, e.g. Ada or C suitably enhanced. However, it will no longer be reasonable to expect the end-user scientists and engineers, the people who solve PDEs, to learn how to manage this complex computational environment. They will generally not do a very good job of it and, even if they did a good job, it would be a great waste of talent and duplication of effort. The potential benefits of parallel computation will not be achieved if every user has to master (even partially) how to manage such complex machines.

The solution to this problem is to substantially raise the level of the user's ''programming'' language. He must be able to say in a natural and succinct way what is to be done. In the PDE context they should be able to say things like:

1. Solve
   $(1+x^2)u_{xx} + u_{yy} - \sin(\alpha y)u = \text{Force}2(x, y)$
   on the Domain #12
   with $u = 1$ on the boundary.
2. Use finite differences with a 40 by 40 grid
   plus SOR iteration

3. Show me plots of u , u_x and u_y

In fact, we must aim eventually for the situation where statement 2. is replaced by

2a. Obtain an accuracy of about 0.5 percent

Then, between such a program and the Fortran level is a layer of software which has two components. The first is a set of *problem solving modules* written by people who are relatively expert in solving the problems at hand and experienced in how parallelism (or other special capabilities available) can be exploited. There will be different methods (or, at least, different implementations) in the modules suitable for important subclasses of machines.

The second component of this layer is a set of *computation management facilities* written by people who are relatively expert in memory management, network scheduling, program transformations, etc. They have spent the time to learn how to provide such facilities well and have embedded much of their expertise into their software. These two components are then integrated to provide a bridge between the high level user input and a Fortran-like program targeted for the particular machine (or machines) to be used to solve the problem.

The obvious advantage of this methodology is that, if it works, there is a dramatic reduction in programming effort. This is, of course, the goal of introducing the methodology. Note that this not being done just to reduce software costs, the "mass-market" viability of parallel computation depends on introducing a methodology which hides the underlying complexity from most users.

The obvious disadvantage of this methodology is that the intermediate layer might introduce so much in efficiency that the power of parallelism is seriously weakened or even lost. It is clear that no foreseeable software for managing a computation can be as clever, resourceful and effective as clever, experienced people. This fact is a smokescreen that obscures a much more relevant "fact": people, even clever and experienced ones, almost never get close to "optimal" computations because they do not take the time to do it, it is inordinately expensive to do so. The result is that a good software system, one with many flaws which does many obviously stupid things, consistently can produce moderately good implementations which are significantly better than the ones people consistently produce. Scientific evidence to support this fact is scarce, but there is one solid data point.

Figure 8 shows a program written in DEQSOL, a high level PDE problem solving language under development at Hitachi. No attempt is made here to explain DEQSOL. Hitachi has two PDE application programs that were written in FORTRAN prior to their vector supercomputer and DEQSOL efforts. These programs were brought into their vectorizing Fortran compiler environment and hand tuned to run well on their machines. The problems being solved were later reprogrammed in DEQSOL which produces a Fortran program which then use the vectorizing Fortran compiler but no hand tuning. The results of this experiment are shown below.

```

Figure 8. A DEQSOL program for solving a partial differential equation. This is a three dimensional, time dependent diffusion equation.

	A	B
FORTRAN:		
lines of code	1361	1567
execution time (sec.)	2.3	5.8
DEQSOL:		
lines of code	127	132
execution time	0.6	1.8
speed up factor	3.8	3.2

We see that not only was the programming effort reduced by the least an order of magnitude, but there was also a very worthwhile *gain* in execution speed. Keep in mind that a speedup of 3 or 4 is the typical total benefit achieved from using vector hardware on Cray and Cyber 205 machines.

We illustrate the power that can be achieved using such high level languages by considering the Plateau problem:

$$(1 + u_x{}^2)u_{xx} - 2u_x u_y u_{xy} + (1 + u_y{}^2)u_{yy} = 0$$
$$u(x, y) \text{ given on the boundary of a region } R \qquad (1)$$

This is classical difficult PDE problem, its solution is the surface that a soap film takes on for a wire frame bent according to the value specified on the boundary of R. We solve this problem for the domain R (shaped like a piano top) explicitly defined in Figure 9. The high level language used is that of ELLPACK[4] one that provides modules and facilities for solving linear PDEs.

Figure 9 shows an ELLPACK program to implement Newton's method for (1). We do not explain the ELLPACK language here. A simple initial guess is made and the convergence is quite rapid in spite of the fact that the solution has a singularity (the wire has a sharp bend) along one side. The maximum differences between iterates are: 1.24, .30, 9.6×10^{-3}, 2.4×10^{-5} and 5×10^{-7}. The round off level (on a VAX 11/780) is reached at five iterations.

Our final point in the software and programming area concerns the role *regularity* in data structures, in algorithms and in programs. Clever programmers and hardware designers can do a lot of special things to exploit special situations. This exploitation is usually achieved at the cost of more complex software and hardware. Thus there must be a balance between the execution time costs and the design costs of software and hardware. While it is hard to defend general statements on the matter, we believe that the optimum lies nearer to regularity and its attendant simplicity than it does to irregularity and its attendant complexity. However, we feel *extreme* simplicity is not the best approach either.

This view is illustrated by an example in discretizing a domain. Figure 10 shows a physical domain that has been partitioned in six ways for a problem with difficulties near the right boundary:

(A) A fine triangulation of a common type

(B) A fine, uniform, rectangular overlay grid

(C) Mapping the domain to a rectangle and inducing a logically rectangular partition

(D) Triangulation adapted to the difficulty

(E) Rectangular overlay grid adapted to difficulty

(F) Logically rectangular partition adapted to difficulty

```

```

Figure 9. An ELLPACK program for applying Newton's method to solve the Plateau problem. The procedures *bound*, *diffu*, *gessu* = *xy* /4 and *save* are defined by 22 lines of Fortran not shown here.

We believe that the irregular triangulations do not provide any execution time advantage over the more regular partitions (one can do a regular triangulation if one wants). On the other hand, we also believe that the uniformly spaced partitions are too simple and have too large an execution time penalty. We believe the adaption will pay off. The logically rectangular discretization is the simplest to program but the relative execution efficiencies resulting from (E) and (F) are not clear. Thus we believe that the search for the "best" method should be concentrated on partitions like (E) and (F) but there are still many undetermined degrees of freedom.

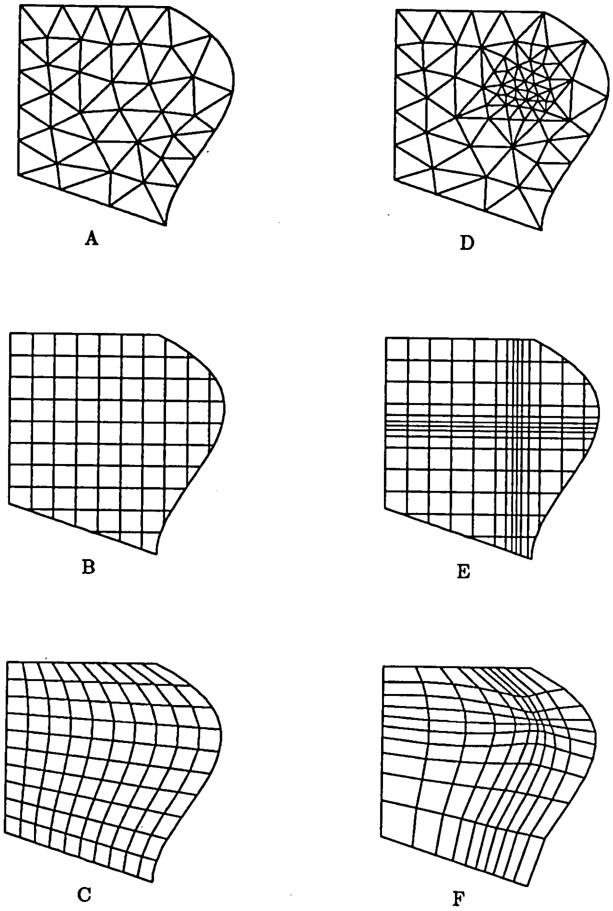

Figure 10. Six ways to partition a domain showing ways to achieve regularity and to adapt to a difficulty. The letters A through F refer to the discussion in the text.

GEOPHYSICAL MODELING - MIGRATION VIEWED AS A SPECTRUM OF SUPERCOMPUTER APPLICATIONS

Olin G. Johnson
Oliver Lhemann

Houston Area Research Center and University of Houston
Cray Research Inc., Minneapolis, Minnesota

ABSTRACT

This paper develops the thesis that no single algorithm is appropriate for all modeling-migration problems. Restricting attention to a single 3D problem size of 200^3 space points and 2,000 time points, the amount of computing required for migration can vary by two orders of magnitude depending on the complexity of the problem.

A review of reported timing results over the past four years leads to the identification of three classes of algorithms appropriate for three corresponding migration problem complexity levels. Both the computational and I/O requirements of these algorithm classes are discussed. Trade-off techniques for swapping I/O for computing are discussed and examples are given for the resulting CPU times. Graphical results from a variety of 3D problems are given.

INTRODUCTION

The successful replication of the methods of reflection seismology in scaled modeling tanks over the past few years has at last turned exploration geophysics into a laboratory discipline. Pioneering organizations such as the Seismic Acoustics Laboratory (SAL) at the University of Houston now have extensive catalogues of seismic sections in both 2D and 3D corresponding to layered structures of known dimensions and acoustic properties.

These data sets are invaluable in research efforts directed to duplicating these techniques with computerized models and in testing seismic codes. The Keck Research Computation Laboratory (RCL), a sister laboratory to SAL, primarily pursues research in the use of supercomputers, array processors and parallel computer ensembles in the 3D exploration geophysics area.

Several modeling and migration algorithms have been studied, programmed and tested for accuracy of results using the SAL data.

Two models and their respective data sections are used here. The Wedge Model, pictured in Figure 1, is a simple three layer model with a silicon rubber wedge setting on a plexiglass plate, all submerged in water. Figure 2 exhibits a 3D seismic section of the SALNOR7 model that illustrates a typical complicated North Sea geological structural sequence. The model consists of seven horizons that represent the top Paleocene, top Cretaceous, J-Unconformity, top Brent, base Brent, top Statfjord and base Statfjord. A 3D data set consisting of 240 traces on 240 lines has been collected. Each trace contains 3000 samples at 1 ms. A complete description of this model is given in (Nelson et al., 1982).

The computational methods reported here fall into two categories: phase shift techniques which allow no lateral variation in velocity and phase shift plus some type of correction which allow "mild" lateral variations. Methods which allow arbitrary lateral variations are available[7]. In the 3D case of size 200^3 space points and 2000 time points, such techniques require several hours of computation on present generation supercomputers.

As will be shown, the computational requirements for these three algorithms can vary by two orders of magnitude.

A primary objective of the RCL program has been to construct the fastest 3D migration program possible. This is accomplished by limiting the data to a single velocity function and optimizing and parallelizing the data handling sections of the code.

HYPERSPEED MIGRATION

In Lhemann[8] a code for 3D migration based on the Phase Shift and PSPI algorithms is described which took less than three minutes of supercomputer wall-clock time to migrate the North Sea data cube of size 256x256x2048.

The Phase Shift migration method is based upon the scalar wave equation

$$\frac{1}{V^2}\frac{\partial^2 p}{\partial t^2} = \frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial y^2} + \frac{\partial^2 p}{\partial z^2} \qquad (1)$$

where $p = p(x,y,z,t)$ is the pressure field, x and y are the midpoint variables, z is the depth, t is the two-way travel time, and V is the half velocity. Assuming the V does not depend on x or y, the Fourier transform with respect to x, y and t leads to the following equation

$$k_x^2 P + k_y^2 P + \frac{\partial^2 P}{\partial z^2} = \frac{w^2 P}{V^2} \qquad (2)$$

with $P(k_x,k_y,z,w) = FFT_{x,y,t}[p(x,y,z,t)]$. Grouping all terms depending on P on one side, one gets

$$\frac{\partial^2 P}{\partial z^2} = (\frac{w^2}{V^2} - k_x^2 - k_x^2)P$$

Let $$k_z = \pm \sqrt{(\frac{w^2}{V^2} - k_x^2 - k_y^2)}$$

then $$\frac{\partial^2 P}{\partial z^2} = - k_z^2 P. \qquad (3)$$

The non-negative (complex) value of k_z is taken reflecting the downward extrapolation of the recorded seismic data in the migration process.

This last equation (3) has an analytical solution

$$P(k_x,k_y,z+\Delta z,w) = P(k_x,k_y,z,w)\exp(ik_z\Delta z) \qquad (4)$$

In practice, a phase shift migration first reads the seismic data $p(x,y,z=0,t)$ and performs a triple Fourier transform to get $P(k_x,k_y,z=0,w)$. The Phase Shift Factor (PSF) $\exp(ik_z\Delta z)$ is then calculated, and downward extrapolation is applied as given by equation (4). The migrated result (in the space domain) is obtained after $P(k_x,k_y,z,w)$ has been calculated for all w by summing over all w[7].

$$P(k_x,k_y,z,t=0) = \sum_w P(k_x,k_y,z,w). \qquad (5)$$

The final section $p(x,y,z,t=0)$ is obtained by performing a double inverse Fourier transform in the space domain.

The Phase Shift algorithm has a lot of practical advantages, it is unconditionally stable, accurate and the amount of computation involved is limited. Gazdag's[8] generalization of this algorithm, Phase Shift Plus Interpolation (PSPI), treats laterally varying velocity fields and consists of two steps. In the first step, the wave field is extrapolated as described above, using n different laterally uniform velocity fields. In the second step the actual wave field is computed by interpolation from the n reference wave fields. In the usual case where n is equal to 3 (minimum, maximum and average velocities) one obtains three fields P1, P2 and P3 at depth $z+\Delta z$. To get the actual field $P(k_x,k_y,z+\Delta z,w)$ one must perform an interpolation between the 3 previous fields. Since this interpolation depends on the velocity structure, a double inverse Fourier transform must be performed for each of the fields ($P1(k_x,k_y,z+\Delta z,w)$, $P2(k_x,k_y,z+\Delta z,w)$ and $P3(k_x,k_y,z+\Delta z,w)$ to get $p1(x,y,z+\Delta z,w)$, $p2(x,y,z+\Delta z,w)$ and $p3(x,y,z+\Delta z,w)$.

This is then followed by a three-point Lagrangian interpolation.

$$p(x,y,z,t = \frac{(\frac{1}{V} - \frac{1}{V3})(\frac{1}{V} - \frac{1}{V2})}{(\frac{1}{V1} - \frac{1}{V3})(\frac{1}{V1} - \frac{1}{V2})}\, p1(x,y,z,t)$$
$$+ \frac{(\frac{1}{V} - \frac{1}{V1})(\frac{1}{V} - \frac{1}{V3})}{(\frac{1}{V2} - \frac{1}{V1})(\frac{1}{V2} - \frac{1}{V3})}\, p2(x,y,z,t)$$
$$+ \frac{(\frac{1}{V} - \frac{1}{V1})(\frac{1}{V} - \frac{1}{V2})}{(\frac{1}{V3} - \frac{1}{V1})(\frac{1}{V3} - \frac{1}{V2})}\, p3(x,y,z,t)$$

The velocities V1, V2 and V3 are the reference velocities defined previously. $V = V(x,y,z)$ is the actual 3D velocity field. The migrated result at depth $z+\Delta z$ is obtained by summing over w all the planes $p(x,y,z+\Delta z,w)$. To go deeper one must take the double Fourier transform of the previous plane and repeat the process just described.

The PSPI program requires a complete 3D velocity model and is much slower than simple phase shift. However, phase shift is quite adequate for sedimentary sections and can serve as the basis of a hyperspeed code.

A first estimate of the amount of I/O required by the Phase Shift algorithm to migrate the SALNOR7 model gives ($4*10^6$ sectors) and so, assuming the average transfer time of a sector to be 0.7 ms, results in a time of 2800 s for the I/O. This number is much bigger than the estimated CPU time (around 140 s) required by present supercomputers.

A second look at the algorithm indicates that the minimization of disk transfers is equivalent to keeping in memory, as long as possible, each plane $P(k_x,k_y,z,w)$. An obvious solution simply consists in switching the frequency and the depth loops. $P(k_x,k_y,z=0,w)$ is loaded only once for a fixed w, and all extrapolation steps can be performed in core to get $P(k_x,k_y,z=z+\Delta z,w)$, $P(k_x,k_y,z=z+2\Delta z,w)$ ... up to the maximum depth $P(k_x,k_y,z=z+NZ\Delta z,w)$.

If there is not enough space in main memory, the previous planes will have to overwrite each other during the execution of the program. But before doing this each of them must be added as described in equation (5). Since present supercomputers do not have sufficient memory to treat large 3D problems in core, the trick is to work with several frequencies at the same time to reduce the I/O transfers in proportion.

If 16 frequencies are grouped together, a new estimation of the amount of I/O required by the modified algorithm is now around 175 s, instead of 2800 s. This can be reduced further by simultaneous I/O transfers. Hence, the resulting 3D migration code is compute bound.

The SALNOR7 model was padded with null traces to get 256 lines of 256 traces each for use with the FFTs. For the same reason all traces were truncated to keep only 2048 samples at 1 ms since all relevant information is at less than 2 s.

The size of the data cube is now equal to 256x256x2048, which represents a volume of 64 M words.

The maximum depth of the migrated section is equal to NZSTEP*ΔZ, where NZSTEP is the number of iterations of the depth loop. To get a good resolution, ΔZ = 10 meters and NZSTEP = 128 were used to reach the bottom of the model at Z = 1280 meters.

As seen previously, the Phase Shift migration algorithm uses a one-dimensional velocity structure. Rather than choosing average values as one would usually do, we have selected a particular section (line 120) and taken for the velocity function the actual values at a position corresponding to the middle trace. This was done in order to compare the output with previously migrated results for this particular section.

The frequency spectrum of seismic data is very limited, usually under 70 Hz. In the case of the SALNOR7 model the data were filtered by a 6 - 60 Hz band-pass filter. Since Δt is 1 ms and the number of samples is 2048, it follows that ΔHz = 1/2.048. So it is necessary to sum the computed results for the first 128 frequencies only.

To migrate the entire SALNOR7 model on presently available supercomputers, it only takes 131 s of CPU and 11 s of I/O, which gives a total run-time of 142 s. The amount of memory required by this migration program is 3.2 M words.

WAVE EXTRAPOLATION EQUATIONS

In the presence of lateral inhomogeneities in the velocity field, the extrapolation equations obtained from the Phase Shift algorithm are usually approximated and solved using finite difference extrapolators. A review of some of these approximations is given below. To simplify notation, equations are developed only for the two dimensional (2D) case. The extension to the 3D case is straight forward.

The theory of wave extrapolation is based on the assumption that the zero offset pressure data, defined in the (x,z) domain, satisfy the wave equation

$$\frac{1}{V^2}\frac{\partial^2 p}{\partial t^2} = \frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial z^2} \qquad (6)$$

with p = p(x,z,t) where x is the distance along the surface, z the depth, t the two-way traveltime, and v the half velocity.

In the case where the velocity v does not vary laterally, a double Fourier transform with respect to x and t is performed on the previous equation. We obtain

$$\frac{w^2}{V^2} P = K^2xP + \frac{\partial^2 P}{\partial z^2} \qquad (7)$$

with $P(Kx,z,w) = FFT_{x,t}[p(x,z,t)]$. From this equation, an analytical solution to the downward extrapolation problem can be deduced[6].

$$P(Kx,z+\Delta z,w) = P(Kx,z,w) * EXP(iKz\Delta z) \qquad (8)$$

$$\text{with } Kz = \pm \, SQRT(\frac{w^2}{V^2} - K^2x).$$

Among the two possible solutions, only the one with the positive sign in the exponential (or phase shift) factor is relevant. This comes from the fact that in the migration process we are only interested in waves moving in the reverse time direction.

In the case where the velocity v is a function of both x and z, the analytic solution given in (8) is no longer valid. This comes from the fact that in taking a double Fourier transform of (6), with respect to t and x, we do not get equation (7) anymore but the following

$$\frac{\partial^2 P}{\partial z^2} = w^2 \text{ FFTx } (\frac{1}{V(x)^2}) \oplus p - K^2 xp \qquad (9)$$

where ⊕ is defined as the convolution product.

The product of the inverse of the velocity by the pressure field P is now replaced by a product of convolution which rules out all chances of finding a simple analytical solution. A common method employed to circumvent this problem is to use the analytical solution derived in the constant velocity case and modify it in such a way that it can accommodate lateral velocity variations.

For this purpose, one uses the following equation

$$\frac{\partial P}{\partial z} (Kx,z,w) = i(\frac{w}{v}) \; [1-(\frac{Kxv}{w})^2]^{1/2} \; P(Kx,z,w) \qquad (10)$$

which has as solution equation (8) and is thus the exact extrapolation equation for the constant velocity case. Lateral variations of the velocity are possible if we inverse transform over x by letting iKx = Δx. Regrettably, this transform can only be performed if the square root is regarded as some kind of truncated series expansion. The square root can be developed into a Taylor series expansion[5], or as it was first suggested by Francis Muir[4], into continued fractions. In this second method, the square root

$$R = (1 - K^2)^{1/2} \qquad (11)$$

is expanded according to the following recurrence relation

$$R_{n+1} = 1 - \frac{K^2}{1 + R_n} \qquad (12)$$

in which R_n is the nth order approximation. Starting from $R_o = 1$, we obtain

$$R_1 = 1 \; \frac{K^2}{2} \qquad (13)$$

and

$$R_2 = 1 - \frac{K^2}{2 - K^2/2} \qquad (14)$$

Francis Muir showed that the original 15 degree and 45 degree methods developed by J. Claerbout[3] correspond to the expansion defined by R1 and R2 respectively.

The substitutions K = Kxv/w and Rn = Kzv/w give us the dispersion relations corresponding to these expansions. For example, the dispersion relation of the 45° method is

$$Kz = \frac{w}{V} - \frac{(v/2w)K^2x}{1 - (Kxv/2x)^2} \cdot \qquad (14a)$$

This expression can be used to replace the square root term in (10) to give us an approximated extrapolation equation

$$\frac{\partial^2 P}{\partial z^2} = i \; [\frac{w}{V} - \frac{(v/2w)K^2x}{1 - (Kxv/2w)^2}] * P. \qquad (14b)$$

Such an equation can be solved using a finite-difference scheme in the (x,w) domain. A method of resolution is discussed in Gazdag and Sguazzero[6].

These are several problems associated with finite-difference migration methods, including numerical errors resulting from the finite-different approximation used and predisposition to instability. Numerical erros can be reduced by using a small integration step ΔZ and the stability problem, is kept under control by using implicit methods. Unfortunately, such improvements appear to be quite costly in CPU time, especially for 3D problems.

THE PHASE SHIFT PLUS CORRECTION ALGORITHM

In this section, a migration algorithm suitable for variable velocity fields is introduced. Basically, the idea is first to perform a downward extrapolation of the pressure field using the phase shift algorithm and a constant reference velocity v̄. A correction term is then introduced, to take into account the lateral velocity changes in the velocity field.

If v is the actual velocity field, it is known from the previous section that the exact dispersion relation in the two dimensional case can be written in the form

$$Kz(v) = (\frac{w}{v}) * \text{SQRT } [1 - (\frac{Kxv}{w})^2] \qquad (15)$$

which, if we use the relation

$$Kz(v) = Kz(\bar{v}) + (Kz(v) - Kz(\bar{v})] \qquad (16)$$

is also equivalent to

$$Kz(v) = (\frac{w}{\bar{v}}) * \text{SQRT } [1 - (\frac{Kx\bar{v}}{w})^2] +$$

$$[(\frac{w}{v}) * \text{SQRT}[1-(\frac{Kxv}{w})^2] - (\frac{w}{\bar{v}}) * \text{SQRT}[1-(\frac{Kx\bar{v}}{w})^2]]. \qquad (17)$$

As in the previous section, velocity variations will be introduced after inverse transforming over x by Kx = Δx. This transformation is possible if the second term is developed as some kind of truncated series. Using a Taylor development and keeping only the first three terms of the development, equation (17) becomes

$$Kz(v) = (\frac{w}{\bar{v}}) *SQRT[1-(\frac{Kx\bar{v}}{w})^2] + (\frac{1}{v} - \frac{1}{\bar{v}})w \tag{18}$$

$$-(v - \bar{v}) \frac{K^2x}{2w} - (v^3 - \bar{v}^3) \frac{K^4x}{8w^3}.$$

To see how this expression can be used practically, let us first consider the case where only the firt term of the expansion is kept (first order PSPC).

$$Kz(v) = (\frac{w}{\bar{v}}) *SQRT[1 - (\frac{Kw\bar{v}}{w})^2] + (\frac{1}{v} - \frac{1}{\bar{v}})w. \tag{19}$$

After substituting this dispersion relation into equation (8), we obtain the following expression

$$P(Kx,z + \Delta Z,w) = \tag{20}$$

$$P(Kx,z,w) *EXP \{i(\frac{w}{\bar{v}})[1 -$$

$$(\frac{Kx\bar{v}}{w})^2]^{1/2} \Delta Z\} *EXP \{i(\frac{1}{v} - \frac{1}{\bar{v}})w\Delta Z\}.$$

So, by defining

$$P^*(Kx,z + \Delta Z,w) = \tag{21}$$

$$P(Kx,z,w) *EXP \{i(\frac{w}{\bar{v}})[1 -(\frac{Kx\bar{v}}{w})^2]^{1/2} \Delta z\}$$

(20) becomes

$$P(Kx,z + \Delta Z,w) = \tag{22}$$

$$P^*(Kx,z + \Delta Z,w) *EXP \{i(\frac{1}{v} - \frac{1}{\bar{v}})w\Delta Z\}$$

After inverse transforming this expression into the real domain, one obtains an expression in which we can vary the velocity,

$$p(x,z + \Delta Z,w) = p^*(x,z + \Delta Z,w) *EXP\{i(\frac{1}{v} - \frac{1}{\bar{v}})w\Delta Z\}. \tag{23}$$

As it is seen from this equation, the extrapolation is performed in two steps. The Phase Shift algorithm is first applied in the wave-number domain with a constant reference velocity $\bar{v}$ in order to obtain P^*. A correction term is then applied in the real domain to take into account lateral variations in the velocity field. In the first order scheme, the correction term is merely equivalent to a time-shift, no correction is performed on the diffraction term.

Let us now concentrate on the second order approximation (the development of the third order expression is similar and it will not be treated), where the dispersion relation reads

$$Kz(v) = (\frac{w}{\bar{v}}) *SQRT [1 - (\frac{Kx\bar{v}}{w})^2] + \tag{24}$$

$$(\frac{1}{v} - \frac{1}{\bar{v}})w\Delta Z - (v - \bar{v}) \frac{Kx^2\Delta Z}{2w}$$

Using the same notation as in the previous case, the downward extrapolation equation is now of the form

$$P(Kx,z + \Delta Z,w) = P^* (Kx,z + \Delta Z,w) \tag{25}$$

$$*EXP\{i(\frac{1}{v} - \frac{1}{\bar{v}}) w\Delta Z\} *EXP\{-i(v - \bar{v}) \frac{Kx^2\Delta Z}{2w}\}$$

Because of the Kx^2 term in the last exponential, we cannot perform an inverse transform as previously to go back in the x-domain. The solution is to replace the exponential by its first order Taylor development. In other words, we replace

$$EXP\{-i(v - \bar{v}) \frac{Kx^2\Delta Z}{2w}\} \tag{26}$$

by

$$1 - i(v - \bar{v}) \frac{Kx^2\Delta Z}{2w}. \tag{27}$$

This is valid only if the value of the expression inside the exponential is small enough. In order to evaluate it, let us write it in the following form

$$(v - \bar{v}) \frac{Kx^2\Delta Z}{2w} = (\frac{v}{\bar{v}} - 1) (\frac{Kx\bar{v}}{w}) (\frac{Kx\Delta Z}{2}). \tag{28}$$

If the following condition for the velocities is assumed

$$0.5 \leq \frac{v}{\bar{v}} \leq 1.5 \tag{29}$$

we have

$$|\frac{v}{\bar{v}} - 1| \leq 1/2. \tag{30}$$

The inequality assumed in (29) puts some restrictions on the velocity field. More specifically, the method is applicable only if the velocity field is such that, for each depth step, the ratio of the largest over the smallest velocity is less or equal to 3. Let us now concentrate on the second term of (28). We show that we have the following inequality

$$(\frac{Kx\bar{v}}{w}) \leq 1. \tag{31}$$

This inequality is related to the problem of the elimination of the evanescent energy. For a laterally uniform medium $\bar{v}$, the evanescent solutions are defined by the relation[7].

$$Kx \le \frac{\bar{w}}{v}. \qquad (32)$$

Thus, when P^* is computed with the constant velocity $\bar{v}$, we keep only the waves such that

$$Kx \le \frac{w}{\bar{v}}. \qquad (33)$$

When the velocity field varies laterally, the identification of the evanescent field becomes less clear cut. However, in our case, we choose to apply inequality (33) everywhere, and so (31) is verified. It has thus been shown that

$$|(v - \bar{v}) \frac{Kx^2\Delta Z}{2w} | \le \frac{Kx\Delta Z}{4} \qquad (34)$$

or

$$|(v - \bar{v}) \frac{Kx^2\Delta Z}{2w} | \le \frac{\pi\Delta Z}{8\Delta X} \qquad (35)$$

because of the inequality $Kx \le \frac{\pi}{2\Delta x}$. So finally,

if ΔZ is small enough compared to ΔX, the first order development of the exponential term will be accurate. In practice, one can choose ΔZ such that

$$\Delta Z \le \frac{\Delta X}{3}. \qquad (36)$$

Now our extrapolation relation defined in (25) can be written in the form

$$P(Kx,z + \Delta Z,w) = P^*(Kx,z + \Delta Z,W) * \qquad (37)$$

$$[1 - i(v - \bar{v}) \frac{Kx^2\Delta Z}{2w}] *EXP \{i (\frac{1}{v} - \frac{1}{\bar{v}}) w\Delta Z\}$$

An inverse transform to go back in the x-domain gives us our final extrapolation expression for the second order PSPC method.

$$p(x,z + \Delta Z,w) = [p^* (x,z + \Delta Z,w) + \qquad (38)$$

$$i(v - \bar{v}) \frac{\Delta Z}{2w} \frac{\partial^2 p^*}{\partial x^2} (x,z + \Delta Z,w)] *EXP \{i \frac{1}{v} - \frac{1}{\bar{v}}) w Z\}$$

The partial derivative term is computed by the Fourier method.

ACCURACY OF THE MIGRATION ALGORITHM

In this section we study the PSPC algorithm both from a theoretical and a practical point of view. From what was shown in the previous section, we know that the accuracy of the PSPC method mainly depends on two factors. The first of these factors is the order of the Taylor development used to approximate the dispersion relation defined by (Equation 17). The second important factor is the ratio $R = v/\bar{v}$.

If we refer to the wave extrapolation equations section, we see that in term of complexity, the first order PSPC approximation is comparable to the 5 degree method, the second order approximation to the 15 degree method, and the third order approximation to the 45 degree method. Figure 3 compares the dispersion curve of the 5 degree method and of the first order PSPC approximation for different values of R, to the exact dispersion relation.

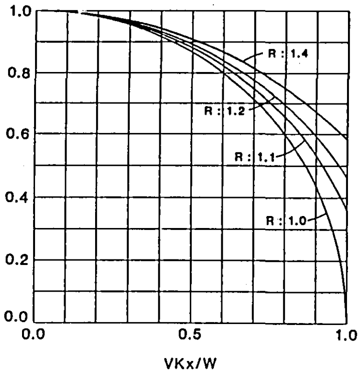

Figure 3. Dispersion Curve of the First Order PSPC Method.

Compared to the 5 degree method, dispersion curves of the first order PSPC method follow much better the exact dispersion curve. Figure 4 plots, for different values of R, the angle where the curve departs from the exact dispersion relation. For the values of R between 0.8 and 1.5 the first order PSPC method approaches the exact curve up to 9 degree dips or better.

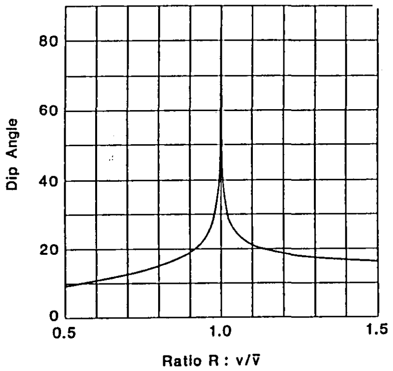

Figure 4. Theoretical Accuracy of the First Order PSPC Method.

Figure 5 compares the dispersion curve of the 15 degree method and of the second order PSPC approximation for different values of R, to the exact dispersion relation. Again, the behavior of the dispersion curves is quite good. Figure 6 plots, for different values of R, the angle where the curve departs from the exact dispersion relation. For the values of R between 0.8 and 1.5, the second order PSPC method approaches the exact curve up to 15 degree dips or better.

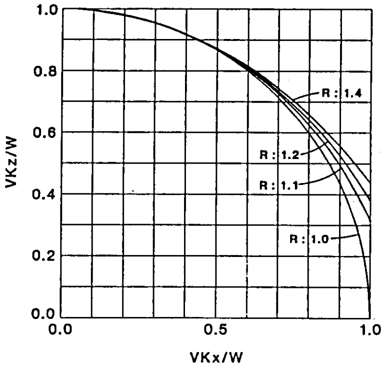

Figure 5. Dispersion Curve of the Second Order PSPC Method.

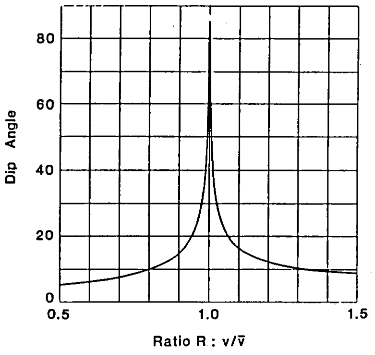

Figure 6. Theoretical Accuracy of the Second Order PSPC Method.

In order to test our algorithm, we have chosen to migrate a section that was collected in the acoustic modeling tank at the Seismic Acoustic Laboratory at the University of Houston. The same model was used by Kosloff and Baysal to test their migration algorithm with the full acoustic wave equation[7]. The model is a buried wedge structure, which is represented in Figure 1. The wedge was made of low-velocity rubber, whereas the base was made of high-velocity plexiglas. The whole model was immersed in water.

The dimensions of this model were chosen so that the data would represent field data. The scale factors used in the experiment are as follows:

Parameter	Model	Field
Time	$0.2\mu s$	1 msec
Length	2.5 cm	300 m
Velocity	V	2.4 V

In the following all parameters will be discussed in terms of field units. The zero offset line that was collected in the tank is made of 512 traces, with a shot spacing of 15 m. The first sample of each trace starts at T = 400 ms. This section is shown in Figure 7, for clarity reasons only every other trace (256 of the 512 traces) has been plotted.

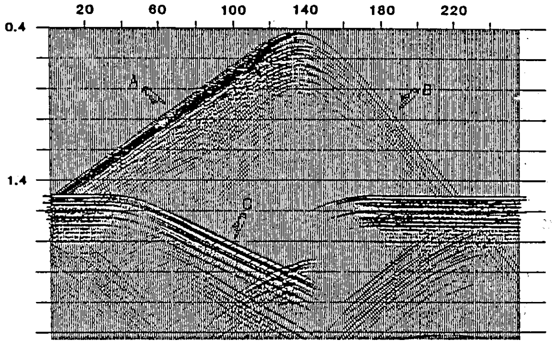

Figure 7. Time Section from a Zero-Offset Line Shot in the Physical Modeling Tank.

In a first test, this section has been migrated using the Phase Shift algorithm and a uniform velocity. The value used was 3600 m/s, which corresponds to the scale water velocity in the tank. The result of this migration is shown in Figure 8. The program was designed so that it is possible to skip the water in one single step, which explains why the depth section starts at Z = 600 m. Events A and B are correctly migrated, but event C, the plexiglas base underlying the wedge is undermigrated. The scale velocity for the rubber is equal to 2400 m/s, which is much slower than the velocity of 3600 m/s that was used in this first migration test.

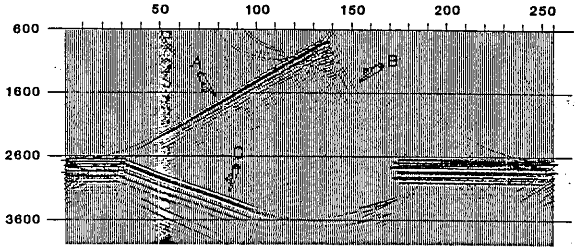

Figure 8. Migrated Section with a Uniform Velocity of 3600 m/s.

e velocity model to test our variable velocity migration programs is shown in Figure 1. The scale velocity for plexiglas was taken equal to 6000 m/s. Figure 9 shows the result of the migration using the first order PSPC method. The plexiglas base under the wedge is now in its proper position, although one portion is missing. According to Kosloff and Baysal[7] this comes from the fact that the energy propagating upward from this portion of the base encounters the steeply dipping side of the wedge at an angle beyond the critical angle for the wedge rubber and water. This type of migration is not accounted for by the exploding reflector model on which the migration is based. In this example the water velocity was used as the reference velocity, which means that although we used only the first order method, the 30 and 60 degrees dips of the wedge are correctly migrated because we are in a situation where R is equal to 1. On the other hand, if one chooses to use for the reference the wedge velocity, R is now equal to 1.5, which is the worst situation. The migrated section for this case is shown in Figure 10. Reflectors A and B are not properly positioned. The shape is preserved, but the dip angles are not recovered correctly.

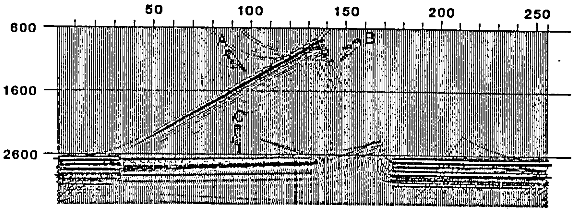

Figure 9. Migrated Section with a Variable Velocity. First Order PSPC with a Reference Velocity Equal to 3600 m/s.

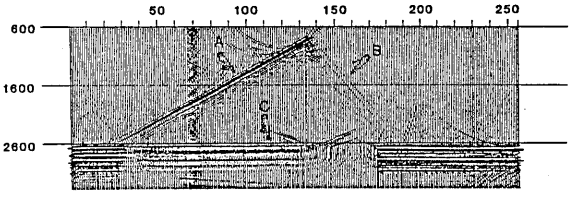

Figure 10. Migrated Section with a Variable Velocity. First Order PSPC with a Reference Velocity Equal to 2400 m/s.

Another interesting remark is that, contrarily to what reported Kosloff and Baysal for their migration algorithm with the full acoustic wave equation, our migration method is relatively insensitive to small changes in the values of the velocities. For example, a slight perturbation in the wedge velocity does not significantly modify the alignment of the plexiglass base under the wedge.

A 3D EXAMPLE: THE SALNOR7 MODEL

One of the main motivation for developing our Phase Shift Plus Correction migration method was to come up with an algorithm suitable for 3D processing. The purpose of this section is to report on 3D migration tests performed with this algorithm.

The SALNOR7 model, Figure 2, is used for the 3D test. As previously, all parameters will be discussed in terms of scaled units. A 3D zero-offset data set consisting of 240 traces on 240 lines has been collected in the tank. Each trace contains 3000 samples at 1 ms, the shot spacing in both directions is equal to 30 m. As our program works in the Fourier domain, it is more convenient to have dimensions that are power of 2 and so the model was padded with null traces to get 256 lines of 256 traces each. For the same reason data were truncated to keep only 2048 samples at 1 ms (all relevant information is at less than 2 s).

The size of the model for the migration is now equal to 256^*256^*2048, which represents a volume of 64 Mwords. Figure 11 shows a section (line 120) of this model. This section was first migrated using the Phase Shift algorithm, and a uniform velocity for each of the 128 depth steps. This first migration was completed in 142 s wall-clock time on a dedicated Cray X-MP 48 (using only one CPU). Figure 12 shows the result of this migration on line 120.

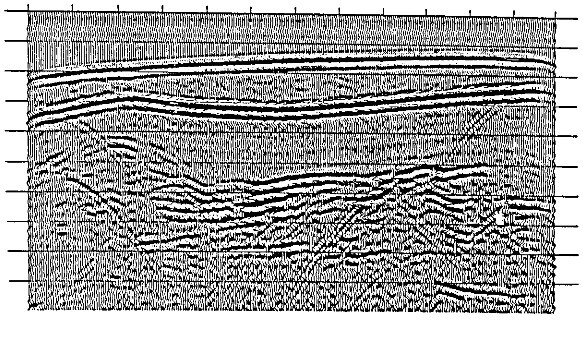

Figure 11. Line 120 of the SALNOR7 Model. Zero-Offset Time Section.

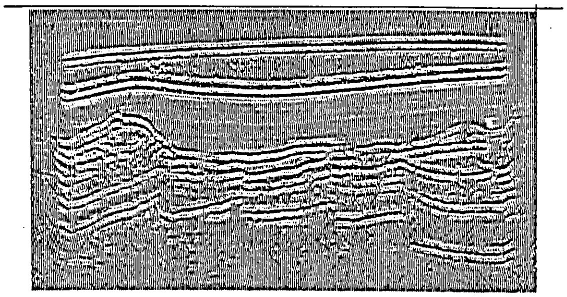

Figure 12. Line 120 of the SALNOR7 Model. 3D Migrated Depth Section Using The Phase Shift Method.

For our second test we ran the first order PSPC algorithm, with a laterally variable velocity field. Due to the fact that the SALNOR7 is a very complex model and that our tools are not appropriate, we used only a simplified 3D velocity structure. The migrated results thus do not show much difference over the previous case, however, this does not affect our benchmark results. Using the same parameters than in the previous case, plus the 3D velocity structure, the first order PSPC migration program requires 28 minutes wall-clock time on the Cray X-MP 48, using only one CPU. Table 1 gives a summary of these results, including some estimates on the performance that we can expect for the multitasked versions. All the results include both CPU and Input/Output waiting time.

Version	Size	Steps	Main Memory	Wall-Clock Time
Phase Shift 1-CPU	256 X 256 X 2048	128	1.8 Mwords	142 s
PSWC1 1-CPU	256 X 256 X 2048	128	2.1 Mwords	1719 s
PSWC1 4-CPU	256 X 256 X 2048	128	3.7 Mwords	470 s (estimated)
PSWC2 1-CPU	256 X 256 X 2048	128	2.3 Mwords	2300 s (estimated)

Table 1. 3D Migration Benchmark Results on a Dedicated Cray X-MP 48.

A TUTORIAL ON FINITE DIFFERENCE METHODS AND ORDERING OF MESH POINTS

David M. Young* - David R. Kincaid*

* The University of Texas at Austin, U. S. A.

ABSTRACT

This paper contains introductory material related to a tutorial on finite difference methods and ordering of mesh points.

We wish to illustrate a central mathematical idea which has grown in importance with the advent of the modern computer, namely, that one can approximate a differential equation by a system of linear algebraic equations and solve the resulting linear system on the computer to obtain an approximate solution to the original problem. The derivatives in the differential equation are approximated by difference quotients which are obtained from truncated Taylor series in many cases. This entire procedure goes by the name "finite difference methods."

In this discussion we will be primarily concerned with linear second-order partial differential equations of the form

$$Au_{xx} + 2Bu_{xy} + Cu_{yy} + Du_x + Eu_y + Fu = G \qquad (1)$$

where A, B, C, D, E, F, and G are given functions of x and y which are continuous in some region R in the (x,y) plane. A typical problem is the following: given a region R with boundary S, find a function u(x,y) which is twice differentiable and satisfies (1) in R, which is continuous in R + S and which satisfies prescribed conditions on S.

Let us consider the generalized Dirichlet problem involving a bounded and connected region R and a continuous function g(x,y) prescribed on S. The function u(x,y) is required to be continuous in R + S, to satisfy (1) in R and to satisfy u(x,y) = g(x,y) for $(x,y) \in S$. If (1) is an "elliptic equation" ($B^2 - AC < 0$ in R) and if $F \leq 0$ in R, then the generalized Dirichlet problem has a unique solution under fairly general conditions. A special case of the generalized Dirichlet problem is a classical problem in applied mathematics—the Dirichlet problem involving Poisson's

$$u_{xx} + u_{yy} = G\ .$$

This problem is used as a "model problem" in both theory and applications.

In principle, we can make a change of independent variables so that the coefficient B of the mixed derivative u_{xy} in (1) vanishes identically in R + S. (See Young and Gregory [1973].)

The method of finite differences involves superimposing a mesh over the region R and replacing the differential equation (1) by a difference equation at each mesh point. In this discussion we assume that a square mesh of horizontal and vertical lines with mesh spacing h in both the horizontal and vertical directions is used. At a mesh point (x,y) we replace the partial derivatives appearing in (1) by standard three-point central difference quotients

$$\begin{cases} u_x \cong [u(x+h,y) - u(x-h,y)]/(2h) \\ u_y \cong [u(x,y+h) - u(x,y-h)]/(2h) \\ u_{xx} \cong [u(x+h,y) + u(x-h,y) - 2u(x,y)]/h^2 \\ u_{yy} \cong [u(x,y+h) + u(x,y-h) - 2u(x,y)]/h^2 \end{cases}$$

Substituting in (1) with B = 0 and multiplying by $-h^2$, we obtain the difference equation

$$\begin{aligned} &a_0u(x,y) - a_1u(x+h,y) - a_2u(x,y+h) \\ &- a_3u(x-h,y) - a_4u(x,y-h) = t(x,y) \end{aligned} \qquad (2)$$

where

$$\begin{cases} a_1 = A(x,y) + \frac{h}{2}D(x,y)\ , & a_3 = A(x,y) - \frac{h}{2}D(x,y) \\ a_2 = C(x,y) + \frac{h}{2}E(x,y)\ , & a_4 = C(x,y) - \frac{h}{2}E(x,y) \\ a_0 = a_1 + a_2 + a_3 + a_4 - h^2F(x,y), & t(x,y) = -h^2G(x,y) \end{cases}$$

The difference equation (2) is valid if the point (x,y) and the four adjacent points (x ± h,y), (x,y ± h) are in R + S. Special formulas are available for more general situations including cases involving curved boundaries. (See, e.g., Forsythe and Wasow [1960], Young and Gregory [1973], or Birkhoff and Lynch [1984].)

CH2345-7/86/0000/0556$01.00 © 1986 IEEE

In the case where B = 0 and (1) is "self-adjoint", i.e., $D = A_x$, $E = C_y$, we can write (1) in the form

$$(Au_x)_x + (Cu_y)_y + Fu = G \tag{3}$$

For this equation, we can derive a difference equation which has the same accuracy as (2) and such that the resulting linear system is symmetric. This is done by replacing $(Au_x)_x$ and $(Cu_y)_y$ by the difference quotients

$$(Au_x)_x \cong \{A(x+\frac{h}{2},\ y)[u(x+h,y) - u(x,y)] - A(x-\frac{h}{2},\ y)[u(x,y) - u(x-h,y)]\}/h^2$$

and

$$(Cu_y)_y \cong \{C(x,y+\frac{h}{2})[u(x,y+h) - u(x,y)] - C(x,y-\frac{h}{2})[u(x,y) - u(x,y-h)]\}/h^2$$

Substituting in (3) and multiplying by $-h^2$

$$\begin{aligned} &a_0u(x,y) - a_1u(x+h,y) - a_2u(x,y+h) \\ &\quad - a_3u(x-h,y) - a_4u(x,y-h) = t(x,y) \end{aligned} \tag{4}$$

where

$$\begin{cases} a_1 = A(x+\frac{h}{2},\ y)\ , & a_3 = A(x-\frac{h}{2},\ y) \\ a_2 = C(x,y+\frac{h}{2})\ , & a_4 = C(x,y-\frac{h}{2}) \\ a_0 = a_1 + a_2 + a_3 + a_4 - h^2F(x,y), & t(x,y) = -h^2G(x,y) \end{cases}$$

If (1) is not self-adjoint and B = 0, it may be possible to obtain a self-adjoint equation by multiplying (1) by an "integrating factor" $\mu(x,y)$. In this case, (1) is "essentially self-adjoint" and the following condition must hold

$$\frac{\partial}{\partial y}\left(\frac{D - A_x}{A}\right) = \frac{\partial}{\partial x}\left(\frac{E - C_y}{C}\right)$$

Thus for example the equation $u_{xx} - x^{-1}u_x + u_{yy} = 0$ is essentially self-adjoint and can be made self-adjoint by multiplying by the integrating factor $\mu(x,y) = x^{-1}$ obtaining $(x^{-1}u_x)_x + (x^{-1}u_y)_y = 0$.

As an example, we consider the difference equation corresponding to the Poisson equation

$$u_{xx} + u_{yy} = G(x,y) \tag{5}$$

where G(x,y) is a given function. Evidently, we have A = C = 1, B = D = E = F = 0, and

$$\begin{cases} a_1 = a_2 = a_3 = a_4 = 1 \\ a_0 = 4, \quad t(x,y) = -h^2G(x,y) \end{cases}$$

If we wish to solve this problem on the unit square $0 \leqq x \leqq 1$, $0 \leqq y \leqq 1$ where the values on the boundary are given by $u(x,y) = g(x,y)$, then a uniform square mesh with spacing h can be established over the region. With this mesh subdivision, the finite difference approximation to Poisson's equation at each interior grid point (x_i,y_i) is an equation of the form

$$\begin{aligned} 4u_{ij} - u_{i+1,j} - u_{i-1,j} - u_{i,j+1} - u_{i,j-1} \\ = -h^2G(x_i,y_i) \end{aligned} \tag{6}$$

using either (2) or (4). Here $u_{ij} = u(x_i,y_j)$ and $x_i = x_0 + ih$, $y_i = y_0 + jh$ for $0 \leqq i \leqq m+1$, $0 \leqq j \leqq m+1$ and $h = 1/(m+1)$.

Let us now consider the case where $h = \frac{1}{4}$ which leads to nine linear equations—one for each interior grid point. We label the mesh points as indicated in Figure 1.

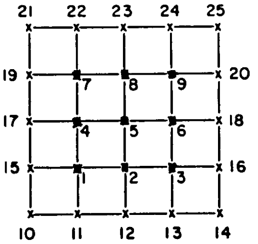

Figure 1. Natural ordering for point partitioning.

The interior points are numbered first in the "natural" order and then the boundary points are numbered. From (6) we obtain, after transferring known values to the right-hand side

$$\begin{bmatrix} 4 & -1 & 0 & -1 & & & & & \\ -1 & 4 & -1 & 0 & -1 & & & 0 & \\ 0 & -1 & 4 & 0 & 0 & -1 & & & \\ -1 & 0 & 0 & 4 & -1 & 0 & -1 & & \\ & -1 & 0 & -1 & 4 & -1 & 0 & -1 & \\ & & -1 & 0 & -1 & 4 & 0 & 0 & -1 \\ & & & -1 & 0 & 0 & 4 & -1 & 0 \\ & 0 & & & -1 & 0 & -1 & 4 & -1 \\ & & & & & -1 & 0 & -1 & 4 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \\ u_5 \\ u_6 \\ u_7 \\ u_8 \\ u_9 \end{bmatrix} = \begin{bmatrix} g_{11} + g_{15} - h^2G_1 \\ g_{12} - h^2G_2 \\ g_{13} + g_{16} - h^2G_3 \\ g_{17} - h^2G_4 \\ - h^2G_5 \\ g_{18} - h^2G_6 \\ g_{19} + g_{22} - h^2G_7 \\ g_{23} - h^2G_8 \\ g_{20} + g_{24} - h^2G_9 \end{bmatrix} \tag{7}$$

Here we have let the k^{th} component u_k be the unknown corresponding to the mesh point marked k. Similarly, g_k and G_k are the values of these functions at the labelled mesh points in Figure 1.

This system can be written in matrix form as

$$Au = b \tag{8}$$

Notice the simple pattern of 0's in the coefficient matrix (7) with this natural ordering. We can write the system as

$$\begin{bmatrix} A_{1,1} & A_{1,2} & 0 \\ A_{2,1} & A_{2,2} & A_{2,3} \\ 0 & A_{3,2} & A_{3,3} \end{bmatrix} \begin{bmatrix} U_1 \\ U_2 \\ U_3 \end{bmatrix} = \begin{bmatrix} F_1 \\ F_2 \\ F_3 \end{bmatrix}, \tag{9}$$

where

$$A_{i,i} = \begin{bmatrix} 4 & -1 & 0 \\ -1 & 4 & -1 \\ 0 & -1 & 4 \end{bmatrix}$$

and

$$A_{i,i+1} = A_{i+1,i} = \begin{bmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & -1 \end{bmatrix} .$$

Using Figure 2, the unknowns for line k are denoted U_k and we have a grouping according to lines.

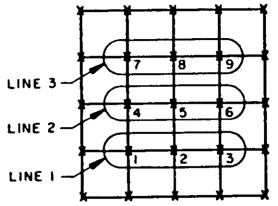

Figure 2. Natural ordering for line partitioning.

The submatrix A_{ij} gives the coupling of the unknowns from line i to those on line j. Since the coefficient matrix is symmetric, we have $A_{ij} = A_{ji}^T$.

Another ordering of the interior mesh points is the "red/black ordering" in which every other point is given either a red or black label as on a checkerboard. (See Figure 3.)

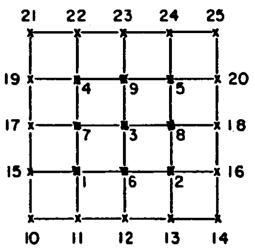

Figure 3. Red/Black ordering for point partitioning.

For this ordering of the unknowns, the difference equations (6) for each interior grid point can be expressed in the matrix form

$$\begin{bmatrix} 4 & & & & & -1 & -1 & 0 & 0 \\ & 4 & & 0 & & -1 & 0 & -1 & 0 \\ & & 4 & & & -1 & -1 & -1 & -1 \\ 0 & & & 4 & & 0 & -1 & 0 & -1 \\ & & & & 4 & 0 & 0 & -1 & -1 \\ -1 & -1 & -1 & 0 & 0 & 4 & & & \\ -1 & 0 & -1 & -1 & 0 & & 4 & 0 & \\ 0 & -1 & -1 & 0 & -1 & & 0 & 4 & \\ 0 & 0 & -1 & -1 & -1 & & & & 4 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \\ u_5 \\ u_6 \\ u_7 \\ u_8 \\ u_9 \end{bmatrix} = \begin{bmatrix} g_{11} + g_{15} - h^2G_1 \\ g_{13} + g_{16} - h^2G_2 \\ - h^2G_3 \\ g_{19} + g_{22} - h^2G_4 \\ g_{20} + g_{24} - h^2G_5 \\ g_{12} \quad - h^2G_6 \\ g_{17} \quad - h^2G_7 \\ g_{18} \quad - h^2G_8 \\ g_{23} \quad - h^2G_9 \end{bmatrix} . \tag{10}$$

The red unknowns u_1, u_2, u_3, u_4, u_5 can be grouped in a vector u_R and the black unknowns u_6, u_7, u_8, u_9 in a vector u_B. We can write such a system in a red/black partitioned form

$$\begin{bmatrix} D_R & H \\ K & D_B \end{bmatrix} \begin{bmatrix} u_R \\ u_B \end{bmatrix} = \begin{bmatrix} F_R \\ F_B \end{bmatrix} \tag{11}$$

where D_R and D_B are diagonal matrices and $K = H^T$.

A red/black ordering for the line partitioning corresponding to the numbering given in Figure 4 would have the red lines of unknowns in variables U_1 and U_2 while the black lines unknowns are in U_3. The resulting partitioned system is of the form

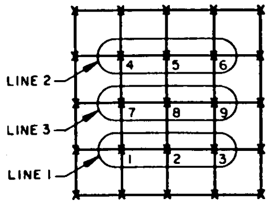

Figure 4. Red/Black ordering for line partitioning.

$$\begin{bmatrix} A_{1,1} & 0 & A_{1,3} \\ 0 & A_{2,2} & A_{2,3} \\ A_{3,1} & A_{3,2} & A_{3,3} \end{bmatrix} \begin{bmatrix} U_1 \\ U_2 \\ U_3 \end{bmatrix} = \begin{bmatrix} F_1 \\ F_2 \\ F_3 \end{bmatrix}. \tag{12}$$

Now if we partition by red and black lines by letting $u_R = [U_1, U_2]^T$ and $u_B = U_3$ then we obtain the red/black partitioned system (11) where

$$D_R = \begin{bmatrix} A_{11} & 0 \\ 0 & A_{22} \end{bmatrix} , \qquad D_B = A_{33} ,$$

$$H = \begin{bmatrix} A_{13} \\ A_{23} \end{bmatrix}, \quad K = [A_{31} \quad A_{32}]$$

In the point red/black ordering, D_R and D_B are diagonal matrices whereas in the line red/black ordering they are block diagonal.

The solution of a difference equation involves the solution of the system (8). To obtain an accurate solution of the differential equation it is often necessary to use a very small mesh size h. This results in a large system of equations. These can be solved numerically using direct methods or using iterative methods (see, e.g., Varga [1962], Wachspress [1966], Young [1971], Hageman and Young [1981], and Birkhoff and Lynch [1984]). In each case special procedures should be used to take advantage of the fact that the coefficient matrix of the linear system is "sparse", i.e., that most of the elements are zero. Frequently-used iterative methods include the successive overrelaxation method, the Jacobi method and the incomplete Cholesky method. The latter two methods are often combined with an acceleration procedure such as Chebyshev acceleration or conjugate gradient acceleration to speed up the convergence.

Iterative methods are ideal for such systems since they produce no "fill-in". Partitioning such as (9) and (11) can be used to advantage in special iterative methods for solving the linear system. Iterative methods which utilize the unique structure of these partitioning require that the subsystems

$$A_{ii}U_i = \hat{F}_i, \quad D_R u_R = \hat{F}_R, \quad D_B u_B = \hat{F}_B \tag{13}$$

can be "easily" solved since this must be done repeatedly for every iteration—the "inner-iteration" step.

If the coefficients appearing in the differential equation are sufficiently well-behaved and if the region R is sufficiently "regular" then the accuracy of the solution of the difference equations (2) or (4) is of order h^2. Greater accuracy can be achieved in some cases by the use of higher order difference equations. The use of a 9-point stencil $(x + \sigma h, y + \tau h)$ where $\sigma, \tau = -1, 0, 1$ can sometimes be used. It has the advantage that for many problems the same stencil can be used throughout the region. Other stencils can be used such as the 9-point stencil $(x + \sigma h, y + \tau h)$ where $\sigma = -2, -1, 0, 1, 2$ and $\tau = 0$ or $\sigma = 0$ and $\tau = -2, -1, 0, 1, 2$.

Finite difference methods may be used to solve problems involving more general boundary conditions such as

$$\alpha(x,y)u + \beta(x,y) \frac{\partial u}{\partial n} = \gamma(x,y)$$

where α, β, and γ are given functions defined on R. In the case of curved boundaries the procedure for representing the boundary conditions can be difficult. For points on a horizontal or vertical boundary, simpler procedures are available. A procedure for deriving difference equations at boundary points and at interior points, even when some of the coefficients of the differential equation are discontinuous, is given in Varga [1962].

We wish to thank Thomas C. Oppe and John R. Respess for reading this paper and making suggestions.

FINITE ELEMENT METHODS

J. Tinsley Oden

Texas Institute for Computational Mechanics
The University of Texas at Austin, Austin, TX 78712

Abstract. This note summarizes the features of finite element methods that are responsible for its great success as a tool for the numerical solution of partial differential equations. Arguments are also given as to why the method will continue to be dominant in the future development of numerical schemes for solutions of complex boundary and initial value problems.

Finite elements; perhaps no other family of approximation methods has had a greater impact on the theory and practice of numerical methods during the twentieth century. Finite element methods have now been used in virtually every conceivable area of engineering that can make use of models of nature characterized by partial differential equations.

A natural question that one may ask is: why have finite element methods been so popular in both the engineering and mathematical community? There is also the question, do finite element methods possess properties that will continue to make them attractive choices of methods to solve difficult problems in physics and engineering?

In answering these questions, one must first point to the fact that finite element methods are based on the weak or variational formulation of boundary and initial value problems. This is a critical property, not only because it provides a proper setting for the existence of very irregular solutions to differential equations (e.g. distributions), but also because the solution appears in the integral of a quantity of a domain. The simple fact that the integral of a bounded measurable function over an arbitrary domain can be broken up into the sum of integrals over an arbitrary collection of almost disjoint subdomains whose union is the original domain, is in fact a vital observation in finite element theory. Because of it, the analysis of a problem can literally be made locally, over a typical subdomain, and by making the subdomain sufficiently small one can argue that polynomial functions of various degrees are adequate for representing the local behavior of the solution. This summability of integrals is exploited in every finite element program. It allows the analyst to focus his attention on a typical finite element domain and to develop an approximation independent of the ultimate location of that element in the final mesh.

This simple property has important implications in physics and in most problems in continuum mechanics. Indeed, the classical balance laws of mechanics are global, in the sense that they are integral laws applying to a given mass of material, a fluid or solid. From the onset, only regularity of the primitive variables sufficient for these global conservation laws to make sense is needed. Moreover, since these laws are supposed to be fundamental axioms of physics, they must hold over every finite portion of the material: every finite element of the continuum. Thus once again, one is encouraged to think of approximate methods defined by integral formulations over typical pieces of a continuum to be studied.

These rather primitive properties of finite elements lead to some of their most important features:

1) Arbitrary geometries. The method is essentially geometry-free. In principle, finite element methods can be applied to domains of arbitrary shape and with quite arbitrary boundary conditions.

2) Unstructured meshes. While there is still much prejudice in the numerical analysis literature toward the use of coordination-dependent algorithms and mesh generators, there is nothing intrinsic in finite element methodology that requires such devices. Indeed, finite element methods by their nature lead to unstructured meshes. This means that, in principle, the analyst can place finite elements anywhere he pleases. He may thus model the most complex types of geometries in nature and physics, ranging from the complex cross sections of biological tissues to the exterior of aircraft to internal flows in turbo machinery, without strong use of a global fixed coordinate frame.

3) Robustness. It is well known that in finite element methods the contributions of local approximations over individual elements are assembled together in a systematic way to arrive at a global approximation of a solu-

CH2345-7/86/0000/0560$01.00 © 1986 IEEE

tion to a partial differential equation. Generally this leads to schemes which are stable in appropriate norms and, moreover, insensitive to singularities or distortions of the mesh. There are notable exceptions to this, of course, and these exceptions have been the subject of some of the most important works in finite element theory. But, by and large, the direct use of Galerkin or Petrov-Galerkin methods to derive finite element methods leads to conservative and stable algorithms for most classes of problems in mechanics and mathematical physics.

4) Mathematical foundation. Because the extensive work on the mathematical foundations done during the seventies and eighties, finite element methods now enjoy a rich and solid mathematical basis. The availability of methods to determine a-priori and a-posteriori estimates provide a vital part of the theory of finite elements, and make it possible to lift the analysis of important engineering and physical problems above the traditional empiricism prevalent in many numerical and experimental studies.

When one attempts to project into the future trends in numerical methods for partial differential equations, it makes sense to pose some fundamental questions in this subject. We feel that the issue of optimality of numerical methods is central, and this issue is embodied in two questions: how good are the answers one obtains from a numerical analysis of a model of a physical phenomenon?; how can one obtain the best possible answers for a fixed level of computational cost or effort? -

The answer to the first is mathematical in essence: determine a-posteriori error estimates. The answer to the second question is computational: knowing an estimate of the error, change the structure of the approximation to reduce it in an efficient way. The implementation of such an optimal numerical strategy thus requires several basic properties of the methods in use: a rich mathematical basis since sharp error estimates must be obtained, a structure independent of geometry and coordinates, since the mesh and mesh properties must be dynamically changed to reduce error; robustness, since the method must be stable under changes in structure; and it must admit to supercomputing strategies. We feel that finite element methods represent one of the very few - and perhaps the only - class of approaches that can fulfill these requirements.

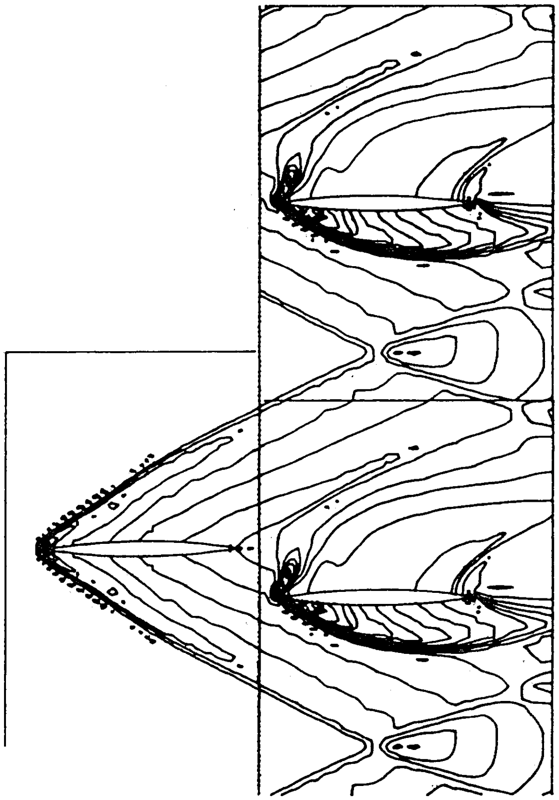

Fig. 1.

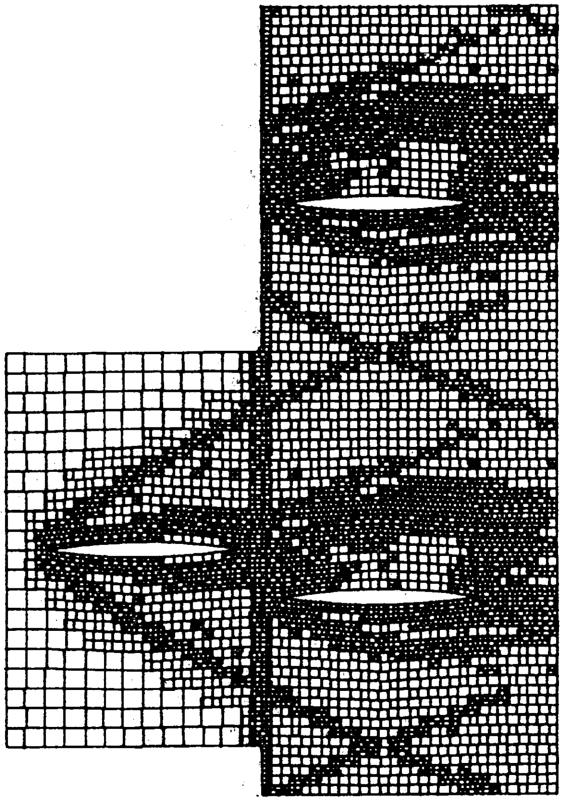

Fig. 2.

An example of the great adaptability of finite element methods is shown in Figs. 1 and 2. There one observes a calculation of supersonic flow of a compressible gas flowing through a set of spinning turbine blades. The finite element algorithm tests local errors and automatically refines the mesh to attempt to produce the best possible accuracy using the least number of elements; this being done dynamically as the phenomenon evolves in time. Larger elements are used where the error is small. Also shown are computed pressure contours which exhibit the evolution of shock and shock interaction.

For the above reasons, it is certain that finite element concepts will continue to occupy a dominant role in applications and in research on the numerical solution of partial differential equations.

BOUNDARY ELEMENT METHODS

S. R. KENNON*

* Graduate Research Assistant, Dept. of Aerospace Engineering and Engineering Mechanics, University of Texas at Austin, Austin, TX.

Abstract

The boundary element method (BEM) is surveyed and shown to be a powerful tool for the accurate and efficient solution of a certain class of field problems. We discuss the application of the method to an important model problem, discuss some computational aspects of the technique, and point out some advantages and disadvantages of the method. Finally, some applications of the BEM are discussed, with particular reference to inverse design problems. A short bibliography of relevant literature is included.

Introduction

The boundary element method (BEM)[1,2] is a powerful sub-class of finite element techniques for the accurate and efficient solution of a wide class of problems posessing a special structure. The method, where applicable, can give more accurate solutions to certain problems than finite difference or finite element methods. Moreover, the method can in most cases provide an order of magnitude increase in efficiency over finite difference or finite element methods. The gain in efficiency and ease of use is due to the fact that solution of the partial differential equation in the entire domain is reduced to the solution of an integral equation on the boundary of the domain. Therefore, only the boundary of the domain being studied need be discretized (this is especially important in complex, multiply connected domains). Thus in two-dimensional problems, only a one-dimensional domain (e.g. the boundary) need be discretized. In addition, since exact, analytic solutions of the governing partial differential equation are used in the approximate solution, the BEM is inherently more accurate. For these reasons, the method is particularly appealing in either time-dependent or inverse design problems since a field problem needs to be solved at either every time-step or every design iteration.

This paper gives the basic concepts underlying the method and shows how it is applied to an important model problem. Next we show some standard applications of the method, discuss the BEM for non-linear problems, and finally show how the BEM can be used for very efficient inverse design.

A Model Problem[1]

To present the power and ease of application of the BEM we will consider the solution of the Dirichlet/Neumann problem in a two-dimensional domain Ω (Fig. 1). The problem can be stated mathematically as

P1: Find the function $u(x,y)$ such that

$$\Delta u = 0 \quad \text{in } \Omega$$

$$u = \underline{u} \quad \text{on } \Gamma_1$$

$$q = \partial u/\partial n = \underline{q} \text{ on } \Gamma_2 \qquad (1)$$

where $\underline{u}$ and $\underline{q}$ are given functions, $\Gamma = \Gamma_1 + \Gamma_2 = \partial\Omega$ the boundary of Ω and Δ is the Laplacian operator ($\Delta u = \partial^2 u/\partial x^2 + \partial^2 u/\partial y^2$). This is the standard potential problem and is the governing equation for such physical problems as heat and/or electrical conduction in homogeneous media and ideal fluid flow.

The Weighted Residual Statement

In the BEM, we use a weighted residual statement of the problem. The weighted residual statement is achieved by multiplying the governing partial differential equation with a sufficiently smooth weighting function $u^*(x,y)$ and integrating the product over the domain. In addition, we weight the boundary conditions giving the following integral statement of the problem:

P2: Find $u(x,y)$ such that

$$\int_\Omega (\Delta u)u^* \, d\Omega = \int_{\Gamma_2} (q - \underline{q})\, u^* \, d\Gamma \; - \int_{\Gamma_1} (u - \underline{u}) q^* \, d\Gamma \qquad (2)$$

for all admissible u^* and q^*. Problem P2 is equivalent to problem P1. Now we can integrate the left-hand-side of eq. 2 by parts to obtain the following equivalent equation

$$-\int_\Omega \Sigma_k (\partial u/\partial x_k \; \partial u^*/\partial x_k)\, d\Omega \;=\; -\int_{\Gamma_2} \underline{q}\, u^* \, d\Gamma$$
$$-\int_{\Gamma_2} q u^* \, d\Gamma \; - \int_{\Gamma_1} u q^* \, d\Gamma + \int_{\Gamma_1} \underline{u} q^* \, d\Gamma \qquad (3)$$

We can integrate by parts once more and obtain the fundamental equation of the BEM applied to the potential problem

$$-\int_\Omega (\Delta u^*) u \, d\Omega = -\int_{\Gamma_2} \underline{q}\, u^* \, d\Gamma - \int_{\Gamma_2} q u^* \, d\Gamma$$
$$-\int_{\Gamma_1} u q^* \, d\Gamma + \int_{\Gamma_1} \underline{u} q^* \, d\Gamma \qquad (4)$$

In the above, we have made use of the Gauss divergence theorem to relate integrals over the domain Ω to equivalent integrals over the boundary $\partial\Omega$, which is the key to the BEM (the Gauss Divergence formula states that for sufficiently

CH2345-7/86/0000/0563$01.00 © 1986 IEEE

smooth functions u(x,y), $\int_{\Omega} \Delta u = \int_{\partial\Omega} \partial u/\partial n \, d\Gamma$ where n is the direction normal to the boundary $\partial\Omega$).

The next step is to introduce the fundamental solution to the Laplace equation. Assume that a point charge (or source) is acting at point $\mathbf{x}_i = (x_i, y_i)$ in Ω. Then the fundamental solution u* is required to be a solution of the problem

$$\text{P3:} \quad \Delta u^* + \delta(x - x_i) = 0 \ \text{ in } \Omega \tag{5}$$

where $\delta(x)$ is the Dirac delta distribution. For two dimensions, the fundamental solution is

$$u^* = (1/2\pi) \ln |x - x_i| \tag{6}$$

This solution has the property that

$$\int_{\Omega} (\Delta u^* + \delta(x - x_i))u \, d\Omega = \int_{\Omega} (\Delta u^*)u \, d\Omega + u(x_i) \tag{7}$$

If u* satisfies eq. 5 then

$$\int_{\Omega} (\Delta u^*)u \, d\Omega = -u(\mathbf{x}_i) \tag{8}$$

and the fundamental equation 4 becomes

$$u(\mathbf{x}_i) + \int_{\Gamma_1} uq^* \, d\Gamma + \int_{\Gamma_1} \underline{u}q^* \, d\Gamma = \int_{\Gamma_2} \underline{q}u^* \, d\Gamma + \int_{\Gamma_2} qu^* \, d\Gamma \tag{9}$$

Next, we let $\mathbf{x}_i$ approach the boundary and through a limiting procedure obtain the final boundary integral statement of P2:

$$c_i \, u(x_i) + \int_{\Gamma} uq^* \, d\Gamma = \int_{\Gamma} qu^* \, d\Gamma \quad (x_i \text{ is on } \partial\Omega) \tag{10}$$

where $\Gamma = \Gamma_1 + \Gamma_2 = \partial\Omega$ and we assumed that $u = \underline{u}$ on Γ_1 and $\partial u/\partial n = q = \underline{q}$ on Γ_2. Here c_i is a constant that depends on the smoothness of the boundary (if Γ is smooth then $c_i = 1/2$). Equation 10 is the basic equation to be approximated by the BEM.

Discretization

Notice that eq. 10 only involves quantities on the boundary of the domain in question. Thus we can introduce a discretization of the boundary as shown in figure 2. Here we show several possibilities in which the solution is assumed to be piecewise constant (2a) piecewise linear (2b) and piecewise quadratic (2c) on the boundary. The unknown solution u(s) and q(s) will be approximated at the nodal points s_j where s is a point on the boundary Γ. One can introduce linearly independent basis functions $\varphi_j(s)$ on the boundary Γ that are piecewise constant, linear, quadratic or higher order. Then the approximate solution u and the weighting functions u* and q* can be represented as $u = \Sigma_j u_j \varphi_j$, $u^* = \Sigma_j u_j^* \varphi_j$, and $q^* = \Sigma_j q_j^* \varphi_j$, respectively where $u_j = u(s_j)$. The interpolants φ_j have the property that $\varphi_i(s_j) = \delta_{ij}$, where δ_{ij} is the Kronecker delta. Introducing these approximations into eq. 10 yields (for piecewise constant elements)

$$c_i \, u(x_i) + \Sigma_j u_j \int_{\Gamma_j} q^* \, d\Gamma = \Sigma_j q_j \int_{\Gamma_j} u^* \, d\Gamma \tag{11}$$

The integrals appearing in eq. 11 can be approximated using numerical integration formulas (numerical quadrature). Now, this equation can be written as a system of linear equations

$$\mathbf{Hu} = \mathbf{Gq} \tag{12}$$

where **H** and **G** are n x n matrices (n is the number of nodal points discretizing Γ) and **u** and **q** are n-vectors. Assuming that Γ_1 is discretized by n_1 elements and Γ_2 is discretized by n_2 elements where $n = n_1 + n_2$ we therefore know n_1 values of u_j and n_2 values of q_j from the specified boundary conditions. Thus, eq. 11 can be re-written in terms of the vector **y** containing the unknowns u_j and q_j as

$$\mathbf{Ay} = \mathbf{b} \tag{13}$$

where **A** is an n x n matrix and **b** is an n-vector. Once **y** is solved for, the value of u and its derivatives can be calculated at any point in the domain Ω using eq. 11. The power of the boundary element method is now clear. We began with a second order partial differetial equation with fairly complicated boundary conditions, and reduced it to the problem of solving a linear system of equations in a few unknowns that represent the solution values on the boundary of the domain. We must now note some disadvantages of the method. The matrix of the system eq. 13is full and can become ill-conditioned. For problems with many unknowns (e.g. for three-dimensional or complex two-dimensional problems) eq. 13 becomes difficult to solve using direct methods and thus it might be necessary to use iterative techniques to solve it. When solving a non-homogeneous problem (e.g. a Poisson equation), the entire domain needs to be discretized with sub-regions akin to finite elements to integrate the non-homogeneous term. This does not introduce any new unknowns into the problem but does make the computational complexity of the problem higher since the entire domain Ω needs to be discretized. Finally, the BEM is only applicable to linear problems in which an appropriate Green's identity can be used to reduce the problem to a boundary integral statement. Non-linear problems can be treated with special techniques discussed below. Nevertheless, the method can be claimed to be among the best methods for the class of problems that it is applicable.

Examples of Problems Solvable by the BEM

For reference, we list some other types of problems and their associated partial differential equations that can be solved by the BEM[2]:

1) Linear elasticity (Navier's equation)
2) Helmholtz equation
3) Darcy flow equation (flow through a porous medium)
4) Wave equation

Non-Linear Problems

In cases where the problem to be solved can be written in the form

$$Lu = Nu \text{ in } \Omega \text{ (plus boundary conditions)} \qquad (14)$$

where L is a linear operator that can be treated with the BEM and N is a non-linear operator, then the BEM can be applied in an iterative fashion. Essentially, the linear part of the equation is discretized as usual (a weighted integral statement is derived, basis functions are introduced and a linear system of equations is formed). The non-linear part of the equation is treated as a non-homogeneous term that must be evaluated and integrated in the interior of the domain. The procedure results in a discrete system of the following form

$$\mathbf{Ay} = \mathbf{b} + \mathrm{N}(\mathbf{y}) \qquad (15)$$

where N(y) is the non-linear analog of the non-linear part of eq. 14. This equation can be solved, for example, by the following algorithm

```
Algorithm:
y := y^0  an initial guess for the solution
k := 0
while || δ || > ε do
    begin
        k := k + 1
        Solve  Aδ^k = − Ay^k +  b + N(y^k) for δ^k
        y^{k+1} := y^k + δ^k
    end                                                    (16)
```

An example of this type of problem is the full potential equation[3] governing isentropic irrotational flow of a perfect gas:

$$\Delta\phi = N(\phi) \text{ (plus appropriate boundary conditions)} \qquad (17)$$

where $N(\phi)$ is given by

$$[\ \phi_x{}^2\phi_{xx}\ - 2\ \phi_x\phi_y\phi_{xy} + \phi_y{}^2\phi_{yy}\ ]\ /\ [\ c_1 + c_2(\ \phi_x{}^2 + \phi_y{}^2\ )\ ]$$

and c_1 and c_2 are constants. Fig. 3 shows a plot of the surface pressure distribution on an airfoil calculated using the non-linear BEM[3]. The results compare well with other methods.

Inverse Design Applications

As mentioned above, the BEM provides a very efficient method for accurately solving heat conduction problems. We now consider a special application of the BEM for analysis and design of turbine blade coolant flow passage shapes. Turbine blades in gas turbine engines are subjected to extremely high temperatures from the combustor portion of the engine. Jet fuel is burned in the combustor and then the by-products are allowed to expand and accelerate through the turbine section. To keep the blades from melting, cooler air from the compressor portion of the engine is passed through holes in the interior of the blade. The turbine blade designer faces the problem of how many holes to drill in the blade and where to place them.

Ref. 4 presents an application of the BEM to the analysis of heat conduction in turbine blades with holes. Special attention is paid to mixed type boundary conditions and the use of the BEM to determine interior solutions given experimentally determined data on the exterior of the blade.

The problem of blade design can be attacked with the use of the BEM in conjunction with an optimization procedure to iteratively adjust the position and size of the holes so that an optimal design is achieved. In Refs. 5 and 6 this method was developed and tested on some practical turbine design problems. Fig. 4 shows a result of an optimization sequence. This figure shows the initial and subsequent evolution of the position and size and of the holes in a turbine blade. The BEM is used at each iteration to solve the heat conduction problem in the solid portions of the hollow blade. The BEM solution is coupled with an optimization routine to iteratively adjust both the size and position of the holes. The function being minimized in this example is the difference between a specified and calculated heat flux on the exterior surface of the blade. This procedure allows the designer to specify a low enough temperature on the surface of each hole, so that the blade retains its structural integrity and does not melt when subject to hot combustor gases.

Conclusions

We have discussed the BEM and its applications to a model problem. In addition, special applications of the method were detailed. The BEM was shown to be a powerful alternative to finite element or finite difference methods for the solution of boundary value problems in engineering science.

Abstract

A survey of techniques for the numerical generation of computational grids is presented. These methods are shown to be a powerful addition to the numerical analyst's tools for simulation of complex physical processes. Computational grids are classified into their various forms and methods for generating each type of grid are discussed. In addition to the mathematical and numerical details of each method, examples of the application of each method are shown. A short bibliography of these methods is also given to assist the interested reader in finding more information about this important part of computational mechanics.

Introduction

This paper presents a survey of methods for the numerical generation of computational grids used in the simulation of physical problems governed by partial differential equations. Computational grids are required to represent a given region of space as a discrete collection of sub-regions. Within these sub-regions, the solution of the governing partial differential equation is assumed to be of a certain form representable on a computer. The discrete system can then be solved on a computer and the results analyzed. The problem of generating good quality grids is very difficult for complex regions and has been a pacing item in computational mechanics. As grid generation techniques have become more powerful, they have allowed analysts to simulate more and more complex and realistic physical problems. Moreover, with the advent of supercomputers, grid generation methods are now required for discretizing arbitrary three-dimensional regions such as the region surrounding an aircraft in flight, prior to solution of three-dimensional field equations in these domains. Researchers in a wide range of fields have developed some very sophisticated methods for computational grid generation. We begin this survey by first classifying different types of grids as either structured, quasi-structured or unstructured and discuss the different topologies of each. Next we discuss various popular methods for generating grids and give some discussion of their relative merits. Finally we note some special topics including grid improvement methods and adaptive grid generation.

Classification of Computational Grids

We define a computational grid in a domain Ω (subset of R^n) as a collection of M sub-domains Ω_i such that the intersection of Ω_i and Ω_j is empty for all i and j, $i \neq j$, i,j = 1,2,...M and the union of the Ω_i is "close" to Ω. Therefore, we exclude the possibility that any of the Ω_i overlap each other and we ensure that there are no 'gaps' in the grid (except possibly right at the boundary of Ω). Moreover, we do not allow the volume (area in 2-d or length in 1-d) of any of the Ω_i to vanish (see fig. 1). We will be primarily concerned with Ω_i that have boundaries $\partial\Omega_i$ that are representable by polynomials. For example, in a two-dimensional domain we can have straight sided quadrilaterals representable by linear functions of the nodal points. We define nodal points as special points on the boundary of Ω_i that are used to construct the polynomial representing the boundary of Ω_i (fig. 1b) and are normally the points at which the approximate numerical solution is evaluated.

Computational grids can be classified into three main groups: 1) structured, 2) quasi-structured, and 3) unstructured. Structured grids are those that can be logically associated with (mapped, or transformed to) another base grid that has a regular repeatable structure. The base (also called the canonical or computational) domain is constructed entirely of a repetition of the same sub-domain througout the domain. Thus if Ω^* is the base domain, then the base grid is the collection of Ω_i^* where each Ω_i^* has the same size and shape. Examples of different types of base grids are shown in figures 2 a) and b). One can see that a base grid can be defined very easily as a array of the nodal points and a simple rule that determines which nodal points belong to which sub-domains and which elements are connected to each other. Moreover, the discretization of a partial differential equation on the base grid assumes a very simple (essentially canonical) form. For this reason, structured grids have been the most popular grids to date, especially in the finite difference literature. One important aspect of quadrilateral structured grids is that the sides of the elements can be associated with generalized coordinate directions. Thus to generate a quadrilateral structured grid is tantamount to specifying a transformation function that maps the computational space with coordinates $\xi = (\xi_1, \xi_2, ..., \xi_n)$ into the physical domain Ω with coordinates $\mathbf{x} = (x_1, x_2, ..., x_n)$. This transformation can be stated as $\xi = \xi(\mathbf{x})$. This fact is extensively used in finite difference methods where the governing equation in the physical coordinates $\mathbf{x}$ is transformed into the computational coordinates using the map $\xi(\mathbf{x})$ and then the equation is solved in the regular base domain Ω^*. This has the advantage that the finite difference equations are essentially the same at each nodal point and

CH2345-7/86/0000/0568$01.00 © 1986 IEEE

therefore are easy to code in a computer program. Finite element methods generalize this concept with the idea of a master element. The master element is the computational domain and consists of only one sub-domain that can be mapped to every element in the physical domain. The discretized governing equation assumes a canonical form on the master element and therefore, the solution procedure becomes easy to program on a computer.

We define a quasi-structured grid as a grid consisting of a union of structured grids. The union is required to discretize the domain as we require for sub-domains. These grids are used in cases where there does not exist a simple transformation that defines a structured grid (for example in multiply connected domains). Thus the domain to be discretized is broken into a few sub-domains that each form a structured grid. These grids are sometimes termed composite or zonal grids and are used extensively in finite difference methods.

Finally, we define unstructured grids as those that are neither structured nor quasi-structured. These types of grids have been used extensively in finite element methods, although the grids were mostly generated by hand. Only fairly recently have automatic unstructured grid generation methods become common.

Transformations and Computational Coordinates

Structured grid generation methods are based on the existence of a transformation from the physical domain Ω to the computational domain Ω^*. We now show how derivatives of quantities in the physical space transform into their respective derivatives in the computational space (we show this for a two-dimensional domain only). Assume we want to determine the derivatives $\partial/\partial x$ and $\partial/\partial y$ of some function u(x,y) in terms of derivatives $\partial/\partial\xi$ and $\partial/\partial\eta$ in the computational coordinates (ξ,η). Using the chain rule of partial differentiation we find

$$\begin{aligned}\partial u/\partial x &= \partial\xi/\partial x\, \partial u/\partial\xi + \partial\eta/\partial x\, \partial u/\partial\eta \\ \partial u/\partial y &= \partial\xi/\partial y\, \partial u/\partial\xi + \partial\eta/\partial y\, \partial u/\partial\eta\end{aligned} \tag{1}$$

This can be written as a matrix equation

$$\begin{bmatrix}\partial u/\partial x \\ \partial u/\partial y\end{bmatrix} = \begin{bmatrix}\partial\xi/\partial x & \partial\eta/\partial x \\ \partial\xi/\partial y & \partial\eta/\partial y\end{bmatrix}\begin{bmatrix}\partial u/\partial\xi \\ \partial u/\partial\eta\end{bmatrix} \tag{2}$$

We can similarly use the chain rule on the derivatives $\partial u/\partial\xi$ and $\partial u/\partial\eta$ to obtain the relations

$$\begin{bmatrix}\partial u/\partial\xi \\ \partial u/\partial\eta\end{bmatrix} = \begin{bmatrix}\partial x/\partial\xi & \partial y/\partial\xi \\ \partial x/\partial\eta & \partial y/\partial\eta\end{bmatrix}\begin{bmatrix}\partial u/\partial x \\ \partial u/\partial y\end{bmatrix} \tag{3}$$

The matrix can be inverted to obtain the relation

$$\begin{bmatrix}\partial u/\partial x \\ \partial u/\partial y\end{bmatrix} = \frac{1}{J}\begin{bmatrix}\partial y/\partial\eta & -\partial y/\partial\xi \\ -\partial x/\partial\eta & \partial x/\partial\xi\end{bmatrix}\begin{bmatrix}\partial u/\partial\xi \\ \partial u/\partial\eta\end{bmatrix} \tag{4}$$

where J is the Jacobian and is given by $J(\xi,\eta) = \partial x/\partial\xi\, \partial y/\partial\eta - \partial y/\partial\xi\, \partial x/\partial\eta$. Equating coefficients of the two matrices in eq. 2 and 4 gives the following relationships:

$$\begin{aligned}\partial\xi/\partial x &= (\partial y/\partial\eta)/J & \partial\eta/\partial x &= (-\partial y/\partial\xi)/J \\ \partial\xi/\partial y &= (-\partial x/\partial\eta)/J & \partial\eta/\partial y &= (\partial x/\partial\xi)/J\end{aligned} \tag{5}$$

These are the required relations that determine how derivatives of a function in physical space transform into derivatives in the computational space. We now discuss some techniques for the generation of structured grids.

Conformal Mapping Methods

Conformal mapping methods are based on the use of complex analytic conformal transformations. That is, the map from computational to physical space is accomplished with the use of complex valued analytic functions. If we let $z = x + iy$ $(i = \sqrt{-1})$ be the physical complex-valued coordinate and $\zeta = \xi + i\eta$ be the computational complex-valued coordinate then grids are determined by specifying analytic transformations from ζ to z:

$$z = F(\zeta) \tag{6}$$

Since all analytic transformations are conformal (except at singular points) then these transformations will produce conformal maps. A conformal transformation is one that preserves both the magnitude and the sense of angles. Thus, if the base grid consists of mutually orthogonal lines, then the physical grid will also be orthogonal. This fact is an advantage for conformal mapping techniques because if the physical grid is orthogonal, the resulting discretization of the partial differential equation becomes greatly simplified, and truncation errors are reduced. However, it is most usual to use conformal mappings to map the physical space to a simpler non-orthogonal domain and then use simple algebraic transformations to map the intermediate domain to the computational grid. This makes the resulting physical grid non-orthogonal. An example of a nearly orthogonal grid generated using a conformal mapping is shown in fig. 3.

Conformal mapping methods (like the algebraic methods discussed below) are extremely efficient and thus were widely used in the past[1,2,3].

Algebraic Methods[1]

The algebraic grid generation method is based on interpolation of known values of the nodal values of the physical grid on the boundary $\partial\Omega$ throughout the domain. We begin with a short discussion of one-dimensional interpolation. Assume that we have a function $r(\xi)$ that we know the values of at some points ξ_i. We wish to interpolate this function with a simple interpolant that posesses certain desirable properties. We construct interpolants $\varphi_i(\xi)$ that have the property that $\varphi_i(\xi_j) = \delta_{ij}$ (where δ_{ij} is the Kronecker delta). Thus, we can write

$$r(\xi) = \Sigma_i\, r(\xi_i)\ \varphi_i(\xi) \qquad (7)$$

where we assume that ξ varies from 0 to 1. The functions $\varphi_i(\xi)$ can take many forms, but it is most usual to use polynomial interpolants such as the Lagrange or Hermite polynomials. It is also possible to use cubic splines, B-splines or other types of spline functions for the uni-directional interpolation. Now assuming that we know the values of the grid point coordinates on the boundary of the transformed space, that is we know

$$\begin{aligned} &\mathbf{r}(\xi,\eta)\ \text{ for } \eta = 0 \text{ or } 1\\ &\mathbf{r}(\xi,\eta)\ \text{ for } \xi = 0 \text{ or } 1 \end{aligned} \qquad (8)$$

then we can construct two interpolants based on interpolating **r** in the ξ and η directions separately:

$$\begin{aligned} \mathbf{r}(\xi,\eta) &= \Sigma_{i=1,2}\ \mathbf{r}(\xi_i,\eta)\ \varphi_i(\xi)\\ \mathbf{r}(\xi,\eta) &= \Sigma_{j=1,2}\ \mathbf{r}(\xi,\eta_j)\ \psi_j(\eta) \end{aligned} \qquad (9)$$

These two functions exactly interpolate the values of **r** on the boundaries $\xi = 0$ or 1 and $\eta = 0$ or 1 respectively. We can add the two interpolants together, but the resulting function does not interpolate **r** on the boundaries. However, we can interpolate the discrepancies on the boundaries, and subtract off this error from the total interpolant. This results in the transfinite interpolant:

$$\begin{aligned} \mathbf{r}(\xi,\eta) = \Sigma_{i=1,2}\ \mathbf{r}(\xi_i,\eta)\ \varphi_i(\xi) + \Sigma_{j=1,2}\ \mathbf{r}(\xi,\eta_j)\ \psi_j(\eta)\\ \Sigma_{i=1,2}\ \Sigma_{j=1,2}\ \varphi_i(\xi)\ \psi_j(\eta)\ \mathbf{r}(\xi_i,\eta_j) \end{aligned} \qquad (10)$$

This function exactly interpolates the values of **r** on all four boundaries of the rectangular computational space. By uniformly dividing the computational space, and applying the interpolating function we can generate the grid in the physical space, a very efficient process. The algebraic method can be easily generalized to three-dimensional grids, and to generate grids posessing any desired order of smoothness by an appropriate choice of the basis functions. However, the user of this method does not have complete control over such grid quantities as orthogonality and clustering.

The Maximum Principle

Solutions of the Dirichlet problem

$$\begin{aligned} &\Delta u = 0 \ \text{ in } \Omega\\ &u = \underline{u} \ \text{ on } \partial\Omega\\ &(\,\Delta = \partial^2/\partial x^2 + \partial^2/\partial y^2\,) \end{aligned} \qquad (11)$$

exhibit a very special and useful property known as the maximum principle. This principle states that the solution achieves its maximum and minimum values on the boundary of the domain. This fact can be used to generate grids that are guaranteed not to be overlapped and in addition are very smooth. The smoothness of the grid results from the inherent smoothness of solutions to the Dirichlet problem. Methods that are based on the maximum principle are popular and include the elliptic grid generation methods of Winslow (ref) and Thompson *et. al.*[1] and the variational method of Brackbill and Saltzman[4].

Elliptic Grid Generation

The elliptic grid generation method[1] is based on the numerical solution of the following equations

$$\begin{aligned} &\Delta\xi = 0\\ &\Delta\eta = 0 \end{aligned} \qquad (12)$$

Solutions to these equations will satisfy the maximum principle. Thus, the maximum and minimum values of ξ and η will be reached on the boundary of the physical space and thus there is no possibility that grid overlap can occur in the domain. To generate the grid, these equations are transformed using relations (5) above to relate the derivatives in the computational space to derivatives in physical space. The result is the following non-linear elliptic system of partial differential equations to be solved for the physical grid

$$\begin{aligned} &\alpha\, x_{\xi\xi} - 2\,\beta\, x_{\xi\eta} + \gamma\, x_{\eta\eta} = 0\\ &\alpha\, y_{\xi\xi} - 2\,\beta\, y_{\xi\eta} + \gamma\, y_{\eta\eta} = 0 \end{aligned} \qquad (13)$$

where

$$\alpha = x_\eta^2 + y_\eta^2$$
$$\beta = x_\xi x_\eta + y_\xi y_\eta$$
$$\gamma = x_\xi^2 + y_\xi^2$$

These equations are discretized using finite differences and then solved using iterative techniques. The method can be modified so that interior grid point clustering can be controlled by the addition of non-homogeneous terms to the right-hand-side of eq. 12. This results in a coupled system of non-linear Poisson equations to be solved. An Example of the type of grid generated by this method is shown in fig. 4.

The Variational Grid Generation Method

The variational grid generation method[4] is based on some heuristic principles concerning what a good quality grid consists of. These principles are 1) the grid should be as smooth as possible, 2) orthogonal as possible, and 3) should cluster in specified regions of the physical domain. These principles can be stated mathematically by minimizing appropriate measures of the smoothness, orthogonality and clustering functions. The smoothness of the grid is measured by the following functional

$$I_s = \int_\Omega (\nabla\xi)^2 + (\nabla\eta)^2 \text{ dx dy} \qquad (14)$$

The orthogonality of the grid is measured by the functional

$$I_o = \int_\Omega \nabla\xi \cdot \nabla\eta \text{ dx dy} \qquad (15)$$

Finally, the grid clustering is measured by the functional

$$I_w = \int_\Omega w(\xi,\eta)\ J(\xi,\eta) \text{ dx dy} \qquad (16)$$

Now we can form one functional that is a weighted average of all three quantities we wish to minimize:

$$I(\xi,\eta) = \lambda_s I_s + \lambda_o I_o + \lambda_w I_w \qquad (17)$$

where λ_s, λ_o, and λ_w are scalars that give different weighting to each functional. Minimizing $I(\xi,\eta)$ will produce an optimal grid with respect to the chosen grid quality measures. The $\boldsymbol{\xi}$ coordinates are transformed to the physical **x** coordinates using eq. 5 and then the Euler-Lagrange equations are formed. The resulting system is similar to the system of eq. 13 and is solved using finite difference discretization and iteration. One can see that where the weighting function is large, the grid cell size will be small, achieving the required clustering. Therefore, the method is particularly suited to generation of adaptive grids. The usual procedure is to choose the weight function as a measure of the rate of change of the solution to the equation we are trying to solve on the grid. One example of this adaption is shown in fig. 5. Note how the grid adapts to the steep gradients in the vicinity of the shock waves in the solution.

It is possible to directly discretize and minimize $I(\xi,\eta)$ before applying the Euler-Lagrange equations. This method was used in refs. 5 and 6 to generate structured and quasi-structured grids. Functionals analogous to I_s, I_o and I_w were developed to measure the grid quality. The grid points are solved for by minimizing the grid quality measures using a conjugate gradient optimization algorithm. An example grid generated by this procedure is shown in fig. 6. This method is also applicable to unstructured grids and is further discussed below.

Quasi-Structured Grids

Quasi-structured (zonal, composite or patched) grids have been used by many[1,2] to take advantage of the simplicity of finite difference methods while allowing the discretization of more general domains. The physical domain is first subdivided into a small number of regions, each of which can be separately associated with a rectangular computational domain. The grids are generated in each sub-domain and then patched together along common boundaries. These interfaces between the domains can be fixed or allowed to float along with the nodal points in the grid generation procedure. A method for generating composite grids based on the method of ref. 5 was developed in ref. 6. An example of using this procedure is shown in fig. 7. This is a composite grid consisting of two structured grids, one an O-type grid about a gas turbine engine blade and the second a C-type grid surrounding the O-type grid. The quasi-structured grid approach is a powerful tool; however, it is not as general as the unstructured grid methods.

Unstructured Grids

Unstructured grids afford the most geometric generality. In fact, one can discretize an arbitrary domain using an appropriate unstructured grid. For this reason, these types of grids have been receiving much attention recently, as solutions of field equations are required on more and more complex geometries. Unstructured grids can be generated by hand (or with the use of a digitizing tablet), but this method is tedious, time-consuming and has a large human error factor. Thus, we are led to automatic methods for unstructured grid generation. The most general automatic unstructured grid generation methods are those based on the n-simplex (triangle in 2-d and tetrahedra in 3-d). The procedure is to first specify the positions of the N nodal points which in this case are just the vertices of the triangles or tetrahedra. (The positions of the nodal points can, for example, be generated pseudo-randomly). Next, a scheme is used to connect the N points to form the triangular elements forming the grid. The points x_j, j = 1,2,...N, can be joined using purely heuristic or semi-optimal rules[7]. The optimality of the grid can be measured by how similar each element is to an equilateral triangle (similarly in 3-d). It is striking that there exists a very simple rule for joining the vertices that ensures that the grid is optimal--the Delaunay criterion[8,9]. First we define the Voronoi polygon surrounding a point $\mathbf{x}_i$ as the set of points closer to $\mathbf{x}_i$ than any other point

$$V(\mathbf{x}_i) = \{ \mathbf{x} \mid d(\mathbf{x},\mathbf{x}_i) \leq d(\mathbf{x},\mathbf{x}_j) \quad \text{for all } j=1,2,\ldots,N\}$$

where $d(\cdot,\cdot)$ is the Euclidean metric ($d(\mathbf{x},\mathbf{y})$ = distance between $\mathbf{x}$ and $\mathbf{y}$). Two points $\mathbf{x}_i$ and $\mathbf{x}_j$ are termed Voronoi neighbors if their respecive Voronoi polygons share a common edge. Thus, the Delaunay criterion states that node $\mathbf{x}_i$ is to be connected to node $\mathbf{x}_j$ if they are Voronoi neighbors. This procedure produces grids such as the one shown in fig. 8 for two airfoils in a wind tunnel. Note that the procedure has to be modified for non-convex domains such as this. In effect, the connections are checked to see if they cross any of the required boundary edges, and if so, one of the nodes is deleted from the search for Voronoi neighbors. This triangulation procedure can be made to take on the order of NlogN operations, and thus is very efficient.

Grid Improvement and Adaption Methods

In general, a given computational grid is not the optimal one for solving a problem. For example, it is usually required to have the grid clustered in some regions of the domain in which the solution to the problem is varying rapidly. Since the solution is not known *a priori*, we are led to methods that dynamically adapt the grid to the solution. This adaption can take either of two forms: 1) the main grid is held fixed while individual sub-domains are refined into smaller sub-domains (this is called adaptive refinement) or 2) the basic logical structure of the grid is held fixed and the grid points are allowed to move such that they become clustered in required regions (this is just called an adaptive grid). The effect of either of these types of adaptions is to make the grid spacing smaller in the required regions, and therefore increasing the accuracy of the numerical solution. An example of adaptive grid refinement[10] is shown in fig. 9. Note how the grid is refined in certain regions requiring resolution. An example of an adaptive grid is shown in fig 5. The grid points have moved and clustered in the required regions. The method of ref. 5 can be modified so that it is applicable to unstructured grids. Thus, unstructured adaptive grids could be generated analogously to structured adaptive grids. In conclusion, adaptive methods are one of the most promising techniques for improving the accuracy of numerical solutions to partial differential equations.

Conclusions

Numerical methods for the generation of computational grids have been presented. These methods have been shown to be very powerful tools for use in the simulation of complex physical processes governed by partial differential equations.

Abstract. Symmetries occur naturally in many types of problems. (An example is the eight queens problem under rotation or flip of the chessboard). The performance of search algorithms in solving such problems can be improved by recognizing as early as possible that two partial solutions are equivalent under symmetry. However, most uses of symmetry in searching are problem specific and may not take full advantage of the potential improvements. In this paper we describe a general method for incorporating symmetries in search methods. The input to our procedure is a problem together with an abstract representation of its underlying symmetries (known as a *group*). The method automatically calculates the symmetry tests to be performed at each stage in searching, making use of efficient algorithms for computing with groups. In this way the full benefit of the symmetries is obtained without the need for *ad hoc* techniques.

1. Introduction

Searching is an important method for solving difficult problems. A great deal of effort has been directed into making search methods more "intelligent", in order to improve their efficiency. There are two common approaches. One method is to guide the search by using known properties of the problem under investigation. A second approach is to develop general methods which do not depend on the nature of the problem. A common characteristic of such general methods is the ability to reject large numbers of possible solutions simultaneously, rather than having to consider each one individually. The most popular intelligent search method of this type is known as *backtracking.* The basic idea of backtracking is to build a solution to a problem one piece at a time. If it is possible to identify a partial solution as one that cannot be extended to a full solution, then we eliminate from the search space all possible extensions of this partial solution.

To do well with backtracking, it is necessary to develop tests that can eliminate partial solutions as early as possible. Most efforts to improve backtracking programs for individual problems concentrate on developing better criteria for eliminating partial solutions. While important, such improvements tend to be problem-specific, so there is little or no carry-over to other problems. There are also general methods, such as search rearrangement [4,18], that allow the criteria to be applied earlier in the search process. Search rearrangement can lead to a very significant improvement in the behavior of a backtrack program. For some problems there is another possibility: the existence of symmetry in the potential solutions to the problem may allow certain sections of the search space to be omitted altogether.

Symmetries occur naturally in many types of backtrack problems. For example, consider the problem of embedding a graph $\mathcal{G}_1$ in another graph $\mathcal{G}_2$. If the automorphism group G of $\mathcal{G}_2$ (the group of one-to-one edge-preserving maps of $\mathcal{G}_2$ onto itself) is known, then a partial embedding can be tested by seeing if it is equivalent under some automorphism to a partial embedding that has already been examined. If such an equivalence is found, then the current partial solution can be discarded.

In many problems, there are variables that play interchangable roles. This is another manifestation of symmetry. As a simple example, consider the missionaries and cannibals problem. Three missionaries and three cannibals must cross a river using a two-man boat. Either one or two people can take the boat across the river. The problem is to devise a plan for crossing in which the cannibals never outnumber the missionaries on either side of the river. This problem is typically given to beginning classes in artificial intelligence to be solved using backtracking. The missionaries are clearly interchangable amongst themselves, as are the cannibals. Thus, it is only necessary to consider solutions where the missionaries cross the river in some particular order, and the same for the cannibals. Any other solution can be obtained from such a solution by permuting the names of the missionaries, and of the cannibals, amongst themselves.

In general, it is not necessary to try all combinations of values for interchangable variables. For example, if there are n interchangable Boolean variables, then we need only test $n+1$ sets of values (no variables equal to zero, one variable equal to zero, ..., n variables equal to zero) instead of the 2^n different combinations that would otherwise be needed.

CH2345-7/86/0000/0576$01.00 © 1986 IEEE

Symmetry can also arise from the underlying structure of the problem. As an example, consider the eight queens problem: place eight queens on a chessboard so that none of them is attacking any of the others. Any solution to the problem can be converted to another (possibly different) solution by rotating the board through 90, 180, or 270 degrees, or by flipping it to a mirror image position. How can this fact be used to reduce the search space? Let us refer to the queens as $Q_1, \ldots, Q_8$. Since no two queens can be in the same row, we assume that Q_i goes in row i. Then we need only consider placing Q_1 in columns 1 to 4, since any solution with Q_1 in column $4+i$ can be obtained from a symmetrical one with Q_1 in column $5-i$ by flipping to the mirror image. This observation eliminates half of the search space.

It is less obvious how to apply the rotational symmetries. A little thought shows, for example, that if we can rule out any solution with Q_1 in column 1, we do not need to try putting a queen in any corner of the board. But what we really need is a systematic way of applying knowledge about symmetries to reducing the search space.

The systematic study of symmetries is the province of group theory. The obvious symmetries of the eight queens problem form a well-known group: the dihedral group of order eight. In recent years there has been a great deal of activity in the field of computational group theory, inspired in part by the classification of all finite simple groups [3]. Several systems for performing basic group theory operations are currently available [8].

It is very common for a problem to display one or more of the types of symmetry described above. By taking advantage of such symmetries to reduce the search space, knowledge about the problem that is not explicit in the predicates can be exploited. We are developing a systematic procedure for applying group-theoretic methods to exploit the existence of symmetries in backtracking problems. This procedure includes methods for representing the symmetries and for automatically calculating the tests to be applied at each stage in the backtracking process in order to take maximum advantage of them. We are also working on developing and improving the group-theoretic algorithms required for these calculations.

Some care is needed if the symmetry testing is to speed up a search program, not just reduce the number of nodes. A naive approach would use time proportional to the size of the symmetry group at each node. Since the maximum reduction in the number of nodes is also proportional to the size of the symmetry group, little or no savings would result. There are two strategies for improving on the naive approach. The first is to use efficient algorithms for the symmetry testing. We make use of algorithms from computational group theory to carry out the symmetry tests [3,6,15,16,19]. The general test we apply at each node in the search space is essentially equivalent to computing a certain color automorphism group. We have two fairly distinct methodologies for computing this test. The first one is based on a general algorithmic method for computing with permutation groups developed by Sims [19] and refined by Leon [15] and Butler [6]. This method usually does the symmetry testing rapidly, but it can take exponential time. The second only applies where the group is a p-group [11], but it is fast because it uses Luks' color automorphism algorithm [16].

A second approach to reducing the time spent on symmetry testing is to discontinue the testing on portions of the search space where it can have no effect. We have a criterion which establishes certain conditions under which symmetry testing cannot yield any further savings. Since symmetry testing usually has most of its effect near the root of the search tree, this often permits us to save a significant amount of time.

The methods for intelligent searching described in this paper have characteristics similar to other such methods. In practice they may speed up searching greatly, but there is no guarantee of a speed-up on any particular problem, and there is no indication that the method improves the worst-case time for searching.

2. Backtracking and Symmetry

Backtracking is a widely used method for reducing the size of a search space. To apply backtracking to a problem it must be expressed in a suitable form. Many problems may be expressed as predicates on a set of variables. A solution to such a problem is an assignment of values to the variables that makes the predicate true. To do backtracking, we must have a set of *intermediate predicates* available. An intermediate predicate is a predicate over a subset of the variables which is false for a given assignment of values to its variables (which we call a *partial solution*) only if that assignment cannot be extended to a solution to the full problem. In other words, an intermediate predicate is able to identify some partial solutions as dead ends, and therefore cause the program to back up. In the eight queens problem, for example, the intermediate predicate is the check that the queens placed on the board so far do not attack each other.

We call the problem predicate P, and the problem variables $x_1, \ldots, x_n$. Let P_i be the intermediate predicate for $x_1, \ldots, x_i$. We simplify the discussion by assuming that each variable has values in the range $0, \ldots, v$. In addition, we use a special value, u, to represent an unset variable.

Each partial solution X may be thought of as a sequence $X = x_1 \ldots x_n$ of n values. A partial solution is said to be *complete* if all of its variables are set, and *incomplete* otherwise. We will assume that the variables of X are set from left to right. If X is an incomplete partial solution and x_k is the first unset variable of X, then all variables x_j of X with $j \geq k$ would normally be unset. However, as we shall see, our use of symmetry will often allow us to set certain variables $x_j, j \geq k$, to v. Accordingly, we assume that all variables $x_j, j \geq k$, are either unset or set to v. We need a partial order $\prec$ on the set of all partial solutions with the property that if $X \prec Y$ and if X and Y are incomplete, then all possible extensions of X to a complete solution will be examined before any attempt to extend Y. The partial order we use is defined by $X \prec Y$ if there is a prefix $y_1 \dots y_k$ of Y consisting of set variables which satisfy the following properties:

1. For $j < k$, either $y_i = x_i$, or $y_i = v$ and $x_i = u$.
2. x_k is set and $y_k > x_k$.

In the case where X and Y are complete, $\prec$ is the usual lexicographic ordering.

Let S_n be the symmetric group of degree n. The group S_n may be described as the set of all permutations of the set $\Omega = \{1, 2, \dots, n\}$, with the group action being ordinary composition of functions. We denote an application of $g \in S_n$ to $i \in \Omega$ by the exponential notation i^g. The group S_n acts naturally on the set of all sequences of length n by permuting the sequence values according to the permutation of their indices. To describe the action formally, let g be an element of S_n and $X = x_1 x_2 \dots x_n$ be a sequence of values. Then $Y = X^g$ is the sequence defined by setting $y_j = x_i$, where $j = i^g$. Equivalently, one may write Y as the sequence $x_{1_{g^{-1}}} x_{2_{g^{-1}}} \dots x_{n_{g^{-1}}}$. It is easy to check that according to this definition $X^{gh} = (X^g)^h$ for all sequences X and all elements $g, h \in G$. In many instances it is more convenient to consider $X^{g^{-1}}$ instead of X^g because $X^{g^{-1}} = x_{1^g} x_{2^g} \dots x_{n^g}$.

We are particularly interested in the set G of elements of S_n which leave invariant the set of solution sequences to P. (That is, the elements of G carry solutions into solutions.) It is easy to show that the product of two elements of G preserves all solutions, and so G is a subgroup of S_n. As a consequence, G also preserves the set of sequences which are not solutions to P; either property defines G. For example, the dihedral group of order eight may be used for G in the eight queens problem.

We now describe our method for exploiting the existence of symmetries. Let X be a partial solution for which the values $x_1, \dots, x_{k-1}$, $k > 1$, have already been set, and assume that x_k is the variable under consideration. (The current value of x_k must either be u or some number less than v.) If $x_k = u$, then we initialize the value of x_k to 0. Otherwise, x_k is incremented by 1. Assume that $P_k(x_1, \dots, x_n)$ is true so that, in the normal course of events, the backtracking procedure will continue by attempting to extend the partial solution X.

At this point we call the function *SymTest*, which contains the heart of our application of symmetry to backtracking. SymTest has an argument list of the form $(\mathcal{G}, X, k, \mathcal{H}, g)$, where $\mathcal{G}$ is a list of generators for G, X is the current partial solution, and k is the index of the last variable of concern. SymTest returns a Boolean value which is *true* if there is an element $g \in G$ (such that $X^{g^{-1}} \prec X$) and *false* otherwise. If such an element g exists, it is returned in the last parameter of Symtest; otherwise, variable $\mathcal{H}$ will contain generators for a subgroup H of G which will be defined shortly. In addition, SymTest has the side effect of possibly setting certain variables $x_j, j > k$, to the value v and of restricting the possible values of other variables.

If SymTest returns *false*, then $\mathcal{H}$ will contain a list of generators for the subgroup H of G which preserves a certain coloring $\mathcal{C}$ of the elements Ω induced by X. The colors in $\mathcal{C}$ are drawn from the set $\{0, \dots, v\} \cup \{u\}$. Elements $i, j \in \Omega$ are said to have the same color, denoted $i \sim j$, if and only if either $x_i = x_j$ or one has value v and the other u. (For reasons which will become clear later, we consider u and v to be the same color.) We then define $H = \mathcal{C}_\Omega(G)$ to be the set of all elements $g \in G$ which preserve the coloring $\mathcal{C}$; i.e. $g \in H$ iff $i^g \sim i$ for all $i \in \Omega$. It is straightforward to show that H is closed under composition, and hence forms a subgroup of G.

In our implementation of SymTest, we essentially attempt to compute the color automorphism group H with modifications made to suit our backtracking environment. At this time, it is not known if there is a polynomial time algorithm to solve the color automorphism problem. However, there do exist special cases (which depend on the structure of G) for which polynomial time algorithms are known [16]. We have two different methodologies for computing H. The first method is based on a general approach for computing with permutation groups develped by Sims [19] and the second method utilizes an especially efficient algorithm [11] based on methods of Luks [16] for computing H in the case where G is a $p-$group, i.e. G has order a power of a prime p. It seems likely that the computations needed for our application will be relatively inexpensive in either case. We sketch the Sims' type method in Section 5; see [5] for a complete description of both methods.

Although our two methodologies for implementing SymTest are rather different, we present a somewhat simplified view of what both are attempting to accomplish. The basic idea is to incrementally compute permutations g that preserve $\mathcal{C}$. As g is extended to the next variable, we check whether it gives us a reason to back up. Thus, SymTest is designed to successively examine the values of x_{j^g}, $1 \leq j \leq k$, and to take appropriate action according to which of the the following cases occurs. Initially, $\mathcal{H}$ is the empty list, and at any given time $H = \langle \mathcal{H} \rangle$ is the group generated by H (the empty list generates the identity subgroup). We start by choosing an arbitrary element g of

G and setting j to 1. The more realistic versions of the algorithm differ from this naive version by not actually examining each g separately.

1. j = k+1. If we eventually arive at this case, then we know that $x_{i^g} = x_i$ for $1 \leq i \leq k$. Since x_j, $j > k$, is either set to v or is unset, it follows that g preserves $\mathcal{C}$. We then add g to $\mathcal{H}$ and choose an element not yet considered in $G - H$. If no such element exists, then we return false and $\mathcal{H}$ will then contain a set of generators for $\mathcal{C}_\Omega(G)$.

2. $x_j = x_{j^g}$. In this case, we increment j and continue to examine g.

3. $x_{j^g} < x_j$. In this case, $X^{g^{-1}} \prec X$ and SymTest returns true with its last parameter set to g . At this point in the backtracking procedure we need not consider X further, since X is equivalent under symmetry to a smaller partial solution.

4. $x_j < x_{j^g}$, or $x_j < v$ and $x_{j^g} = u$. Two subcases arise in this case. If x_{j^g} is set, then it is unnecessary to consider g further, since $X^{g^{-1}} \succ X$. If $x_j < v$ and $x_{j^g} = u$, then if x_{j^g} were later set to a value less than x_j while we were in the current branch, then we would have $X^{g^{-1}} \prec X$. Thus we should keep track of this information and not set x_{j^g} to any value less than x_j. This information represents a constraint on the future values of x_{j^g}, so this part of the method is reminiscent of constraint satisfaction methods. In either case, we choose a new element to consider from $G - H$.

5. $x_j = v$ and $x_{j^g} = u$. In this case, $x_j = v$ and $x_{j^g} = u$. If, at some later time, we were to set $x_{j^g} = r$ with $r < v$, then we would have $X^{g^{-1}} \prec X$. Therefore, we may avoid additional work by setting $x_{j^g} = v$ now and continuing to extend the definition of g.

In cases 1 and 4, if we have exhausted all elements of $G - H$, then we return false with $\mathcal{H}$ a set of generators for $\mathcal{C}_\Omega(G)$. It should be noted that each time we add a generator to $\mathcal{H}$ we at least double the size of H.

Much of the useful work done by SymTest occurs during the attempt to extend an element $g \in G$ to all indices $\{1, \ldots, k\}$. Each time a variable is set or its domain of definition is restricted, as in case 4, we remove a large portion of the search space.

SymTest returns either an element $g \in G$ with the property that $X^{g^{-1}} \prec X$, if one exists, or else return a set of $O(n)$ generators for the subgroup H. In the latter case, it may still be possible to set some additional variables. To see how this is done, suppose $g \in H$. This leads to the partial solution given by the sequence $X^{g^{-1}} = x_{1^g} \ldots x_{n^g}$ (it is more convenient to consider the image of X under g^{-1} than g). By definition of H, for $i \leq k$, we must have $x_i = x_{i^g}$ whenever $x_i < v$; however, we may have $x_i = v$ and $x_{i^g} = u$. As noted before, if at some later time, we were to set $x_{i^g} = r$ with $r < v$, then the symmetry g^{-1} would have the property that $X^{g^{-1}} \prec X$. Therefore, we may set all variables x_{i^g} currently set to u to have value v. Applying g to $X^{g^{-1}}$ then results in the original partial solution X with possibly one or more unset variables now set to v. Each such setting represents a decrease by one in the number of unset variables of X, and thus effectively decreases by one variable the size of the remaining backtrack problem on the branch being investigated.

A more efficient method for accomplishing the above procedure is to simply compute the orbit j^H for each position $j \leq k$ that contains a v, and to make sure that the variables corresponding to the positions in each of these orbits is set to v. In other words, for each such j compute

$$j^H = \{\, r : r = j^g,\ g \in H \}$$

and set $x_r = v$ for each r in the orbit. The advantage in using this method is that the cost of computing an orbit of H is proportional to the product of n and the number of generators of H. In general, H can be compactly described by a set of at most $n-1$ *strong generators* [19] (the notion of a strong generator will be discussed in Section 4). Thus the cost of applying the symmetry information is linear in the number of generators times n, whereas a naive method would take time proportional to the size of H times n.

We now formulate a backtracking algorithm to incorporate these ideas. There are many possible data stuctures which may be used for representing groups. For our purposes, we will represent a group by a list of generating elements.

Backtracking with Symmetry Test. Input: Variables $\{x_1, \ldots, x_n\}$ and intermediate predicates P_i. In addition, a set $\mathcal{G}$ of generators for a group G of symmetries for the problem. Output: all sets of values for the variables such that P is true. Variables used: a stack S_X to store the partial solution X. The primitive stack operations are *Push, Pop* and *TopOf.* The algorithm calls the procedure *SymTest* with argument list $(\mathcal{G}, X, k, \mathcal{H}, g)$. SymTest returns a Boolean variable which is true if an element $g \in G$ is found such that $X^{g^{-1}} \prec X$. In this case g is returned in the last parameter. Otherwise, SymTest returns false and a list of generators for $\mathcal{C}_\Omega(G)$ is returned in $\mathcal{H}$.

```
1. [Initialize]
   $k \leftarrow 0$; $S_X \leftarrow \Lambda$;
   for $i \leftarrow 1$ to $n$ do $x_i \leftarrow u$ endfor
2. [Solution?]
   if $k \neq n$ then goto Step 3
   else print($X$); goto Step 4 endif
3. [Search deeper]
   $k \leftarrow k + 1$;
   if $x_k = v$ then goto Step 6 {$x_k$ previously set }
```

```
4. [Try next value]
   if $x_k = v$ then goto Step 7
   elseif $x_k = u$ then
      $S_X \leftarrow Push(S_X, X)$; $x_k \leftarrow 0$
   elseif $x_k < v - 1$ then
      $X \leftarrow TopOf(S_X)$; $x_k \leftarrow x_k + 1$
   else $\{x_k = v - 1\}$;
      $X \leftarrow Pop(S_X)$; $x_k \leftarrow v$ endif;
   if $P_k(X)$ is false then goto Step 4 endif
5. [Apply Symmetry Check]
   if $SymTest(\mathcal{G}, X, H, k, g)$ then goto Step 4;
   $\mathcal{O} \leftarrow \{i \in \Omega : i = j^g, x_j = v, g \in H, j \leq i\}$;
   foreach $i \in \mathcal{O}$ do $x_i \leftarrow v$
6. [Check predicate]
   if $P_k(X)$ then goto Step 2 endif
7. [Backtrack]
   $k \leftarrow k - 1$;
   if $k = 0$ then stop
   elseif $x_k = 0$ then goto Step 4
   else goto Step 7 endif.
```

In Step 4, x_k is initally set to u. Once we set $x_k = 0$ and call SymTest, we may well alter some of the variables $x_j, j > k$. Therefore, it is necessary to stack the previous values of X. If we backtrack to variable x_k, then we have to restore the previous environment. In the case where we enter Step 4 with x_k set to $v - 1$, it is unnecessary to save the environment stored on the stack, since it will never be used again. Consequently, we may pop the stack and store the result in variable X, before setting $x_k = v$.

3. The Four Queens

Let us consider the effect of applying symmetry considerations to the problem of placing queens on a chessboard, as described in the introduction. In order to make the size of the problem tractable for illustrations, we consider placing four queens on a four by four board. The four queens problem is normally formulated in terms of four variables, $Q_1, \ldots, Q_4$, where the value of Q_i is the number of the column that the queen in row i has been placed in. This formulation takes advantage of the fact that no two queens can be in the same row to reduce the number of variables from sixteen binary variables (representing the sixteen squares on the board) to four variables, each of which can take on four possible values.

The four queens problem has two (symmetrical) solutions; the ordinary backtrack tree, which has 61 nodes, is shown in Fig. 1. (The black squares are those occupied by queens.) Most programmers notice and take advantage of the obvious column symmetry, which means that Q_1 need be tested only for values 1 and 2; any solution with Q_1 equal to 3 or 4 can be obtained by rotating the board on its vertical axis. This observation gives a tree with 31 nodes.

Formulating the problem in terms of row variables, the only symmetry that we can express as a subgroup of the permutation group of the variables is the row symmetry which interchanges rows 1 and 4 and rows 2 and 3: in cycle notation, (14)(23). In order to make any use of the symmetry, we must set the two variables in one orbit before the two variables in the other, giving search order Q_1, Q_4, Q_2, Q_3 or Q_2, Q_3, Q_1, Q_4. In this problem, variables in adjacent rows are more likely to eliminate each other than more widely-separated variables, so the second order is preferable. The search tree for the second search order is shown in Figure 2. It has 35 nodes altogether. Eliminating the right side of the tree gives a tree with 30 nodes, one less than before. (The tree for the first search order has 55 nodes; 42 remain when the right subtree is removed.)

We would like to retain the convenience and efficiency of the row-variable formulation of the problem, while taking advantage of the rotational symmetries as well as the row and column symmetries. This can be done by finding a mapping of the row variables onto the variables of the underlying problem (*square variables*) which preserves the search order in the row-variable problem. A partial solution in the row-variable problem is also a partial solution in the square-variable problem. Any partial solution in the row-variable problem which survives the predicate has only one queen per column; hence, it maps onto another partial solution to the row-variable problem under rotational and column symmetry, as well as under row symmetry.

We number the squares of the board with their row and column indices; this gives a set of variables $R_{i,j}, 1 \leq i, j \leq 4$. A search order consistent with the normal order for the row variables is $R_{1,4}$, $R_{1,3}$, $R_{1,2}$, $R_{1,1}$, $R_{2,4}$, $R_{2,3}$, $R_{2,2}$, $R_{2,1}$, $R_{3,4}$, $R_{3,3}$, $R_{3,2}$,$R_{3,1}$, $R_{4,4}$, $R_{4,3}$, $R_{4,2}$, $R_{4,1}$. Using this search order, the partial solutions for the square-variables problem that are also partial solutions for the row-variables problem occur in the same order as in the row-variables problem. The existence of this ordering justifies the use of the symmetries for the square-variables problem on partial solutions for the row-variables problem. Similar orderings exist for other search orders on the row variables.

This justifies the use of the rotational symmetries to prune the search tree for the row-variables problem. Using the normal search order, we obtain a tree with 35 nodes. The results are again better if we choose the search order Q_2, Q_3, Q_1, Q_4. This gives a tree of 28 nodes; if we count in the same way as for the other cases, eliminating the right subtree altogether, then we have 26 nodes. This tree is shown in Figure 3.

On such a small problem, it is very difficult to obtain much improvement, since the predicates are quite effective by themselves and the search tree is already small. The column symmetries (removing the right half of the tree) are usually recognized and used by experienced programmers. We were able to remove one additional node from the left side of the search tree by using row symmetries alone; using both row and rotational symmetries, we eliminated five additional nodes. These results indicate that the application of symmetries, combined with an intelligent search order, will yield very significant improvements on large backtrack problems where symmetry is found.

4. Group Theory Algorithms

We briefly review some fundamental concepts which underlie both the computer implementation and theoretical analyses of algorithms for permutation groups. Let $Sym(\Omega)$ be the group consisting of all permutations of some arbitrary finite set Ω with n elements. A subgroup G of $Sym(\Omega)$, denoted $G \leq Sym(\Omega)$, will always be identified with a list of generators.

A base Γ for G is a subset of Ω with the property that only the identity of G fixes each element of Γ pointwise. The notion of a base was invented by Sims [19] as a means of testing equality of two elements of G. If $g, h \in G$ and g and h agree on Γ, then $g = h$. This idea is useful because many subgroups of $Sym(\Omega)$ have bases which are substantially smaller than n.

Let $\Gamma = \{b_1, b_2, \ldots, b_m\}$. Define the chain of subgroups

$$\{1\} = G_{m+1} \subseteq G_m \subseteq \ldots \subseteq G_1 = G$$

where G_i is the subgroup of G which fixes all the points of $\{b_1, b_2, \ldots, b_{i-1}\}$. A *strong generating* set for G is a set S of generators for G such that if

$$S_i = \{s \in S : s \in G_i, i \geq 1\}$$

then S_i is a set of generators of G_i.

A base and strong generating set is the basic data structure used to encode information about permutation groups. Perhaps the most fundamental result in computational group theory is that if G is specified by a small set of generators then a base and strong generating set can be computed in polynomial time. The original algorithm was given by Sims [19] and will be referred to as Sims' algorithm. An alternative version together with a proof that the algorithm runs in polynomial time was later given by Furst, Hopcroft and Luks [10]. Sims' algorithm can be used to show that the following problems have polynomial time solutions ([10],[19]):

1. (Order) *Compute the order of G.*
2. (Membership) *Given $x \in Sym(\Omega)$, determine if $x \in G$.*
3. (Pointwise stabilizer) *Generators for the subgroup $G_{a_1,a_2,\ldots,a_r}$ of G which fixes pointwise the subset $\{a_1, a_2, \ldots, a_r\}$ of Ω.*

5. SymTest Using Sims' Method

In describing our implementations of SymTest, we shall assume that $\Omega = \{1, 2, \ldots, n\}$ and denote $Sym(\Omega)$ by S_n. Recall that SymTest has argument list $(\mathcal{G}, X, k, \mathcal{H}, g)$ where $\mathcal{G}$ is a list of generators for G, X is the partial solution, x_k is the variable under consideration and $\mathcal{H}$ and g are the output parameters. SymTest returns *true* if there is an element $g \in G$ such that $X^{g^{-1}} \prec X$; otherwise, SymTest returns *false* and $\mathcal{H}$ contains a set of generators for the color automorphism group $H = \mathcal{C}_\Omega(G)$.

The version of SymTest described in this paper is based on a general method for computing with permutation groups developed by Sims [19] and later refined by Butler [6] and Leon [15]. Our goal is to simply sketch the highlights of this method and refer the reader to our forthcoming paper [5] for full details. Sims' method has a wide range of applications and forms the basis of many of the group theory algorithms implemented in the CAYLEY system [8].

We will assume that the first m elements $\{1, \ldots, m\}$ of Ω form a base Γ for G. A sequence $T = (t_1, \ldots, t_j)$ of distinct points of Ω is called a *partial image*. If $j = m$, then T is called a *complete image*. For any partial image T and subgroup $H \subseteq G$,

$$H(T) = \{g \in H : (1, \ldots, j)^g = T\}$$

and if T is incomplete then

$$X_H(T) = \{y \in \Omega : H(T \cup y) \neq \emptyset\}.$$

Think of $X_H(T)$ as the possible ways of extending a valid partial image (i.e. $X_H(T) \neq \emptyset$) to another valid partial image.

The following result describes $X_G(T)$ precisely (see [6], Proposition 1).

Proposition 1

Let $T = (t_1, \ldots, t_{j-1})$ be a partial image and let $g \in G(T)$. Then

$$X_G(T) = (j^{G_j})^g.$$

Suppose now that P is a certain property defined on G and we are trying to find an element of G, or possibly all elements of G, which have this property. Let

$$P(T) = \{g \in G(T) : g \text{ has property P}\}$$

and let

$$X_P(T) = \{y \in \Omega : P(T \cup y) \neq \emptyset\}.$$

For our purposes, g has property P if g preserves the coloring C. Equivalently, g has property P if $x_i = x_{i^g}$ for all $j, 1 \le j \le k$. In general, it is difficult to compute $X_P(T)$. Instead, we use an easily computed approximation $\bar{X}_P(T)$. Given $T = (t_1, \dots, t_{j-1})$, with $1 \le j \le k$, and $g \in G(T)$, if $x_j < v$, define

$$\bar{X}_P(T) = \{t \in (j^{G_j})^g : x_t \le x_j\}.$$

If $x_j = v$, let

$$\bar{X}_P(T) = \{t \in (j^{G_j})^g : x_t \le x_j \text{ or } x_t = u\}.$$

Note that by Proposition 1,

$$X_P(T) \subseteq \bar{X}_P(T) \subseteq X_G(T).$$

Let us briefly describe how some of these notions will be utilized in SymTest. Suppose we are attempting to extend T in such a way that $g \in G(T)$ will lead to a partial solution $X^{g^{-1}}$ which is smaller than X. This will happen, for example, if we can find a t in $\bar{X}_P(T)$ such that x_t is set and $x_t < x_j$. For then, by Proposition 1, there exists an element $h \in G_r$ such that $hg \in G(T \cup t)$ and so $X^{(hg)^{-1}} \prec X$. Otherwise, assuming that $X_P(T) \ne \emptyset$, we choose the smallest element $t \in \bar{X}_P(T)$. Either $x_j < v$ and $x_t = x_j$, or $x_j = v$ and $x_t \in \{v, u\}$. Again, by Proposition 1, there exists an $h \in G_r$ such that $r^h = t$. If $x_j = v$ and $x_t = u$, we set $x_t = v$. We then make the assignments $g \leftarrow hg, T \leftarrow (T \cup t)$, in which case $g \in G(T)$, and continue the process of extending T. Eventually, we arrive at an image T such that one of the following occurs:

(i) $\bar{X}_P(T) = \emptyset$. We then set $T \leftarrow (t_1, \dots, t_{r-1})$ and attempt a further extension of the new T, or

(ii) There exists a $g \in G(T)$ such that $X^{g^{-1}} \prec X$, or

(iii) T is a complete image and $x_i = x_{i^g}$ for $1 \le i \le m$.

In case(iii), there exists a unique element $g \in G(T)$ (by the definition of a base) and g has the property that $x_i = x_{i^g}$ for each $i \in \Gamma$. If $k \le m$, then $g \in C_\Omega(G)$; otherwise we need to check g on the remaining values $\{m+1, \dots, k\}$ to see if $g \in C_\Omega(G)$. The net effect is that either we find a smaller partial solution than X, we find an element of $C_\Omega(G)$ or we backtrack on T.

As might be expected from this discussion, SymTest is itself constucted as a backtracking algorithm and systematically searches through all possible partial images T. Furthermore the algorithm is organized in such a way that not only do we output a set of strong generators for H, but we also use the subgroups of H that are built up enroute in order to prune the sets $\bar{X}_P(T)$. A careful analysis is required, however, to ensure that we don't at the same time throw out any partial image which corresponds to an element $g \in G$ such that $X^{g^{-1}} \prec X$.

Section 6. A Criterion for Turning SymTest Off

In Section 2 we described the useful work performed by SymTest as we successively examine the values $x_{j^g}, 1 \le j \le k$, for $g \in G$. As variables are set, it becomes more difficult to find an element $g \in G$ which sets new variables or has the property that $X^{g^{-1}} \prec X$. We present a simple criterion for deciding when further use of SymTest will yield no further productive work until we backup past this point. Once this criterion has been met, we may then switch from symmetry checking to another intelligent search method such as search rearrangement.

Suppose that we have set the variables $x_1, \dots, x_k$ and that C is the current coloring of Ω. We say that *Condition U* is *true at k* if for each $j \le k$ and $g \in G$ such that x_i and x_{i^g} have the same color for $1 \le i \le j-1$, $x_{j^g} \ne u$. In the case where $x_j = v$ and $x_{j^\sigma} = u$, we immediately set $x_{j^\sigma} = v$ in our backtracking algorithm, so that this case won't invalidate *Condition U.*

Turnoff SymTest Criterion: *Condition U* is true and $C_\Omega(G)$ is the identity subgroup.

If this criterion is true, then no further information will be gained by applying SymTest until the next time we examine variable x_k. To see why this criterion works, suppose that in the course of searching deeper in this branch, and after setting x_j for some $j > k$, we find an element $g \in G$ such that $X^{g^{-1}} \prec X$. This means there exists an $r \le j$, such that $x_i = x_{i^g}$ for $1 \le i \le r-1$ and $x_r < x_{r^g}$.

We present a proof by contradiction, that no such g exists. This proof depends on the following observations.

Observation I. If any variable x_i is set to v in C. for $i > k$, then x_i is set to v for the coloring C' which arises from setting the additional variables $x_{k+1}, \dots, x_j$.

Observation II. If i satisfies $1 \le i \le \min(k, r-1)$ then i and i^g have the same color in C.

Proof. By the definition of g, i and i^g have the same color in C' for $1 \le i \le r-1$. Furthermore C and C' agree on $\{1, \dots, k\}$. Let $1 \le i \le min(k, r-1)$. If $i^g \le k$, then both i and i^g have the same color in C. Otherwise, choose i to be minimal such that $i^g > k$. Then i^g is colored u or v in C. If i^g is colored u in C, then we can use g to obtain a contradiction to our assumption that *Condition U* is true. Thus i^g is colored v in C. But then i^g is colored v in C' by Observation I and so i is colored v in C', and therefore in C as well. The observation then follows by an easy induction argument.

We now derive a contradiction to the existence of g. If $r > k$, then g preserves C by Observation II. But then g must be the identity element by our Criterion. Thus we may assume that $r \le k$. By Observation II, we know that i^g has the same color as i in C for $1 \le i \le r-1$. If $r^g \le k$, then r^g has the same color in C as in C'. Since, $x_{r^g} < x_r$, it then follows that $X^{g^{-1}} \prec X$ in C. The existence of such a g

would have caused our backtracking program to abandon the present branch rather than attempting to extend C.

Thus we may assume that $r^g > k$. This implies that r^g is colored u or v in C. The case where $x_{r^g} = u$ is a contradiction to our Criterion that *Condition U* holds at k. On the other hand, if r^g is colored v in C, then by Observation II, r^g is colored v in C' as well. This contradicts $x_{r^g} < x_r$ in C' and completes the proof.

TIME-SPACE TRADEOFFS FOR TREE SEARCH AND TRAVERSAL

David A. Carlson

Department of Electrical and Computer Engineering
University of Massachusetts
Amherst, MA 01003

Abstract

Tree search is a fundamental computation that is performed frequently in the application areas of combinatorial optimization and artificial intelligence. There, algorithms that search the state-space tree representation of a problem instance for a solution of minimum cost often use prohibitively large amounts of space. In this paper, we develop new algorithms for tree search that use reduced amounts of space. The algorithms are modifications of depth-first, breadth-first, and heuristic tree search algorithms. They achieve their space reductions by recomputing certain nodes in the tree from scratch. Thus, they require more time than the algorithms they are derived from. However, the time-space tradeoff is a favorable one, since we are able to show that significant savings in space can be achieved at the expense of only a small (constant factor) increase in run time.

1. Introduction

Searching for an item in a set of items is a problem that arises often in computer applications. Since it is a fundamental problem that must be solved frequently, researchers have attempted in the past to develop algorithms with good performance, either in terms of time or space. These are the major resources consumed by a computer algorithm, and developing algorithms having better performance with respect to them leads to a reduction in the overall cost of computing.

Here, we will consider the problem of tree search, which occurs when the set of items to be searched is organized as a tree, as shown in Figure 1. We assume that each item in the tree has associated with it a nonnegative integer cost, and that the problem is to determine the minimum cost item in the tree. Little or no information about the minimum is known in advance, so that it may be necessary to search the entire tree structure in order to guarantee that the minimum has been found. In this situation, tree search can be accomplished by an orderly traversal technique that visits all nodes in the tree.

The problem of searching for a minimum in a tree arises often in a number of important application areas including combinatorial optimization and artificial intelligence. In combinatorial optimization, problems often have associated with them a solution space that is organized as a tree, and the tree must be searched in order to find a solution that optimizes a given criteria. Artificial intelligence problems often take on the same flavor, where a tree structure must be searched in order to find a goal state that minimizes a given objective function. An important property of the tree structures arising in the above applications is that the costs of nodes along a path from the root to a leaf are nondecreasing. Heuristic search algorithms take advantage of this property by maintaining a current minimum and eliminating from the search process subtrees whose nodes exceed in cost the value of the current minimum. Even though a fairly large subset of the tree may not be searched, heuristic search terminates having found a node of guaranteed minimum cost. It shares this property with other algorithms that do a full search of the tree.

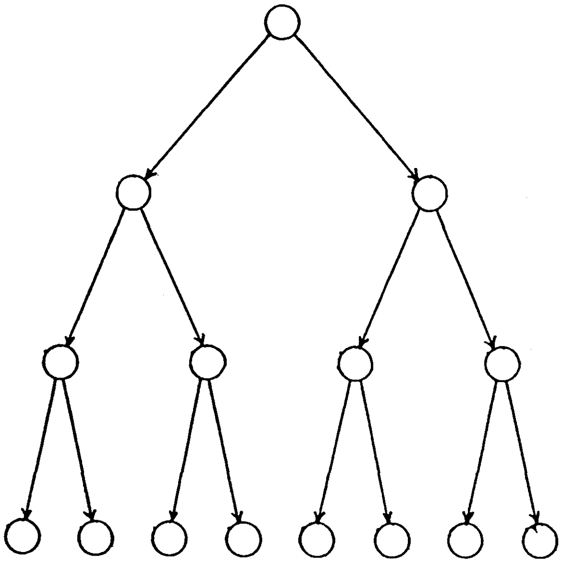

Figure 1: A complete binary tree

In this paper, we will explore the possible tradeoffs between time and space that exist for different algorithmic implementations of full and heuristic tree search. We will develop algorithms that use reduced amounts of space to search a tree for its node of minimum cost, and analyze their time performance. While an increase in time is required in order to achieve a decrease in space, we are able to show that the tradeoff is a favorable one. That is, only a small, constant factor increase in time is associated with algorithms that achieve significant reductions in space. Our results for heuristic search are particularly interesting, since standard heuristic search algorithms often use prohibitively large amounts of space to find a minimum cost item in the tree.

The algorithms that we propose here are variations of full search (either depth-first or breadth-first) and heuristic search applied to tree structures. For depth-first search, instead of saving pointers into the tree on a stack, we recompute them from scratch when required. We further show that breadth-first and heuristic search can be realized using multiple depth-first searches. Thus, the results we obtain for reduced space depth-first search also hold true for reduced space breadth-first and heuristic search.

Previous research on tree search has been fairly limited due to the widespread acceptance of the standard depth-first and breadth-first algorithms. These methods and the potential they offer in solving combinatorial optimization problems are surveyed in most intermediate level textbooks on computer algorithms, including [1,2,4,8]. Knuth [4] goes further to explain methods that eliminate the need for the separate stack used by depth-first search. These methods usually are employed when the tree has grown to exhaust all available space, as often happens in list processing systems that employ garbage collection. Instead of a stack, they use a small amount of extra space in each node of the tree.

Recently, Korf [3], in the context of AI applications, has considered multiple depth-first search to successive levels in a tree and its viability as an alternative to breadth-first search. He also generalizes these ideas to obtain reduced space heuristic search algorithms that can be applied to a wide variety of AI problems. On tree structures whose number of nodes is an exponential function of their depth, Korf argues that a multiple depth-first search strategy is much better in terms of space performance than breadth-first and heuristic search and only increases the number of node expansions slightly.

Another reference where work appears that is related to the results presented here is Pippenger [6]. There, a tradeoff between time and space is proven for a particular problem using a theoretical framework referred to as pebbling. The problem considered by Pippenger is a special case of full tree search where the leaves of the tree must be computed in a certain order.

Here, we will generalize the results of Pippenger to tree structures where the leaves can be computed in any desired order. We will use the theoretical framework of pebbling as a tool to explain our methods in an abstract setting, and to analyze their performance with respect to time and space. The end result will be algorithms similar to those presented in Korf [3] for both full and heuristic tree search that combine significant reductions in the usage of space with small increases in running time.

This paper is organized as follows. Section 2 explains the concept of pebbling and other preliminaries needed in the remainder of the paper. In Section 3, we present reduced space tree search methods based on combining depth-first search on subtrees with the recomputation of certain nodes in the tree. Sections 4 and 5 show how these ideas can be extended to obtain reduced space emulations of breadth-first and heuristic search. Conclusions and directions for further research are given in Section 6.

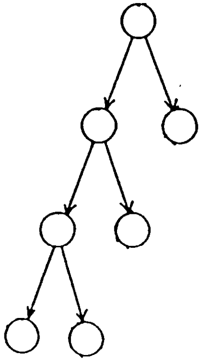
2. Preliminaries

This section explains the basic notion of a tree and the concept of pebbling, which we will use to "compute" the nodes of a tree in an algorithmic manner to be described later in the paper.

Throughout this paper, we will restrict our attention to complete binary trees that have edges directed out from a distinguished root node into the roots of two complete subtrees. In general, such a tree has a branching factor of 2 at each node, and if it has depth d, then it contains 2^d leaf (terminal) nodes. Depth refers to the length, i.e. number of edges, of the longest path from an input (the root) to an output (a leaf). Figure 1 illustrates a complete binary tree of depth 3 (8 leaves).

Our reason for concentrating only on complete binary trees is based on the following observations. First of all, such trees preserve an exponential relationship between the depth of the tree and the number of leaves in the tree, i.e., #leaves=exp{depth}. Other tree structures, such as a serial, chain-like tree (shown in Figure 2), do not have this property. Search trees having this exponential relationship often arise in the modeling of combinatorial optimization problems and AI problems. Usually, the depth of the tree structure corresponds to the number of inputs to the problem (one level for each input), and the difficulty in solving the problem stems from the fact that an exponential number of solutions (settings of the inputs) must be checked in order to find the one which optimizes a given objective function. In the search tree, a node represents a partial setting of values to inputs, and each node has a branching factor b>1; i.e. there are a multitude of values that can be assigned to the next input to obtain a new, more complete partial setting.

Figure 2: A serial, chain-like binary tree



While there are many tree structures that are not complete, but for which #leaves=exp{depth}, such trees are reasonably "close" to a complete binary tree, so that significant information regarding them can be obtained by analyzing only the special case of a complete tree. This will be our approach in this paper: to consider in detail the case of a complete binary tree, which leads to meaningful insights concerning other similar tree structures. The same can be said regarding the branching factor of the tree. Here, we consider only the branching factor b=2, but the results we derive can also be shown to hold true for other branching factors b>1.

At this point, we outline the concept of pebbling, which forms a useful abstraction of how the search of a tree is performed. The "pebble game" has been used mainly in theoretical computer science as a paradigm for analyzing the simultaneous time and space requirements of a computation. First, a graph representation of a computation is formed that models the data dependencies inherent in the computation. On this graph representation, pebbles are then moved from inputs to outputs according to certain rules (hence the term "pebble game"). These rules reflect how a uniprocessor would perform a straight-line computation, the main one being that a non-input node can be pebbled only when all its predecessors hold pebbles. In other words, the uniprocessor can only compute an intermediate result when all the values it depends on are held in temporary storage locations.

An algorithmic solution to the problem being modeled in a pebble game analysis corresponds to a pebbling strategy that places pebbles on each output node at certain points in time. The space requirement of the algorithm is simply the maximum number of pebbles used during this process, and time is measured by the number of movements of pebbles made on nodes of the graph. When the number of pebbles available is reduced, certain nodes in the graph may have to be repebbled in order to pebble all the outputs. This often leads to tradeoffs between time and space for a given computational problem. A good survey of the vast amount of theoretical work that has been done on this subject appears in Pippenger [7]. Here, we will apply the pebble game analysis technique to the problem of searching for the minimum cost item in a complete tree.

As a final point in this section, we will use the big-O notation for expressing the asymptotic behavior of a function. The relevant symbols are:

O $f(n)=O(g(n)$ iff there are constants c and N such that for all $n \geq N$, $f(n) \leq g(n)$

Ω $f(n)=\Omega(g(n))$ iff there are constants c and N such that for all $n \geq N$, $f(n) \geq g(n)$

Θ $f(n)=\Theta(g(n))$ iff $f(n)=O(g(n))$ and $f(n)=\Omega(g(n))$

3. Depth-First Search with Reduced Space

Depth-first search is a well known technique for visiting all the nodes in a graph. When the graph is a tree, it operates by expanding the most recently encountered node until a leaf is reached, and then backtracking to nodes previously encountered having descendants not already expanded. In practice, a stack is used to guide the backtracking process, with a node being placed on the stack when the search procedure moves to one of its descendants. A node is taken off the stack once a leaf is reached. For a complete binary tree of depth d, a stack of size d is required, and the search procedure uses time proportional to the number of nodes in the tree.

Standard depth-first search can easily be viewed as a pebbling strategy for a complete binary tree. We now outline such a strategy to give the reader a feel for the concept of pebbling. The strategy works by placing pebbles on nodes of the tree starting at the root and working towards the leaves. A pebble is held on a node until the point in time when all leaves in the subtree rooted at that node have been pebbled. Further placements of pebbles on the tree are made from the node deepest in the tree that holds a pebble. If its left child has not been pebbled, then a pebble is placed there, otherwise a pebble is placed on its right child. Figure 3 illustrates a configuration of pebbles in this strategy on a binary tree with 16 leaves.

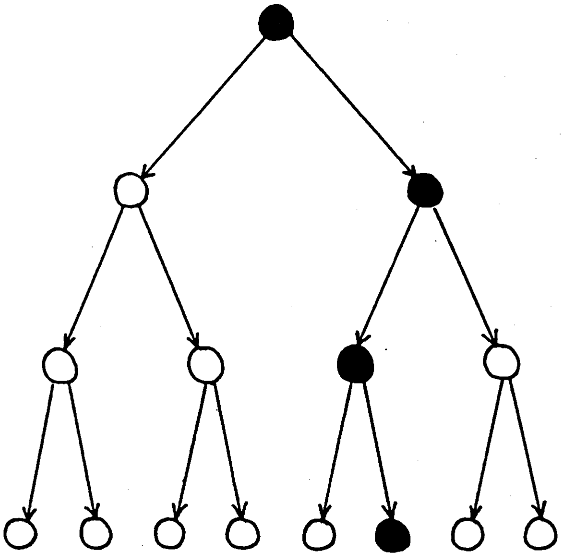


Figure 3: A configuration of pebbles in the depth-first strategy

The pebbling strategy described above emulates depth-first search by making further advances into the tree from the deepest of the nodes that currently hold pebbles. The nodes holding pebbles can be thought of as the contents of the stack in depth-first search, with the node most recently pebbled (i.e. most recently placed in the stack) being selected as the one to be further expanded.

The time and space requirements of our depth-first pebbling strategy are easily analyzed. If a complete binary tree of depth d and 2^d leaves is pebbled using this strategy, the at most d+1 pebbles are used at any point in the strategy, which is the number of nodes in a path from the root to any leaf in the tree. The number of pebble placements or moves made is simply the number of nodes in the tree (each is pebbled exactly once), which can be expressed by the formula

$$T=1+2+2^2+\ldots+2^d=2^{d+1}-1=O(2^d)$$

We note that the strategy is optimal in terms of its time performance, since any strategy must make at least one pebble placement on each node of the tree.

Complementary to the notion of a pebbling strategy that runs in optimal time is one that uses an optimal amount of space. We now outline such a strategy. First, we claim that any leaf in the tree can be pebbled using only one pebble, by simply advancing a single pebble down the unique path that connects the root to the leaf (we are allowing "sliding" in the pebble game, i.e. the movement of a pebble on a predecessor directly onto the node being pebbled). Once the single pebble being used is placed on a leaf, it is not of use in the pebbling of any other leaf, so that to pebble the next leaf the same process must be repeated in its entirety. Doing this for 2^d leaves in the tree, it is easily seen that $T=(d+1)2^d$ pebble placements are made by this strategy.

In comparing the two pebbling strategies outlined above, an intuitive tradeoff between time and space can be observed. A decrease in space from S=d+1 to S=1 requires an increase in time from $T=O(2^d)$ to $T=\Omega(d2^d)$. If we normalize time and space to be functions of the number of nodes in the tree $N=2^d$, then the standard depth-first strategy has $T=O(N)$, $S=\Theta(\log N)$ and the minimum space strategy has $T=\Omega(N\log N)$, S=1.

At this point, we note that if the minimum space strategy is to be implemented in practice, then a means for "guiding" a single pebble down the tree multiple times must be provided. This is easily done using d bits to encode the 2^d unique paths from the root to the leaves. A specific setting of these bits determines a path to move a pebble down, so that once the pebble reaches a leaf, the setting of the d bits must be updated to give a new path to a leaf that has not yet been pebbled. This additional d bit field needed to guide the search is not a lot of overhead, especially when one considers that a pebble must consist of at least d bits in order to properly distinguish between all the different nodes in the tree. Taking this into account, the minimum space strategy requires O(d) bits to implement, whereas standard depth-first search requires $O(d^2)$ bits (O(d) pebbles each requiring O(d) bits).

From a theoretical standpoint, the minimum space strategy outlined above is interesting since it provides an alternative to standard depth-first search. However, in practice, if time $O(2^d)$ can be afforded, then d is relatively small, and the achievable space savings are not that large. For now, the strategy should be viewed more as the exposition of a methodology that reduces space by allowing recomputation. Applying the methodology to other well-known search algorithms has the potential of yielding more significant space savings, as will be seen later in this paper.

We continue our discussion of reduced space depth-first search algorithms by describing methods that fall in between the standard and the minimum space strategies outlined above. As with the minimum space strategy, they are interesting mainly from a theoretical perspective, so the more practically oriented reader may wish to skip ahead to Section 4.

While the minimum space strategy requires time that is non-linear in the size of the tree, it may be that there are other strategies which reduce space yet maintain time $T=O(2^d)$. We claim that such strategies exist, and they use significantly less space than the standard depth-first strategy. We are able to construct them by combining the minimum space strategy with the standard depth-first strategy on appropriate subtrees in the tree structure.

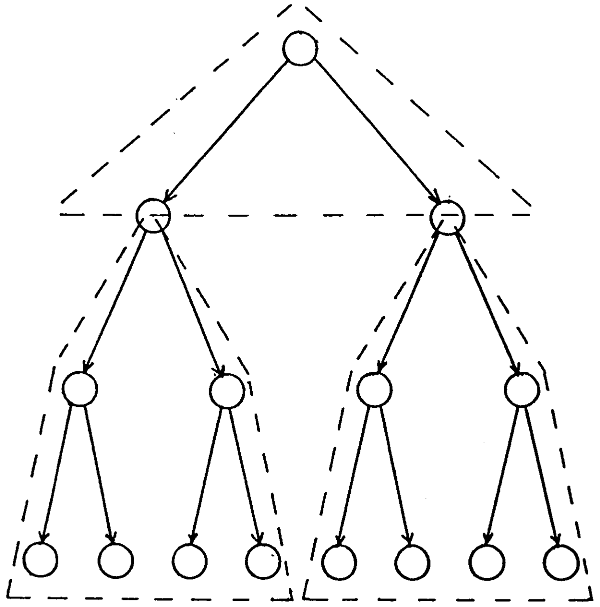
To aid in viewing these new pebbling strategies, we decompose a tree of depth d into a top subtree of depth k, $0\leq k\leq d$, whose leaves are the roots of 2^k disjoint subtrees of depth d-k, as shown in Figure 4. On the top subtree, we will employ the minimum space strategy. Upon reaching one of the top subtree's leaves, we will hold a pebble there while employing the standard depth-first strategy on the bottom subtree. This is repeated for each of the 2^k bottom subtrees rooted at a leaf of the top subtree.

The time and space requirements of this new pebbling strategy can be analyzed as follows. First, d-k+1 pebbles are used, a single one on the top subtree and d-k additional ones on each bottom subtree. Second, the number of pebble placements made can be expressed as follows

$$
\begin{aligned}
T&=(k+1)2^k && \text{(total for top subtree)}\\
&\quad+2^k(2^{d-k}-1) && (2^{d-k}-1 \text{ for each bottom subtree})\\
&=O(k2^k+2^d)
\end{aligned}
$$

The extremes of this new pebbling strategy are k=0, which is the standard depth-first strategy, and k=d, which is the minimum space strategy.

Figure 4: The decomposition of a tree into a top subtree and bottom subtrees



However, it is interesting to observe the time requirements of the strategy for different values of k between 0 and d. For example, if k=d/2 then half the space of standard depth-first search is used, and time remains $O(2^d)$. We can further reduce space to S=logd and still maintain "linear" time. This follows by choosing k=d-logd, i.e. we pebble bottom subtrees of depth logd using the standard depth-first strategy. Time remains proportional to 2^d, since

$$T=O(k2^k+2^d)=O((d-\log d)2^{d-\log d}+2^d)=O(2^d)$$

If space is reduced slightly below S=logd in the above strategy, say to S=(logd)/2, then we obtain $T=O(d^{1/2}2^d)$, which is non-linear in the size of the tree. Thus, we can conclude that further reductions in space below S=logd cannot be made in this pebbling strategy if time $T=O(2^d)$ is to be achieved.

In order to achieve further reductions in space, we modify the way that bottom subtrees are pebbled in our new pebbling strategy. Instead of using a standard depth-first strategy, we apply our new pebbling strategy to each bottom subtree. This decomposes each bottom subtree in a manner similar to the way the entire tree was initially decomposed. For a bottom subtree of depth logd, we break it into a top subsubtree of depth logd-loglogd, below which are multiple bottom subsubtrees each of depth loglogd. We employ a minimum space strategy on the top subsubtree and a standard depth-first strategy on each bottom subsubtree to pebble the entire subtree in time $T=O(2^{\log d})$. It easily follows that the strategy for the entire tree uses space S=loglogd+2 and runs in time $T=O(2^d)$. Further reductions in space to S=logloglogd, etc. for which time remains $T=O(2^d)$ are straightforward and are left to the reader.

The existence of the pebbling strategies outlined above allows us to state the following theorem.

Theorem 1: A complete binary tree of depth d can be pebbled (traversed) in time $T=O(2^d)$ using space S=d, S=logd, S=loglogd, etc.

Theorem 1 shows that significant reductions in space can be made to the standard depth-first pebbling strategy. From it, the question can be asked regarding whether a pebbling strategy exists that is asymptotically optimal with respect to both time and space. In other words, can constant space ($S=O(1)$) and linear time ($T=O(2^d)$) be achieved simultaneously. In an attempt to answer this question, we now investigate pebbling strategies that use a fixed, constant number of pebbles.

We have already considered the case when S=1, and have shown that $T=\Theta(d2^d)$. The case S=2 can be handled in a manner similar to that of the new pebbling strategy presented earlier. We separate the entire tree structure of depth d into a top subtree of depth d-logd and multiple bottom subtrees of depth logd. Our pebbling strategy uses one pebble on the top subtree, which is held on a leaf of the top subtree while the bottom subtree is pebbled using the second available pebble. Analyzing the time requirements of this strategy, we obtain

$$T=(d-\log d)\ 2^{d-\log d}+2^{d-\log d}[(\log d)2^{\log d}]$$
$$=O((\log d)2^d)$$

While this is an asymptotic improvement over the time required when S=1 pebbles are used, it still is not linear in the size of the tree.

It is straightforward to extend the above strategy to S=3, S=4, ... For S=3, two cutoff points are defined so that the tree is separated into a top subtree and bottom subtrees. Each bottom subtree is separated into a top subsubtree and bottom subsubtrees. Time performance $T=O((\log\log d)2^d)$ is obtained when the cutoff points are chosen correctly. For S=4, we obtain $T=O((\log\log\log d)2^d)$, and so forth for higher values of space.

Thus, for constant values of space, we can exhibit pebbling strategies that come close to achieving "linear" time $T=O(2^d)$. The higher the constant, i.e. the more space available, the closer we can come to linear time. However, we can also prove that we cannot truly achieve linear time using constant space by showing that the pebbling strategies presented above cannot be improved upon.

Theorem 2: A complete binary tree of depth d requires pebbling time $T=\Theta((\log^{(c)}d)2^{d})$ when $S=c+1$ pebbles are used to pebble its leaves, where $c\geq 0$ is a constant value with respect to the size of the tree. Here, $\log^{(c)}d$ stands for the c^{th} iterate of the logarithm function, i.e. $\log^{(c)}d=\log(\log^{(c-1)}d)$ and $\log^{(0)}d=d$.

Proof: The upper bound $T=O((\log^{(c)}d)2^{d})$ when $S=c+1$ pebbles are used follows from the above discussion on pebbling strategies that use a fixed, constant number of pebbles. We must prove a matching lower bound of the form $T=\Omega((\log^{(c)}d)2^{d})$ to obtain the result of the theorem.

At this point, we derive a lower bound for the case $S=2$; arguments for other constant values of space are similar. Consider a subtree of depth k in a tree of depth d and the unique path from the root of the tree to the root of the subtree, as shown in Figure 5. If we choose $k=\log d-\log\log d-1$, then we can make the following statement about an optimal pebbling strategy for the tree. While the leaves of the subtree are being pebbled, an optimal strategy holds a pebble at or above the root of the subtree. To verify the claim, consider the opposite, i.e. a pebble is not held at or above the root of the subtree. Then, the path from the root of the tree to the root of the subtree must be pebbled at least twice, for a total of $2(d-\log d+\log\log d+1)$ moves. However by holding a pebble at or above the root, a number of moves $\leq (d-\log d+\log\log d+1)+(\log d-\log\log d-1)2^{\log d-\log\log d-1} \leq(3/2)d$ can be achieved. Thus, the strategy that does not hold a pebble at or above the root of the subtree clearly is not optimal.

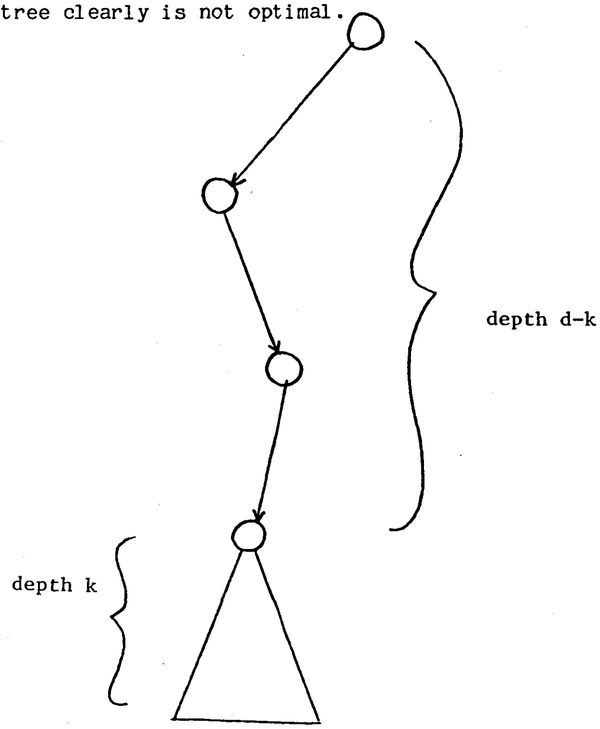


Figure 5: A subtree and its unique path to the root

From the statement above, it follows that each subtree of depth $\log d-\log\log d-1$ must be pebbled with $S=1$ in an optimal strategy. Totalling the number of moves made on these subtrees, we obtain $T=\Omega((\log d)2^{d})$, the desired lower bound. Q.E.D.

The pebbling strategies outlined above, one leading to time $O(2^{d})$ and the other leading to space $O(1)$, can both be viewed in a common light as follows. First, c cutoff points are established at levels logd, loglogd, $\log^{(c)}d$ from the bottom of the tree. Both strategies dedicate one pebble to use between each pair of different levels, and differ only how the bottom set of subtrees (below the last level) are pebbled. Using standard depth-first search on the bottom subtrees gives $T=O(2^{d})$, $S=O(\log^{(c)}d)$ while using minimum space search gives $T=O((\log^{(c)}d)2^{d})$, $S=O(1)$. Another strategy of note operates by establishing the first level at height logd from the bottom, dedicating one pebble for between the root and the first level, and pebbling subtrees below the first level recursively. Analysis similar to that conducted above reveals that this pebbling strategy requires time $T=O(2^{d}\log^{*}d)$ and space $S=O(\log^{*}d)$, where $\log^{*}d$ is the number of applications of the logarithm function required to produce a value ≤ 2. The function $\log^{*}d$ increases at a very slow rate, so that for all practical purposes this strategy can be thought of as achieving linear time and constant space simultaneously.

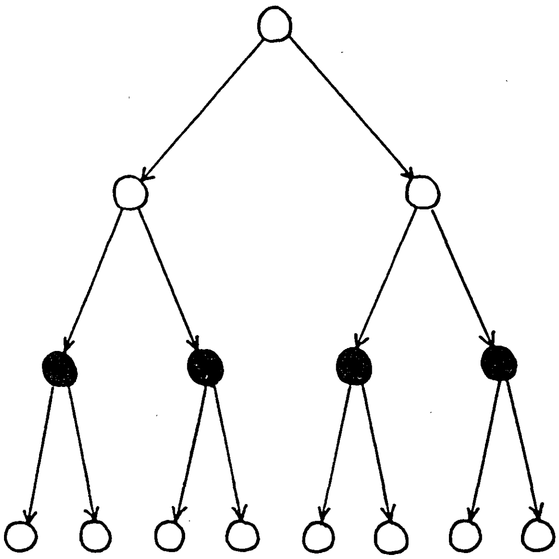
To summarize this section, we have identified time-space tradeoffs for tree search and traversal using the pebble game technique. Our methods show that reductions in space, almost down to a constant value, can be made while still preserving time that is asymptotically optimal, i.e. proportional to the size of the tree. However, there is indeed a time-space tradeoff inherent in the tree search problem, as our results also show that optimal time and optimal space (a constant with respect to tree size) cannot be achieved simultaneously.

4. Breadth-First Search with Reduced Space

In this section, we generalize the ideas developed in Section 3 to breadth-first search of a complete binary tree. We are able to show that significant reductions in space can be made while maintaining time proportional to the size of the tree.

Breadth-first search complements the notion of depth-first search in that it operates by expanding the least recently encountered node in the tree instead of the most recently encountered one. This is done until all children of the node being expanded are encountered, at which point control moves to the next least recently encountered node. In practice, nodes are put on a queue as they are encountered (during the expansion of their parent), and are taken off the queue when they are later chosen for expansion.

Figure 6: A configuration of pebbles in the breadth-first strategy



Breadth-first search can be viewed as a pebbling strategy for a complete binary tree as follows. Starting at the root of the tree, each successive level is pebbled in its entirety before any pebbles are placed on the next level. The expansion of a node corresponds to placing pebbles on both of its two children. Once a node is expanded, it no longer holds a pebble. Figure 6 shows a "snapshot" in the middle of such a strategy where pebbles have been moved from one intermediate level to another.

The time and space requirements of a breadth-first pebbling strategy for a complete tree of depth d are easily seen to be $T=O(2^d)$ and $S=O(2^d)$. Time equal to the number of nodes in the tree is used, which cannot be improved upon, however an enormous amount of space is also used by this strategy. It would be desirable to design a new search strategy that expands the nodes in the tree in the same order as the breadth-first strategy, but which uses significantly less space.

Korf [3] discusses a method for emulating breadth-first search which he refers to as depth-first iterative deepening. The basic idea is to perform multiple depth-first searches to each successive level in the tree. Each depth-first search starts fresh in the sense that it begins at the root and proceeds to visit all the nodes at a particular level in the tree. Thus, a certain amount of recomputation is required, but the strategy does perform a valid emulation of breadth-first search.

It is straightforward to view the multiple depth-first search technique described above as a pebbling strategy, and we now analyze its time and space requirements. For a tree of depth d, it has a space requirement the same as the deepest depth-first search performed, which is a depth-first search of the entire tree. Thus, space can be expressed as $S=O(d)$. The time used by the strategy is simply the sum of the time used in each depth-first search. For $k=0,1,\ldots,d$ a depth-first search to level k is performed, which requires $T\leq 2^{k+1}$ moves. Thus, the total time can be upper bounded by

$$T\leq \sum_{0\leq k\leq d} 2^{k+1}\leq 2^{d+2}=O(2^d)$$

It follows that the pebbling strategy emulates breadth-first search in an amount of time proportional to the size of the tree, while achieving a very significant reduction in space (from linear in the size of the tree to logarithmic in the size of the tree). Korf [3] concludes that the strategy is optimal with respect to space (along with time), since it uses space proportional to the logarithm of the size of the tree. However, this conclusion is incorrect, because he counts only the number of storage locations used by the strategy and ignores the bit level complexity of each storage location. In fact, we now discuss how further reductions in space can be made in pebbling strategies that emulate breadth-first search.

Since the pebbling strategy above is composed of multiple depth-first pebbling strategies, we can apply the ideas of Section 3 to even further reduce the space consumption of an emulation of breadth-first search. For example, we can replace a standard depth-first search to level k in the tree with a pebbling strategy that uses time $T=O(2^k)$ and space $O(\log k)$. Doing this for each successive depth-first search, we obtain a new emulation of breadth-first search that uses time $T=\sum_{0\leq k\leq d} O(2^k)$ $=O(2^d)$ and space $S=O(\log d)$. Generalizing this, we can state analogies to Theorems 1 and 2 for breadth-first search.

Theorem 3: The breadth-first pebbling strategy on a complete binary tree of depth d can be emulated in time $T=O(2^d)$ and space $S=d$, $S=\log d$, $S=\log\log d$, etc. using multiple space-efficient depth-first searches.

Theorem 4: The breadth-first pebbling strategy on a complete binary tree of depth d cannot be emulated in time $T=O(2^d)$ using space $S=O(1)$, i.e. space that is a constant with respect to the size of the tree.

Theorems 3 and 4 show that essentially the same results hold true for both breadth-first and depth-first search of a complete binary tree. Significant reductions in the space consumption of these methods can be made, but linear time and constant space cannot be achieved simultaneously.

5. Heuristic Search with Reduced Space

The space used by standard breadth-first search when it is applied to a complete binary tree makes it an illogical choice for actual implementation. Standard depth-first search uses much less space and does not increase the time required to search the entire tree structure. However, breadth-first search can be generalized to yield heuristic search, which has been applied to many problems having a solution space organized as a tree. Heuristic search has the potential of decreasing the time required to search the tree by eliminating parts of it from consideration. The gains in time that it offers make it desirable for use despite the space inefficiency that it shares with breadth-first search. Pearl [5] discusses and analyzes heuristic search and its application to a variety of different AI problems.

In heuristic search, it is assumed that the cost of nodes along any path from the root to a leaf are nondecreasing. The search procedure operates by assigning a cost to each node in the tree, and choosing as the next node to expand the node with the minimum cost among all those encountered so far. The nodes that have been encountered are maintained in a priority queue, from which the next node to be expanded is selected based on its cost. Expansion of a node causes its children to be inserted into the priority queue.

Heuristic search will always find the leaf in the tree (an entire solution) of minimum cost, and has the ability to eliminate the expansion of large numbers of high cost nodes in the tree. For, when heuristic search terminates, no effort will have been expended in searching subtrees whose roots, and thus all contained nodes, have a higher cost than the minimum found (this is an invariant throughout the search; no expansions are made in subtrees whose roots have a cost higher than the current minimum). This is the major advantage of heuristic search; that it has the potential to significantly reduce the time required to find a minimal cost solution. The amount of time that is saved is very dependent on the function used to determine the cost of an internal node, and the actual instance of the problem being solved.

As with the other tree search methods discussed earlier, heuristic search can be viewed as a pebbling strategy on a complete tree (a tree whose number of leaves is exponential as a function of its depth). At any point in time, the set of nodes holding pebbles forms a cut (possibly ragged) across the entire width of the tree, i.e. the tree is separated into a top subtree that has been completely explored and bottom subtrees that have not been explored at all except for their roots. The pebbling strategy operates by selecting the node in the cut of minimum cost and moving pebbles onto its two children. We can associate with a cut the value of the current minimum, so that nodes in the top subtree all have a cost less than or equal to the value of the cut and the roots of the bottom subtrees (nodes along the cut) are all candidates for selection as the value of the next cut (the next current minimum). When the heuristic search procedure selects a new current minimum, it is easily seen that the number of nodes in the new cut and in the new top subtree both increase by one, since one node is moved from the cut into the top subtree and its two children are added to the cut. Figure 7 illustrates an example of a cut arising in heuristic search. A cut like this also appears in breadth-first search, except there it is confined to at most two successive levels of the tree (see Figure 6).

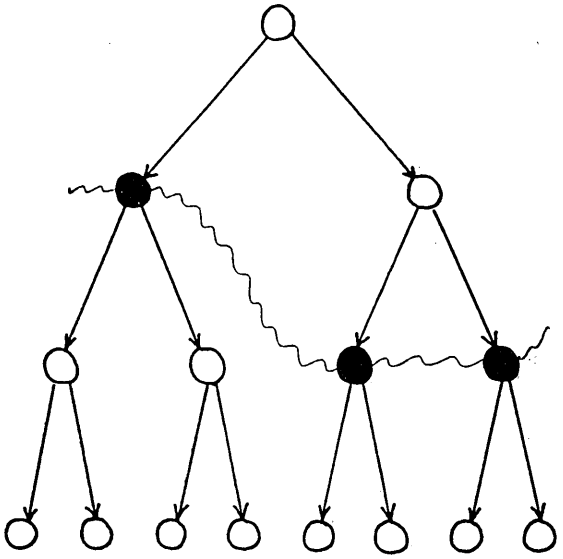


Figure 7: A cut in heuristic search

While heuristic search can decrease the time required to find a minimal cost solution, its space consumption can be large, since it uses separate storage locations organized as a priority queue to keep track of the current cut. In general, a cut across a complete tree can require a number of nodes proportional to the size of the tree, which explains the likelihood of requiring a large amount of space. Thus, we are motivated to reduce the space consumption of heuristic search without significantly increasing the number of nodes expanded. To achieve this, we propose techniques similar to those given earlier for breadth-first search that are based on performing multiple depth-first searches into the tree structure.

We start by considering the top subtree that lies above the current cut in a standard heuristic search procedure. Instead of maintaining the cut with separate storage locations for each node it contains, the top subtree can easily be searched in its entirety using a depth-first procedure that does not expand beyond nodes whose values exceed the current minimum. By keeping track of the lowest cost node whose value exceeds the current minimum (i.e. it is on the "fringe" of the top subtree) while performing such a depth-first search, the value of the next minimum that standard heuristic search would find is obtained. Executing multiple depth-first searches in this manner yields a valid emulation of heuristic search. In essence, what we are doing is a depth-first search of the top subtree associated with each cut that arises in standard heuristic search.

The strategy explained just above for emulating heuristic search is also presented in Korf [3]. There, it is claimed that the multiple depth-first emulation is optimal in time performance, i.e. it is within a constant factor of the run time of standard heuristic search. This claim is incorrect, as we will now demonstrate. Assume that standard heuristic search makes ℓ node expansions in searching a tree structure. Each time a node expansion is made, both the top subtree and the cut associated with a new current minimum grow by one node. Thus, multiple depth-first searches are performed on top subtrees of size (number of nodes) $1,2,\ldots,\ell$. Each depth-first search requires time proportional to the size of the current top subtree, resulting in total time $T=1+2+\cdots+\ell=O(\ell^2)$. Other strategies must be devised if time $O(\ell)$ is to be achieved.

The emulations of breadth-first search presented in Section 4 were based on moving from one level to the next in the tree structure. Time was increased by just a constant factor due to the fact that an entire top subtree located above a certain level only has twice as many nodes as its bottom level. Rather than maintain the bottom level using a large amount of space, the entire top subtree could be depth-first searched in proportionately the same amount of time.

With the above observations in mind, we propose the following strategy for emulating standard heuristic search that operates by moving from level to level in the tree structure. For each successive level, the node of minimum cost at that level is found. This is done by first estimating the minimum cost of the nodes at a particular level. Such an estimate is easily determined by examining children of the minimum cost node found at the previous level in the tree. Then, a depth-first search to the desired level is performed. During the depth-first search, a current minimum for the level is maintained (it initially is the estimate), and nodes of cost greater than the current minimum are not expanded.

<u>Algorithm for Heuristic Search with Reduced Space</u>

```
** initialize current minimum **
currentmin:=root;
** perform multiple depth-first searches to each
   level **
for k:=2 to d do
  ** calculate initial estimate of minimum cost
     node for level k **
  if cost(left(currentmin))<cost(right(currentmin))
     then currentmin:=left(currentmin)
     else currentmin:=right(currentmin);
  ** depth-first search to level k **
  call depthfirst(root,k);
```

```
** Recursive procedure for depth-first search
   called above. Cuts off the search when at
   bottom level (j=0) and when the cost of a node
   encountered is greater than current minimum **
procedure depthfirst(node,j)
   if j=0 and cost(node)<cost(currentmin)
      then currentmin:=node;
   if j>0 then
      if left(node) not visited and
         cost(left(node))<cost(currentmin)
         then depthfirst(left(node),j-1)
          else if right(node) not visited and
                 cost(right(node))<cost(currentmin)
                 then depthfirst(right(node),j-1)
```

In standard heuristic search, when the minimum cost node at a certain level is first found, a cut exists whose associated top subtree contains that node but no nodes at any deeper level. Our new strategy for performing heuristic search is most easily understood as trying to use depth-first search with a current minimum to efficiently explore this top subtree. The true minimum for the level cannot be known in advance and thus an initial estimate must be generated from the previous iteration of the algorithm.

We now discuss the time performance of our new emulation of heuristic search. First, we note that because the algorithm is based on moving from level to level, it has the potential for achieving run time only a constant factor above that of standard heuristic search. There are two factors that affect the run time of the new algorithm and make it difficult to analyze exactly. One is the fact that an estimate of the true minimum at a level must be used; the other is that the shape of the top subtree can vary away from being complete.

Since we are using estimates of the true minimum during a depth-first search to define something close to the actual cut generated in standard heuristic search, the boundaries of the subtree corresponding to the actual cut may be exceeded when it is explored. But if the estimates converge quickly to a good estimate (i.e. one close to the actual lowest cost), then only a small amount of extra expansions will be made. Also, if the top subtree remains roughly exponential in size as a function of its depth, then space is reduced from being proportional to the size of the subtree to the logarithm of its size, and the total time required is only a constant factor increase over that used by standard heuristic search. Thus, our new heuristic search method holds the promise of exhibiting a very favorable tradeoff of time for space, i.e. significant reductions in space consumption are possible at the expense of only a small increase in time.

Extensions to our new algorithm for heuristic search can be made in an effort to address the two factors mentioned above. To decrease the effect of estimating the true minimum, additional expansions can be made from nodes of cost close to the minimum found at the previous level. The possible noncompleteness of the top subtree can be addressed by performing fewer depth-first searches with each depth-first search extending out to a level more than one unit away from the previous level. Descriptions of these extensions similar to the algorithm presented above are left to the interested reader.

We conclude our discussion of heuristic search by noting again that it is difficult to obtain exact expressions for the time and space requirements of our new algorithm.. Empirical studies should be done to quantify the time-space tradeoffs that exist in it, and probabalistic methods offer a possible way of analyzing the variety of different tree structures that can arise when the algorithm is executed.

6. Conclusions

In this paper, we have analyzed the time and space requirements of tree search, a fundamental computational problem. We found that significant reductions in the space used by standard depth-first, breadth-first, and heuristic search can be made with the expense being only a small constant factor increase in the time required by the search strategy. However, there is a time-space tradeoff inherent in this problem, since we were able to show that strategies using minimum space require time greater than linear in the size of the tree.

The methods we have proposed seem to hold the most promise for heuristic search, since standard implementations of heuristic search reduce the time required by exhaustive search but are often hampered by large space requirements. Future research should be directed towards implementing these reduced space heuristic search methods in practice, so as to judge their actual time performance in comparison to that of standard heuristic search.

A FAST PROBABILISTIC ALGORITHM FOR FOUR-COLORING LARGE PLANAR GRAPHS

Raymond A. Archuleta
Henry D. Shapiro

Department of Computer Science
University of New Mexico
Albuquerque, New Mexico 87131

The problem of four-coloring planar graphs — assigning colors to vertices so that no two adjacent vertices have the same color — is widely known. Backtracking algorithms guaranteed to four-color a graph, even those using sophisticated ordering heuristics, have very large running times on graphs of even moderate size (300–400 vertices). Numerous approximation algorithms have appeared in the literature, though they invariably fail to four-color large planar graphs[8]. In recent work, Morgenstern and Shapiro[5], give an approximation algorithm that experimentally exhibits no failures on graphs of up to 5000 vertices, but which is observed to have non-linear running time. In this paper we present a probabilistic algorithm for rapidly four-coloring large planar graphs. Extensive experimental tests indicate no failures on graphs of up to 15,000 vertices and a roughly linear running time over a wide range of sizes. For graphs of comparable size the algorithm is 100 times faster than any reported in the literature.

INTRODUCTION

Though the long standing four-color conjecture was proved by Appel and Haken in 1976, their proof does not provide a computationally feasible approach to four-coloring large planar graphs. Because of the large running times of exact algorithms based on backtracking, most of the attention of researchers has been focused on algorithms that are rapid, but do not necessarily produce a four-coloring. To put our new approach in perspective and because we use some of the terminology and ideas, we briefly review the strategies of others. One class of approximation algorithms is based on the "greedy" method — the vertices are processed in order, with each vertex assigned to the lowest numbered color class that does not place it in conflict with its previously colored neighbors. Because the vertices adjacent to the current vertex might use all four colors, a fifth, or even sixth, seventh, etc. color may be necessary. When the greedy method needs to create a new color class the vertex is said to be at *impasse*. In an attempt to minimize the total number of color classes required, different algorithms within the general class order the vertices using various heuristics. Some well known ordering schemes are:

Largest-First: The vertices are pre-ordered from highest degree to lowest degree. Because of the large number of ties inherent in the degrees of vertices in planar graphs, which must have an average degree of less than six, a secondary ordering is used to break ties. The size of the second neighborhood, i.e., the number of vertices two steps away, is a natural choice. More sophisticated tie breaking strategies based on the dominant eigenvector of the adjacency matrix have been considered[9].

Smallest-Last: This approach is motivated by the following observation: a vertex of degree three is trivial to color, since its three neighbors can only have used at most three of the four colors. The vertex of lowest degree is placed last in the ordering list, it is then removed from the graph (reducing the degrees of its neighbors), and the procedure is applied recursively to the graph that remains. There are two ways of handling a vertex, v, of degree four so that a conflict cannot arise. One is to perform a *contraction*. Two non-adjacent vertices connected to v (there is always such a pair) are contracted into a single vertex after v is removed. That is, their adjacency lists are merged. The resulting graph is then colored, the contracted pair split apart and v reinserted. Since the two vertices that were contracted have the same color when split apart, the neighborhood of v uses at most three colors. Contraction preserves maximal planarity. A planar graph always has a vertex of degree five; if contraction is not performed, using this ordering scheme guarantees that the greedy algorithm never uses more than six colors. If we use contraction a five-coloring is guaranteed. The other method of handling vertices of degree four is based on Kempe chains and will be taken up shortly.

Saturation: Unlike the previous two schemes that statically order the vertices, saturation dynamically orders the vertices as the algorithm proceeds. The *saturation degree* of a vertex, v, is defined by Brélez[2] as the number of different colors used by vertices adjacent to v. The algorithm always

CH2345-7/86/0000/0595$01.00 © 1986 IEEE

chooses the vertex of highest saturation degree to color next, following the intuition that it has the fewest degrees of freedom. Ties are broken using a secondary ordering scheme, usually largest first.

The greedy method can be refined as follows: when a vertex is at impasse, before enlarging the number of color classes, apply a transformation to the current coloration. If the vertex is not at impasse in the transformed coloration a new color class is not needed. Such transformations are usually based on Kempe chain interchanges, first described in Kempe's false proof of the four-color theorem[7]. The i-j Kempe chain containing vertex u, of color i, is the connected component of the graph consisting of all vertices reachable from u by traversing edges that connect vertices of colors i and j. If the colors of the vertices on an i-j Kempe chain are interchanged no conflicts are created. This can be used to resolve an impasse at a vertex of degree four. Figure 1 shows how this is done. If the a-b Kempe chain containing vertex u_1 does not contain vertex u_3 then an a-b interchange frees color a for use at v. If the a-b Kempe chain contains both u_1 and u_3 then the c-d Kempe chain containing u_2 cannot reach u_4. When a vertex of degree five is at impasse, application of Kempe's method often succeeds in resolving the difficulty, though it is not guaranteed to do so. This technique was coupled with smallest last ordering by Matula[4].

Morgenstern[6] has determined experimentally that when using saturation ordering on maximally planar graphs containing no vertex of degree less than five (MPG5 graphs), both the number of vertices at impasse and the size of the Kempe chains searched during impasse resolution grow linearly with the size of the graph, though the data on the sizes of the Kempe chains is quite erratic, as the large standard deviation indicates. The Kempe chains are sometimes very short, one or two vertices, and at other times they include half the vertices of the graph. We have observed similar behavior (Table 1). This makes the overall average running time of the approximation algorithm using interchange $O(N^2)$, while the simpler, but less effective, methods are $O(N)$ (because distribution sort can be used). The method in Morgenstern[5] is an enhanced version of this Kempe interchange strategy based on the work of I. Kittell[3]. They consider sequences of Kempe interchanges should a single interchange fail to resolve the impasse. A number of heuristics to guide the search and detect repeated colorations are employed to keep down the running time. They report no failures to four-color MPG5 graphs with up to 5000 vertices. Their running times on a VAX 11/780 for problems of this size is roughly 15 minutes. For smaller graphs, with 500–1000 vertices, their running times are about one minute.

IMPASSE RESOLUTION WITH "WANDERING FIFTH COLOR"

The probabilistic coloring algorithm, which we have named *wandering fifth color*, is a compromise between the simple greedy strategies and the complex interchange methods. Like the greedy algorithms, the algorithm attempts to color the next vertex, which can be selected using any of the above ordering schemes. The idea behind impasse resolution can be seen in Figure 2. It may be the case that the color assigned to a neighbor, u, of v, the vertex at impasse, could be assigned to v if the color were not already being used to color u. The pigeonhole principle guarantees this possibility always exists if the vertex has degree seven or less. We assign to v the color of u, uncolor u and see if u can now be recolored without resorting to a fifth color. If u can be colored we have resolved the impasse. If it cannot be colored, then u is now at impasse. We have "wandered" the problem to a new location, where we repeat the process.

Figure 1. Impasse Resolution with Kempe Chain Interchange

Several things can go wrong during this process. First we can wander into a vertex of degree eight or higher in which every color is used twice in the first neighborhood, and so reach a dead end. Even if we prohibit the vertex at impasse from immediately returning to its previous location, there is the possibility of getting stuck in an infinite cycle. We therefore terminate the wandering process if the vertex at impasse attempts to cross the path it has taken during the wandering process. This does eliminate some possibilities, since returning to a vertex does not imply returning to an isomorphic coloration. Nonetheless, this is a reasonable compromise. Of course, it is quite likely that for one of these two reasons the wandering process will fail. We therefore wander the vertex at impasse through all possibilities in a recursive (depth first) search rooted at the original impasse location. The exact algorithm, in high level pseudo-code, is given in Figure 3.

The wandering process can fail to resolve an impasse. When this occurs we abandon the entire coloring process and start over again. We include an element of randomness so that when we restart the algorithm we do not wind up in the same failed configuration. There are several places for randomness to be inserted into the algorithm:

Table 1. Experimentally Determined Properties of MPG5 Graphs

Approximate Size	Number of Impasse Vertices	*a*	Average *b*	Std. Dev. *b*	Average *c*
15000	388.50	0.0257			5.99
12500	326.40	0.0256			6.15
10000	255.90	0.0249			6.20
7500	196.00	0.0254			6.10
5000	132.34	0.0260	0.09	0.14	6.24
2500	67.69	0.0261	0.18	0.16	6.26
1000	25.94	0.0255	0.14	0.18	6.38

a = Number of Impasse Vertices / Number of Vertices

b = Size of Kempe Chain / Number of Colored Vertices at the Time Kempe Chain was Explored. Note: Average *b* is an average of ratios

c = Number of calls to ***recursivewander*** to resolve impasse or admit failure

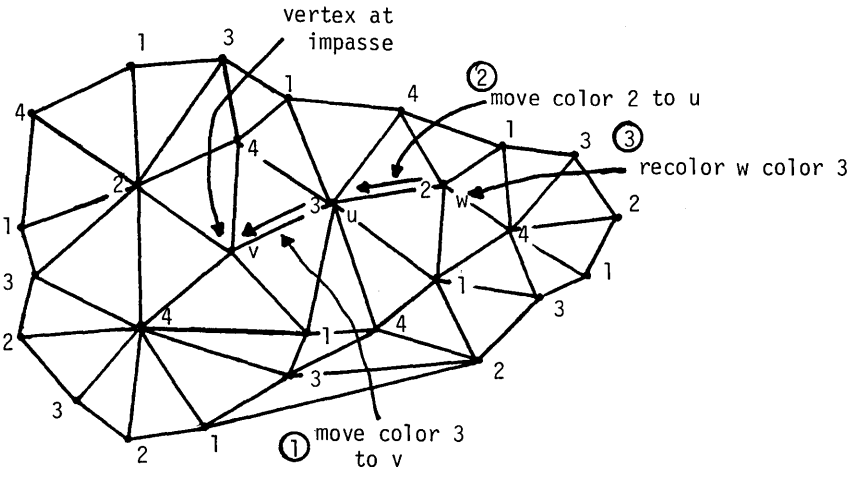

Figure 2. The Idea Behind Wandering Fifth Color

```
procedure wander(w: vertex, var success: boolean);
 procedure recursivewander(v: vertex);
  begin
   (* Try to resolve the impasse in the first neighborhood of v *)
   for each neighbor, u, of v whose color occurs only once in the first
        neighborhood of v do

  recursivewander(w);
  (* If we return to this point we have failed to resolve the impasse *)
  success := false
 end; (* wander *)
```

Figure 3. Impasse Resolution by Wandering

- The vertices can be ordered randomly, or within an ordering scheme, randomness can be used to break ties, instead of relying on a secondary ordering strategy.
- Instead of assigning to a vertex the first available color of lowest index, we can assign it a random color from the colors that do not cause conflicts.

An exact analysis of the running time of the algorithm is impossible, because there are too many secondary interactions in the coloring process. It is possible to provide some experimental data and to make some simplifying assumptions that allow us to predict the running time. The results presented in Table 1 allow us to conclude, at least for graphs of size less than 15,000, that

- The number of vertices at impasse during a successful coloring is a linear function of the graph size. Phrased another way, the inter-impasse distance is constant and not a function of the size of the graph. This is not surprising since (for non-pathological cases) being at impasse is essentially a localized phenomenon.
- The number of steps in the wandering operation, whether it succeeds or fails, is constant on average. This was measured experimentally over a wide variety of graph sizes, ordering heuristics and color assignment strategies. The average is consistently in the 6–7 range. This differs significantly from the Kempe chain approach where the size of the Kempe chains searched increase as the graphs get larger.
- The probability that the wandering process fails to resolve the impasse is a local phenomenon. This is roughly equivalent to assuming that each call to wander is independent of previous actions taken in coloring the graph.

With these assumptions we see that the probability of coloring a graph without need to restart the coloring process is given by

$$(1-p)^{aN} = C^N$$

where p is the probability that the impasse will not be resolved and a is the constant of proportionality for the number of impasses. Since processing a non-impasse vertex and an impasse vertex both appear to take constant time, we get an expected running time proportional to

$$NC^N + 2NC^N(1-C^N) + 3NC^N(1-C^N)^2 + \cdots = N(1/C)^N$$

Though exponential, since $1/C > 1.0$, the value of $(1/C)^N$ is inconsequential over a wide range of N because we estimate $1/C$ to be in the vicinity of 1.00016. This would predict a ratio of running times between graphs of 15,000 vertices and graphs of 5000 vertices of about 15. The observed ratio is closer to 10.

EXPERIMENTAL RESULTS

In this section we give results for various combinations of parameters to the algorithm. We experimented with three static ordering strategies, the classical largest first and smallest last (randomly ordering the vertices within each grouping so as to have randomness in the event of restarts) and "rose petal" ordering. This last is a static ordering created by selecting a vertex for the center and then doing a breadth first search of the graph. The central vertex is chosen randomly (without repeats) so that a different ordering results on each restart, at least until all choices have been exhausted. Largest first did very poorly, actually being unable to four-color some graphs of size N in N restarts for N less than 1000. Rose petal ordering produced the best results and suggested to us that the dynamic saturation ordering might be an appropriate choice. We modified the program to allow the static orderings to be overlaid with saturation ordering, with saturation coming into play at different levels. For example, a level of zero is equivalent to turning our attention immediately to vertices at impasse, instead of waiting for them to be processed according to the order dictated by the static ordering. Notice that when a vertex is first brought to impasse there is necessarily at least one escape route, but if we delay no escape routes might exist when it becomes time to process the vertex and a restart will be necessary. Table 2 presents the results for a number of different combinations and graph sizes for MPG5 graphs. For the smaller sizes fifty trials were run. For the larger sizes only ten trials were made. The complete code can be found in Archuleta[1]. The number of restarts is the main factor affecting running time, though how early within a linear pass through the graph the algorithm fails to resolve an impasse is also important. Largest first consistently performed the worst by a significant margin and is an inappropriate ordering for this algorithm. Smallest last performs best with a level of saturation of one (there is only one possibility left for a vertex, so color it that color), whereas rose petal ordering did better when the saturation level was two. A saturation level of three is equivalent to the saturation ordering without any secondary ordering heuristic. This ordering was observed to perform somewhat erratically, though the small sample size for the larger graph sizes makes drawing firm conclusions unjustified. Because the algorithm is so fast the time to maintain a precise ordering based on secondary ordering heuristics negates any advantage that might be gained.

We also experimented with different strategies for assigning an available color when more than one choice existed. We tried three approaches to assigning colors:

- Skewing the assignment to favor the lowest numbered color classes. This is the classical method of assigning the colors in the greedy method.
- Always giving out the color so as to equalize the number of colors in each color class.
- Assigning a color at random from the available colors. This method has the advantage that it inserts additional randomness into the algorithm.

We found that skewing the colors according to the classical scheme gave the best results. This is the color assignment method used in the tabular results presented in Table 2. We have not explored the reason why a skewed distribution outperforms a balanced one; it may be that the smaller size of color class four makes impasse resolution slightly more likely.

Table 2. Running Times (Seconds)/Restarts for the Wandering Fifth Color Algorithm

	Method			
Approximate Size	Rose Petal Saturation = 2	Smallest Last Saturation = 1	Pure Saturation (No secondary ordering)	Largest First Saturation = 1
15000	73.31/6.80	125.16/6.00	177.93/19.60

FURTHER RESEARCH

We close with some remarks regarding future research. The primary reason that the running time of the algorithm is not linear is that when we cannot resolve an impasse we completely discard the current coloration. For sizes that we have considered this does not occur often enough for it to be of serious concern. One approach to preventing restarts is to switch to a more sophisticated impasse resolution algorithm when wandering fails, for example the one used by Morgenstern. Because of the long running times he reports, using sequences of Kempe interchanges will be profitable only if the expected number of restarts becomes very high. Another approach, based on the intuition that an impasse is a local phenomenon, is to excise a small portion of graph centered around the impasse vertex, say all vertices within distance three or four, and to consider all possible four-colorations, looking for one that agrees with the remainder of the graph on the boundary of the excised region. Because the subproblem we will create in this manner is small, an exhaustive backtracking algorithm can be used.

Table 3. Sizes of Color Classes Using Rose Petal Ordering with Saturation Level = 2

	Color Assignment Method

Techniques for Collision Resolution in Hash Tables with Open Addressing[*]

J. Ian Munro
Pedro Celis
Data Structuring Group, Department of Computer Science,
University of Waterloo, Waterloo, Ontario, N2L 3G1

Abstract

In this paper we focus on the problem of resolving collision in hash tables through open addressing. A number of techniques, both old and new, are surveyed. The results of analyses and extensive simulations are presented.

1 Introduction

Hashing was one of the first techniques proposed for implementing the operations of insert, delete and find in a data structure. Knuth [20] gives credit to Luhn for originating the idea of hashing in an internal IBM memorandum of January 1953.

Ideally, we would like a hashing scheme to determine solely from the identification of a record, called the *record key*, the exact location in which the record is stored. Given a record to be inserted or located, a *key to address transformation* is performed using a *hash function* $h(k) : \mathcal{K} \mapsto \{0, \ldots, m-1\}$ which takes as an argument a key k in the specified universe $\mathcal{K}$ and returns an integer $h(k)$ between 0 and $m-1$, where m is the size of the table. The record is then inserted in the table entry specified by $h(k)$. This causes no problems until a record with key k' has to be inserted and location $h(k')$ is already occupied. In this case we say a *collision* has occurred.

If, as is usually the case, the hash function essentially maps keys to locations at random, then collisions are almost certain to occur even if the table is sparsely populated. The famous "birthday paradox" (see for example [10]) asserts that among 23 or more people the probability that at least 2 of them share the same birthday exceeds 1/2. In other words, if we select a random function that maps 23 records into a table of size 365, the probability that no two keys map into the same location is only 0.4927. In general, a hash table of size m is likely (probability $> \frac{1}{2}$) to have at least one collision by the time it contains about $\sqrt{\pi m}$ elements.

In order to use a hashing scheme, two almost independent decisions must be made; a hash function must be selected as well as method for handling collisions. There are two popular ways of handling collisions, *chaining* and *open addressing.* The idea of chaining is to keep, for each location, a linked list of the records that *hash* to that location. This implies that each entry in the table must have enough space to contain a record and a link field. There are a number of interesting tradeoffs and techniques in connection with chaining. Our interest, however, lies in an approach

[*]This work was supported by the Natural Science and Engineering Research Council of Canada under Grant A8237

which calls for no additional storage, namely open addressing.

2 Open Addressing

Peterson seems to have introduced the notion of collision resolution by open addressing in his seminal paper of 1957 [27]. The idea is to do away with the links entirely, and to insert by probing the table in a systematic way. When a collision occurs, one of the colliding records is selected to keep the table location, while the other one continues probing until inserted. The sequence of table entries to be inspected when inserting or searching for a record is called the *probe sequence*. We can augment the hash function with another parameter, the *probe position* or try number, and use it to generate the probe sequence for a record. Thus the hash function becomes $h(k,i)\colon \mathcal{K} \times \{1,\ldots,\infty\} \mapsto \{0,\ldots,m-1\}$.

Schemes for inserting into a hash table with open addressing can vary in two ways: in how the probe sequence is generated, and in how to decide which of the colliding records is to be rehashed. We call the latter portion of the insertion algorithm the *reordering scheme*. This decision could be based on any knowledge of the record key values, their current probe positions, their future probe sequences and/or the order in which the records were inserted.

In discussing the various hashing schemes we will be interested in comparing the following three performance measures:

— I average number of probes required to insert a record;

— S average number of probes required to find a record in the table;

— U average number of probes required to determine that no record in the table has a given key value.

To determine the value of these performance measures we will often find convenient to study the following random variables:

— the probe sequence length for a key (**psl**),

— the longest probe sequence length (**lpsl**), which is the largest value of **psl** among all the records in the table;

We will compare the expected value (denoted by E[•]), and sometimes the variance (denoted by V[•]), of these random variables for both the case of full and nonfull tables. For large nonfull tables such expressions may be functions of α, the load factor, defined as $\alpha = n/m$, where n is the number of records in the table and m is its size. Several analyses of hashing schemes have been performed for infinite nonfull tables with load factor α, where $\alpha \leq 1-\epsilon$, $\epsilon > 0$. Throughout the paper we refer to these tables as α-full tables.

A very useful but often neglected performance measure of a hash table is the longest probe sequence length (**lpsl**). This metric provides a bound on the cost of both successful and unsuccessful searches. If all records in the table are stored in probe positions between 1 and **lpsl**, then **lpsl** probes into the table will be sufficient to find any record, or to determine that no record with such key exists. This elegant, but sadly underutilized, idea is due to Lyon [23].

The simplest open addressing hashing scheme is known as *linear probing*. It uses the hash function $h(k,i) = (h_1(k) + (i-1) * c) \bmod m$, where $h_1(k)$ is the initial hash function and c is a constant relatively prime to m. This method was discovered independently by Ershov [8] and Peterson [27]. Experience with linear probing shows that the algorithm works quite well until the table is relatively full. The problem with linear probing is that it uses only one circular path to resolve collisions and suffers from a piling-up phenomenon called primary clustering. If r consecutive (mod c) locations are occupied and a new value hashes into any of these spots (or the one before or after this segment) then at least $r+1$ consecutive locations will be occupied. Furthermore, to find this additional key will take about $r/2$ probes on average. This unfortunate event occurs with probability proportional to r, exacerbating the situation.

The performance of linear probing improves significantly if we allow c to be a function of k instead of a constant [1]. This gives rise to a new scheme, called *double hashing*, that uses two independent auxiliary hash functions $h_1(k)$ and $h_2(k)$ to compute $h(k,i) = (h_1(k) + (i-1) * h_2(k)) \bmod m$. The values $h(k,i), i = 1, \ldots, m$ will yield a permutation of the table locations provided $h_2(k)$ is prime relative to m. A simple, and indeed standard, way to guarantee this is to insist that the table size, m, be a prime. Following this simple requirement it is found that double hashing performs much better than linear probing for high load factors as it essentially eliminates the possibility of two colliding records having the same remaining probe sequence.

Two idealizations of open addressing schemes are frequently mentioned in the literature and used as models for analysis. These are *uniform hashing*, under which the hash function provides a random permutation of the numbers $\{0, \ldots, m-1\}$; and *random probing*, in which $h(k,i)$ is simply a number chosen at random from $\{0, \ldots, m-1\}$. The difference between these two schemes is that random probing is memoryless, meaning that a location may be probed several times before some other location is probed for the first time. Random probing is simpler to analyze and has essentially the same performance as uniform hashing for α-full tables under most reordering schemes. Random probing and uniform hashing are not usually implemented, since empirical evidence shows that their performance is close to that of double hashing which is much more reasonable to implement. Guibas [17] has proven that the behavior of double hashing is asymptotically equivalent to uniform hashing for load factors α not exceeding a certain constant $\alpha_0 = .31....$ The difficulty of the proof and the bound on the load factor are indications of the difficulty in other analyses of double hashing. The interest of random probing and uniform hashing lies in the fact that they are simpler to analyze and appear to approximate closely the performance of double hashing.

3 Reordering Schemes

The standard insertion algorithm is to inspect the probe sequence corresponding to the record to be inserted until an empty table location is found, and place the new record there. Hence the reordering scheme consists of giving preference to the record that was inserted first.

The standard search algorithm is to inspect locations in the order of the probe sequence of the key value. Under this scheme, a search can be stopped as unsuccessful when either an empty table location is probed or lpsl probes have been made. Furthermore, $S = \text{E[psl]}$ and $U \leq \text{E[lpsl]}$, regardless of the reordering scheme.

For linear probing and a nonfull tables it can be shown that [20,31]

$$\begin{aligned}\text{E[psl]} &= \frac{1}{2}\left(1 + \frac{1}{1-\alpha}\right) - \frac{1}{2(1-\alpha)^3 m} \\ &\quad + O\left(m^{-2}\right) \\ \text{V[psl]} &= \frac{\alpha(\alpha^2 - 3\alpha + 6)}{12(1-\alpha)^3} - \frac{3\alpha+1}{2(1-\alpha)^5 m} \\ &\quad + O\left(m^{-2}\right)\end{aligned}$$

and for full tables

$$\text{E[psl]} = \sqrt{\pi n/8} + \frac{1}{3} + O\left(n^{-1/2}\right).$$

No closed form results for lpsl have been presented for this method, but Larson [21] gives some numerical results for an approximate analysis. According to his computations, for $m = 10^3$ and $\alpha = 0.6$, E[lpsl] = 23.6. If the load factor is increased to 0.9 this number goes to 288, and if instead of increasing the load factor we increase the table size to 10^6, the number goes up to 67.1.

Peterson proves that, for linear probing with the standard insertion algorithm, the average probe position in a given table in which a record is stored is independent of the order in which the records are inserted. Basically the same proof can be used to show that the average probe position is independent of the reordering scheme used. Hence, regardless of the reordering scheme used, $I = \mathrm{E}[\mathbf{psl}]$. Since the standard search algorithm is used, $S = \mathrm{E}[\mathbf{psl}]$ for the value of E[psl] presented above. Since no analysis for lpsl has been presented, the value of U has not been determined. However, ignoring Lyon's modification, we have that for nonfull tables

$$U = \frac{1}{2}\left(1 + \frac{1}{(1-\alpha)^2}\right) - \frac{3\alpha}{2(1-\alpha)^4 m} + O\left(m^{-2}\right)$$

and if the table is full, $U = n$.

For the standard insertion algorithm with uniform hashing the following equations can be established [27,13,14]: for a nonfull table

$$\mathrm{E}[\mathbf{psl}] = \frac{m+1}{n}\left[H_{m+1} - H_{m-n+1}\right] \approx -\alpha^{-1}\ln(1-\alpha)$$

$$\mathrm{V}[\mathbf{psl}] \approx \frac{2}{1-\alpha} + \alpha^{-1}\ln(1-\alpha) - \alpha^{-2}\ln^2(1-\alpha)$$

$$\mathrm{E}[\mathbf{lpsl}] = -\log_\alpha m - \log_\alpha(-\log_\alpha m) + O(1)$$

and for a full table

$$\mathrm{E}[\mathbf{psl}] = \ln n + \gamma - 1 + o(1)$$

$$\mathrm{E}[\mathbf{lpsl}] = 0.6315... \times n + O(1)$$

where $\gamma = 0.5772156649...$ is Euler's constant. If we also use the standard search algorithm then psl represents the cost of both insertions and successful searches, and lpsl represents a bound on the cost of unsuccessful searches. Hence $I = S = \mathrm{E}[\mathbf{psl}]$ and $U \leq \mathrm{E}[\mathbf{lpsl}]$. We see that uniform hashing, and so presumably double hashing, becomes substantially better than linear probing for relatively full tables. The remainder of this paper will focus on the fact that, unlike linear probing, reordering schemes can be used to advantage under these probing methods.

3.1 Brent's Method

Brent [3] was the first to propose moving stored records to reduce the expected value of the probe sequence length. During an insertion, a sequence of occupied table entries is probed until an empty location is found. Brent's scheme checks to see whether any of the records in these occupied locations can be displaced so that the cost of searching for the new value plus the extra cost of searching for the displaced element is smaller. More formally, let d_i be the number of locations the key in the i-th location probed by the new record has to move before finding an empty location. Then Brent's method selects the value of i that minimizes $i + d_i$, places the new record on its i-th choice and moves the record previously in that location d_i steps ahead. Figure 1 shows graphically how one such insertion of a record R might occur. In the example, instead of inserting the record R in its fifth choice and increasing the total table cost by 5, record R_3 is displaced to its next choice, and then R is placed in its third choice, the place formerly occupied by R_3. The increase in the sum of the probe sequences is thus reduced from 5 to 4.

No analysis of the cost of loading a table has been presented for this method, but simulations presented in [4] support the conjecture that $I = \Theta(1)$ for α-full tables and $I = \Theta(\ln n)$ for full tables. Since the stan-

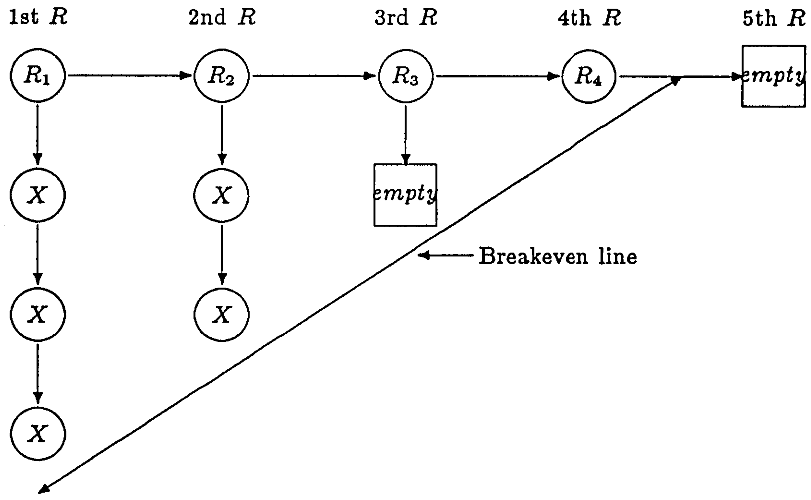

Figure 1: Sample insertion in Brent's method

dard search algorithm is used then S = E[psl] and $U \leq$ E[lpsl].

The tables produced by Brent's scheme have a very good E[psl], even when completely filled. For random probing and α-full tables the expected values are

$$\mathrm{E[psl]} = 1 + \frac{\alpha}{2} + \frac{\alpha^3}{4} + \frac{\alpha^4}{15} - \frac{\alpha^5}{18} + \frac{2\alpha^6}{15} + \frac{9\alpha^7}{80} - \frac{293\alpha^8}{5670} - \frac{319\alpha^9}{5600} + \cdots$$

taking the limit numerically as $\alpha \to 1$ indicates that for full tables

$$\mathrm{E[psl]} \approx 2.4941...$$

This agrees with simulations using double hashing. So, if the standard search algorithm is used, a record can be retrieved in less than 2.5 probes, on average, regardless of the table size. There has been no successful analysis of the expected value for lpsl but, based on simulations and an intuitive argument, it is conjectured [16] to be $\Theta(\sqrt{n})$ for full tables, and $\Theta(\ln n)$ for nonfull tables [4].

Brent's method does not require any extra memory to perform an insertion. If the search for an empty location is done on a depth first basis, as suggested in [3], the expected number of times the $h_2(\bullet)$ hash function will be computed is $\alpha^2 + \alpha^5 + \alpha^6/3 + \cdots$ eventually approaching $\Theta(\sqrt{n})$ for full tables [20]. The disadvantage of searching in this manner is that a number of locations below the breakeven line will be probed. For example the fifth probe position of the record R to be inserted would be probed unnecessarily. The number of additional table positions probed during an insertion is approximately $\alpha^2 + \alpha^4 + \frac{4}{3}\alpha^5 + \alpha^6 + \cdots$ [20].

Another way of searching for the closest empty location is to do a level search as recommended in [14]. This causes an essentially minimal number of locations to be inspected. However, for double hashing, this implies $h_2(\bullet)$ be called up to $\Theta(n)$ times instead of $\Theta(\sqrt{n})$. A further disadvantage of this insertion approach is that duplicate keys are not detected by the insertion algorithm, so if duplicate insertion requests may occur, an unsuccessful search should precede each insertion.

If we are to use Lyon's trick to truncate unsuccessful searches, we must of course update the **lpsl** when insertions are made. This requires a minor twist that is easily incorporated into either of the insertion schemes. **lpsl** may be updated either because the new element is in a position late in its probe sequence, or because the element displaced is moved to a late spot. The former is detected as part of the insertion, the latter requires an extra search.

3.2 Binary Tree Hashing

Binary tree hashing is the natural generalization of Brent's method. Not only is the record being inserted allowed to displace other records in its probe sequence, but these displaced records may further displace other records in their probe sequences. This is illustrated graphically by Figure 2. In the figure, R's first choice is occupied by R_1, hence the next probe position of both R and R_1 are checked. These two locations are also occupied by R_2 and R_3 respectively, hence the next probe position of all four records is inspected (note that the four records are not necessarily distinct). At that point it is found that the next probe position for R_1 is empty, then R_1 will be advanced two positions in its probe sequence and R will be placed in its first choice, the location previously occupied by R_1. This method was discovered independently by Mallach [25] and by Gonnet and Munro [16].

Since this method is a generalization of Brent's, it is expected to produce better tables at a somewhat higher cost. An approximate model [16] yields the following for random probing and α-full tables[1]:

$$\mathrm{E}[\mathbf{psl}] = 1 + \frac{\alpha}{2} + \frac{\alpha^3}{4} + \frac{\alpha^4}{15} - \frac{\alpha^5}{18} + \frac{2\alpha^6}{105} + \frac{83\alpha^7}{720} + \frac{613\alpha^8}{5760} - \frac{69\alpha^9}{1120} + \cdots$$

taking the limit numerically as $\alpha \to 1$ indicates that for full tables

$$\mathrm{E}[\mathbf{psl}] \approx 2.13414\ldots$$

This agrees with simulations using double hashing. There is no analysis for the expected value for **lpsl** but Gonnet and Munro, based on simulation results, conjectured them to be about $\lg n + 1 \approx 1.44 \ln n + 1$ for full tables.

Again the cost of searching is given by the formulas $S = \mathrm{E}[\mathbf{psl}]$ and $U \leq \mathrm{E}[\mathbf{lpsl}]$, since the standard search algorithm is used. As with Brent's scheme, the expected cost of inserting a record has not been successfully analyzed for either of the insertion algorithms described below.

The natural order for inspecting the table when searching for an empty location is by levels, as suggested in [25] and [24][2]. However, the amount of memory required to store the tree of locations probed is large, as Mallach noted. Simulations [6] give credence to the hypothesis that the expected value of I for a full table is about $.5n^{1/2} \ln n$ and the amount of memory required to store the tree about $.15n^{3/2} \ln n$. What is worse, the variance of these two measures is very high, so the probability of requiring, say, n^2 extra memory locations is not insignificant.

Gonnet and Munro [16] show how to use an algorithm for the transportation problem by Edmonds and Karp [9], to insert keys into the table. An enhancement of the algorithm has a worst case runtime of $\Theta(n^2 \ln n)$ [11] which suggests that I could be as high as $\Theta(n \ln n)$. However, simulations [6] suggest that the expected value for I for a full table is $\Theta(n^{1/2} \ln n)$, and the amount of extra memory required is $\Theta(n)$, each with a small variance. While this is a great improvement over the natural algorithm, it is still expensive both in time and memory.

As with Brent's method, a small number of additional probes are required to avoid duplicate keys and

[1] The formula for E[psl] for α-full tables is taken from [14] and differs slightly from the one in [16].

[2] The reader is warned that the analysis presented in [24] is not entirely accurate.

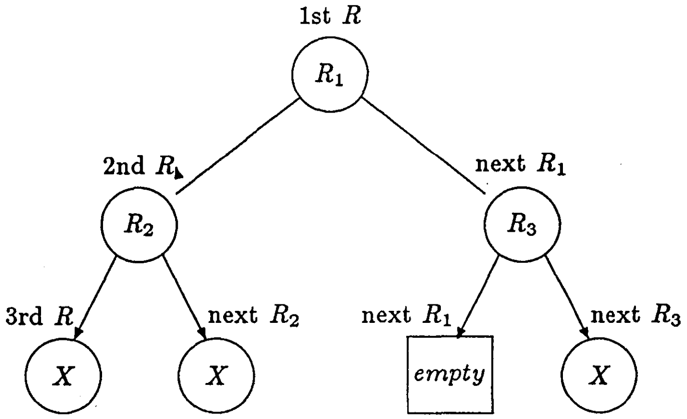

Figure 2: Sample insertion using Binary Tree Hashing

to keep track of the value of lpsl.

3.3 Optimal and Min-Max Hashing

Both Brent's method and binary tree hashing move stored keys forward in their probe sequences. Further reductions in the value for E[psl] could be obtained if records could also be moved back in their probe sequences. Lyon [23] presents simulations results on a different generalization of Brent's method which allows records to be moved back a limited number of steps. Poblete [28] has simulated a generalization of binary tree hashing where records are allowed to move back a limited number of steps. All of these methods present tradeoffs between the cost of insertion (I) and the cost of searching (S and U).

It is natural to ask what reordering scheme minimizes the value of E[psl], or, in other words, minimizes S for the standard search algorithm. Such a scheme is called optimal hashing [29,30,16]. Poonan [29] was the first to note that the optimal placement of keys in a hash table is a special case of the assignment problem [19], which can be solved in $O(n^2 \log n)$ time in the worst case [11]. Neither the expected cost of finding the optimal hash table nor the expected values of psl and lpsl have been determined. For E[psl] and full tables the following bounds exist [7,16]:

$$1.7 < \mathrm{E[psl]} < 2.135$$

Simulations [16,6] indicate that for full tables $\mathrm{E[psl]} \approx 1.82...$, $\mathrm{E[lpsl]} = \Theta(\ln n)$, and $I = \Theta(\sqrt{n})$.

Instead of determining the reordering scheme in the insertion algorithm that will minimize S for the standard search algorithm, we might be interested in minimizing U. This min-max approach has the feature that in addition to minimizing lpsl for the specific table (and hence its expected value), simulations indicate the average psl can be kept to about $1.83\ldots$, that is, very close to the cost of the optimal table. The expected value of lpsl is bounded by [13,4]

$$\ln n + \gamma + \frac{1}{2} + P(\ln n) + o(1) < \mathrm{E[lpsl]}$$
$$< 3\ln n + \lceil \lg(n-2) \rceil + 3\gamma + o(1)$$

where $P(x)$ is a periodic function with period 1 and magnitude $|P(x)| \leq .0001035$ for full tables, and by

$$-\alpha^{-1}\ln(1-\alpha) < \mathrm{E[lpsl]}$$
$$< -3\alpha^{-1}\ln(1-\alpha) + \lceil \lg(m-2) \rceil$$

for α-full tables.

Unfortunately, the approaches used in creating both optimal and min-max hash tables are time consuming and can require $\Theta(n)$ extra memory to process an insertion.

In summary, we can say that binary tree, optimal and min-max hashing reduce the expected values of psl and lpsl dramatically, but at a high cost for table creation. The expected number of operations to construct a table using one of these algorithms is high compared to the standard hashing scheme. They also require a nontrivial amount of extra memory during the creation phase. These methods are best suited for applications in which the set of keys is static and known in advance. In such cases, the cost of constructing the table can be amortized over a large number of search operations, and the additional memory space required can be released as soon as the table has been created.

3.4 Robin Hood Hashing

Robin Hood hashing [5,4] is a reordering scheme for the insertion algorithm that differs from the previous methods in that it does not attempt to reduce the expected value of psl. Instead it tries to reduce the variance of psl, and as a consequence the expected value of lpsl, without significantly increasing the cost of insertions.

The idea is very simple: resolve a collision by giving the location to the record that is further along its probe sequence. The name of the scheme comes from the fact that we take from the rich to give to the poor. For random probing and full tables we have the following

$$E[\text{psl}] = \ln n + \gamma + o(1)$$

$$E[\text{lpsl}] < 3\ln n + \lceil \lg(n-2) \rceil + 3\gamma + o(1)$$

and taking a limit numerically as $\alpha \rightarrow 1$ indicates that for full tables

$$V[\text{psl}] \approx 1.883$$

Hence if the standard search algorithm is used, both S and U will be $\Theta(\ln n)$ for full tables. The cost of inserting will be affected by the cost of determining the probe position of a stored record. If this is determined by doing a "search" for the stored record then $I = \Theta(\ln^2 n)$.

However, better search algorithms have been proposed. These algorithms exploit the fact that the variance of psl is so small, meaning that most records are stored in a probe position very close to the average. The idea is to change the order in which the candidate probe positions are inspected during a search, starting near the average probe position and moving away from the average in both directions. In other words, we start by inspecting first those positions that have a high probability of success. The unsuccessful search (U) will remain at lpsl since all candidate probe positions must be inspected (in any order) before the search can be stopped. The average cost of searching, however, is reduced to $S < 2.6$. We can use the same idea when "searching" for a stored record to determine its probe position to reduce the cost of insertion to $I = \Theta(\ln n)$.

4 Updates

Deletion of unused items is troublesome in open addressing, because unoccupied table positions that had a collision must be marked as "deleted" so as to prevent fallacious, unsuccessful searching. There will then be three kinds of table entries: empty, occupied and deleted. When inserting, deleted table entries are treated as if they were empty, but they are treated as if they were occupied during searches.

For linear probing, deleted entries can be easily avoided by moving back a record that was rejected from the location. However, as we have noted, the performance of linear probing is inferior to the other methods and therefore performs poorly even if no updates have been made.

For random probing and the standard insertion and search algorithms (modified to handle deleted entries correctly), after a sufficiently large number of delete/insert pairs, the cost of searching will be given by $S = (1 - \alpha)^{-1}$. Since all locations in the table are now either occupied or deleted, and the value of the longest probe, **lpsl**, can only increase, unsuccessful searches take m probes. Hence the performance deteriorates to something worse than the performance of linear probing.

Gunjin and Goto [18] present a partial analysis for an algorithm that retraces the probe sequence of every record in the table and marks as empty all those deleted entries that are no longer jumped over by some other record. Their algorithm will improve the processing of unsuccessful searches only. If one is willing to use m additional bits of storage it is better to rehash the table in situ [2]. This will require less time, reduce even further U and reduce greatly S.

We feel the most encouraging result in the area of deletions in open in addressing is a modification to the Robin Hood algorithms [5,4]. The following modification has been studied: to delete a record, mark the table entry as deleted but keep the key value; when inserting, a deleted element is discarded if and only if it would be displaced if it were not flagged as deleted.

This modification causes the expected value of psl to increase without bound, but simulations indicate that the variance remains bounded by a small constant, and is never greater than that of a full table in which no deletions have occurred (i.e. $< 1.88\ldots$). The expected value will increase without bound because once a location contains a record at probe position i, then in the future it can only contain records that are at or past probe position i.

Employing the Robin Hood search schemes noted above, the cost of a successful search after an arbitrary number of insertions and deletions remains bounded by the cost of a successful search in a full table with no deletions. Unsuccessful searches are similarly bounded by those of a full table with no deletions.

Since the average probe position grows without bound, it would appear that the cost of doing an insertion also grows without bound, because each key has probed positions 1 to about the average probe position. This pitfall can be avoided by keeping track of the value of the smallest probe position among the records (deleted or otherwise) in the table. The insertion procedure then starts at a probe position equal to this value, since a placement before that position is not possible. Empty locations are treated as containing a deleted record in probe position 0.

The most efficient way of keeping track of the smallest probe position is to have counters of how many records are at each probe position. We expect only $\Theta(\ln n)$ counters to be needed as simulations indicate that about $1.15 \ln n + 2.5$ different probe positions will contain all the records in the table.

5 Conclusions

Hashing with open addressing does lead to very good tables particularly in the static case, even when the load factor approaches or reaches 1. Brent's scheme and Robin Hood hashing are reasonably fast insertion techniques. As we have noted Robin Hood seems to lead to good dynamic tables even when deletions are permitted. This may be surprising to many who, like us, felt that open addressing was inherently poor when a significant number of deletions were to be made. The analysis of Robin Hood with deletions is the most obvious open problem. We note, however, that a number of results we have quoted are experimental and some analyses are based on simplifying models. More complete analyses of many of the methods are yet undone.

Finally, there is the search for even better approaches to conflict resolution by open addressing.

PERFORMANCE ANALYSIS OF CONCURRENT MAINTENANCE POLICIES FOR SERVERS IN A DISTRIBUTED ENVIRONMENT

by

Farokh Bastani, Wael Hilal, and Ing-Ray Chen

Department of Computer Science
University of Houston - University Park
Houston, Texas 77004

ABSTRACT

One way of improving the performance of a server in a local area network environment is to assign the task of maintaining its data structures to separate maintenance processes. It is frequently suggested that the maintenance processes can be treated as low priority processes. However, our performance analysis shows that this policy can result in unstable systems. That is, eventually the response time for client requests becomes infinite. We propose and analyze several deterministic and stochastic scheduling strategies which ensure that the system is always stable. We also discuss the design of a directory server which incorporates a concurrent maintenance process. We present the experimental measurement of its performance and compare it with an alternative technique using a self-reorganizing data structure.

Index Terms: Degradable systems, maintenance processes, performance analysis, process scheduling strategies, self-reorganization.

I. INTRODUCTION

Many computing environments can be modeled as a set of servers and a set of clients. A typical example of this structure is local area network servers in which each server accepts requests for some operations from the clients and sends back responses. The server can be designed using two communicating processes, namely, a foreground process that interfaces with clients and serves their requests, and a background process that maintains the data-structures. The response time of the foreground process, and hence the response time for serving requests, is improved by shifting the time-consuming task of maintaining the data structures to the background process. For efficiency purposes, the background process updates the data-structure after a group of requests have been served and not after every request. If the primary data-structure is a binary tree, for example, the foreground process can simply mark a tree node as "deleted" in response to a delete request without actually deleting the node leaving the job of the actual deletion to the background process. For a request to add a new node, the foreground process can add this node on a simple auxiliary data-structure leaving the actual insertion of the new node to the background process. As more and more requests are served, the performance of the foreground process deteriorates gradually until the background job performs an "upgrade" to the primary data-structure. Systems whose response time deteriorates as additional requests are served are said to be "degradable". Their response time improves after the upgrade is performed. It is often suggested that the foreground process should be given a higher priority than the background process(es). However, our performance analysis shows that such a policy would result in unstable systems (i.e., systems with infinite queues and waiting times in their steady states).

The approach with foreground/background processes was originally suggested by Dijkstra et al [DIJ 78] in the specific context of concurrent garbage collection. Lampson [LAM 84] and Manber [MAN 84] have proposed this approach for more general applications. An example of an operational system is the concurrent garbage collector for the file server in the Cambridge Ring Network [NEE 82].

Two important issues are of interest in studying programs used in such systems. The first issue is a framework for systematically developing these programs [DIJ 78, BEN 84, JONES 83, BAS 85(A)]. The second important issue is the evaluation of the performance of such systems which is the subject of this paper. One method of performance analysis of such systems is to model the client, foreground and background processes with their average rates of generating requests, deteriorating the data structure (e.g., by creating garbage), and upgrading the data structure (e.g., by removing garbage), respectively [HIC 84]. However, the assumption of uniform flows can mask the effect of the variance of the actual distributions on the behavior of degradable systems. This is evident to some extent in the example of the random activity of termites given by Courtois [COU 85] in which a random process develops pockets of concentrated activities over time. Methods used in analyzing hardware performability problems [FUR 84] (e.g., the loss of a processor in a multiprocessor system) can also be

This research was supported in part by the National Science Foundation under Grant MCS-83-01745. The experiment was performed using equipment donated to the department by AT&T.

used for analyzing software systems. The difference is that in degradable software systems the reliability (correctness) of the data structure is not affected.

In this paper, we present queueing models and performance results for a multiple client degradable server as opposed to the single client model analyzed in [BAS 85(B), MOI 85, YEN 85]. Section II describes an abstract model for multiple client degradable servers. It also contains performance studies of degradable servers using both queueing theory and simulation. Several strategies for scheduling the background process are also discussed. The average waiting time was taken as our performance measure. Section III includes an operational example of a directory server incorporating concurrent foreground and background processes as an example of such systems. It also discusses the experimental evaluation of the directory server as implemented in a 3BNET network [AT&T 84(A)] of 3B2 computers [AT&T 84(B)]. Its performance was compared with that of an implementation incorporating a self-reorganizing data structure without having any background processes. The experimental results indicate that there are cases where self-reorganization has better performance than implementations using separate maintenance processes. Additional experiments have been carried out, though we were not be able to report them in this paper. These indicate that concurrent maintenance has better worst case performance while self-reorganization has better average case performance. Finally, section IV summarizes the paper and discusses some research directions.

II. MODELING AND PERFORMANCE ANALYSIS

The server is modeled by two processes, namely, a foreground process that interfaces with clients and serves their requests, and a background process that maintains the data-structures. The average waiting time for the foreground requests is an important performance measure and is used in our study to evaluate different maintenance policies. In this section, we show that the background process should not be restricted to run only during idle periods. Instead, it needs to have a well-defined scheduling policy that is tested for stability. This policy can be either deterministic or stochastic. An example of a deterministic policy is maintaining the data-structures after satisfying a predetermined number of requests. An example of a stochastic policy is one that probabilistically adjusts the relative priorities of the foreground and background processes.

As more and more housekeeping tasks accumulate, the performance of the foreground process deteriorates. Let the degradation level, d, represent the amount of accumulated housekeeping tasks. Then, the mean service time of the foreground process increases as d increases. This varying service distribution complicates the analysis of the performance of such systems. In this section, we first discuss an approximate queueing model analysis and demonstrate that such systems are basically unstable, i.e., the mean service time approaches infinity with probability 1. Then we investigate the performance of several deterministic and stochastic policies for scheduling the background process using queueing theory and simulation.

2.1. QUEUEING MODEL: In order to illustrate the analysis technique, we make the following simplifying assumptions:

(1) The data structure is a binary search tree. The permissible operations are to create a new node, to delete an existing node, and to inspect or update an existing node.

(2) The arrival of requests from the clients is a Poisson process with average arrival rate of λ. Consequently, the client population is assumed to be large.

(3) The distribution of the service time of the foreground process is exponential with mean $1/M_f(d) = \{1+\log(N+d)\}/\mu_f$, where μ_f is a constant, N represents the number of nondeleted nodes in the tree (assume that N > 0), and d represents the number of deleted nodes in the tree. This expression for $M_f(d)$ is justified since the average search time for a binary tree is proportional to the logarithm of the number of nodes in the tree.

(4) The distribution of the service time of the background process is exponential with mean $1/\mu_b$. This is optimistic to some extent since the background process also slows down as d increases.

Consider the state transition diagram shown in Figure 1. s_0 represents the state in which the data structure is in the ideal state, namely, immediately after an upgrade. In state s_{ij}, $j \leq i$, j-1 requests have been serviced, the jth request is being serviced and there are i-j pending requests. In state $s_{i,i+1}$, the foreground process is idle and the background process is active.

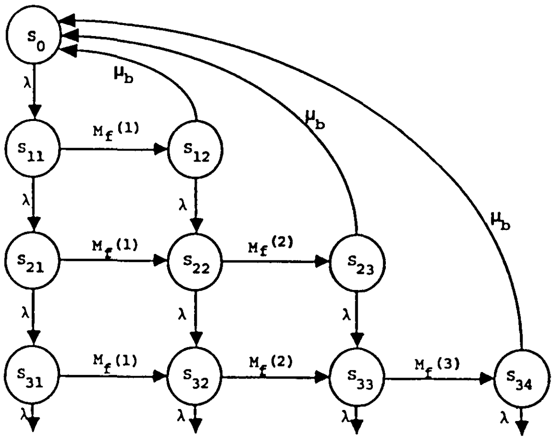

Figure 1. State Transition Diagram for a Simplified Model of Foreground/Background Processes.

Even with these assumptions, the analysis is very complex because $M_f(d)$ is not constant. A simple model which has a <u>smaller</u> average service time than the above is shown in Figure 2. The average service time is smaller for two reasons (1) in Figure 2 it is assumed that the background process instantaneously upgrades the data structure, and (2) during a period with N requests, the first model has average service time equal to $\sum_{i=1}^{N} 1/M_f(i)/N$, while this model has this value as its <u>maximum</u> possible service time.

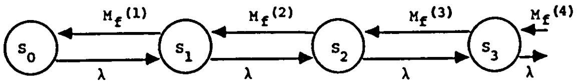

Figure 2. A System having a Smaller Average Service Time than the System in Figure 1.

For the transition diagram shown in Figure 2, the steady state equations are:

state s_0: $\lambda P_0 = M_f(1) P_1$

state s_i: $[\lambda + M_f(i)] P_i = \lambda P_{i-1} + M_f(i+1) P_{i+1}$

also: $\sum_{i=0}^{\infty} P_i = 1.$

From the recurrence equation, we have:

$$P_i = \{\prod_{j=1}^{i} [\lambda / M_f(j)]\} P_0.$$

$$\text{Now, } \sum_{i=0}^{\infty} P_i = \{1 + \sum_{i=1}^{\infty} \prod_{j=1}^{i} [\lambda / M_f(j)]\} P_0 = 1$$

$$\text{i.e., } P_0 = 1/\{1 + \sum_{i=1}^{\infty} \prod_{j=1}^{i} (\lambda [1 + \log(N+j)] / \mu_f)\}$$

$$= 1/\{1 + \sum_{i=1}^{\infty} (\lambda / \mu_f)^i \prod_{j=1}^{i} (1 + \log(N+j))\}$$

$$= 0 \text{ for any } \lambda > 0.$$

Hence, with probability 1, eventually the system is in s_∞, that is, the average response time is infinite. This conclusion is true <u>no</u> <u>matter</u> how fast the foreground process is.

This instability can be qualitatively attributed to the fact that if the system degrades a little then the probability that it will degrade even more increases.

In the following two subsections we propose two methods of avoiding such unstable behavior. Both techniques involve dynamically changing the priority of the background process relative to the foreground process. The first approach, called deterministic control, makes the background process a higher priority process whenever some parameter of the system exceeds a preset value. In the second approach, called stochastic control, at any given time the background process will preempt the foreground process with some probability.

2.2. DETERMINISTIC CONTROL: In this section, two deterministic policies for scheduling the background process are investigated along with their analytical models and performance results. The two analytical models yield results that agree very well with the predictions of the simulation experiments. The service time for the background process is assumed to be a constant while the service time of the kth request since the last upgrade is assumed to be equal to:

$$x(k) = \{1 + \log(N+k)\} / \mu_f$$

POLICY I: In the first policy, the background process is started whenever M requests are served by the foreground process since the last upgrade of the data-structure. Hence, assuming constant service time for the background process is justified.

The system in this case can be modeled by an M/G/1 system. The effect of the delay caused by the background process is taken into consideration by extending the service of the Mth customer since the last upgrade to include the time for upgrading the data structure and is equal to:

$$X(M) = [\{1 + \log(N+M-1)\} / \mu_f] + 1 / \mu_b$$

The arrival rate of the M/G/1 queue is λ, the average arrival rate of requests as before, but the queue utilization combines the foreground and the background utilizations and is equal to:

$$\rho = (\lambda / M) * [\{\sum_{k=0}^{M-1} [1 + \log(N+k)] / \mu_f + (1 / \mu_b)\}]$$

The average foreground waiting time is approximately equal to:

$$W_{f1} = \lambda * E[X^2] / \{2 * (1 - \rho)\}$$

where $E[\cdot]$ denotes the expectation and

$$E[X^2] = (1/M) * \{\sum_{k=0}^{M-2} ([1 + \log(N+k)]^2 / \mu_f^2)$$
$$+ [(1 + \log(N+M-1)) / \mu_f + 1 / \mu_b]^2\}$$

The analysis can be used to determine the value of M that minimizes the average waiting time and the value of M after which the system becomes unstable. It is found by simulation that these values are quite accurate. The latter value could be obtained by finding the smallest value of M such that:

$$\rho \geq 1$$

$$\text{i.e., } (\lambda / M) * \{\sum_{k=0}^{M-1} ([1 + \log(N+k)] / \mu_f) + 1 / \mu_b\} \geq 1$$

Figure 3 shows an example of how the average waiting time of the client's request is affected by the number of requests M that are processed before an update can be performed. For small values of M, the average waiting time decreases as M increases because of the large overhead in running the background process frequently and the accumulation of client requests during this data-structure update. The average waiting time reaches a minimum when M equal to 3 in this example and then increases as M increases as a result of the increase in system utilization and increase in the second moment of the service time.

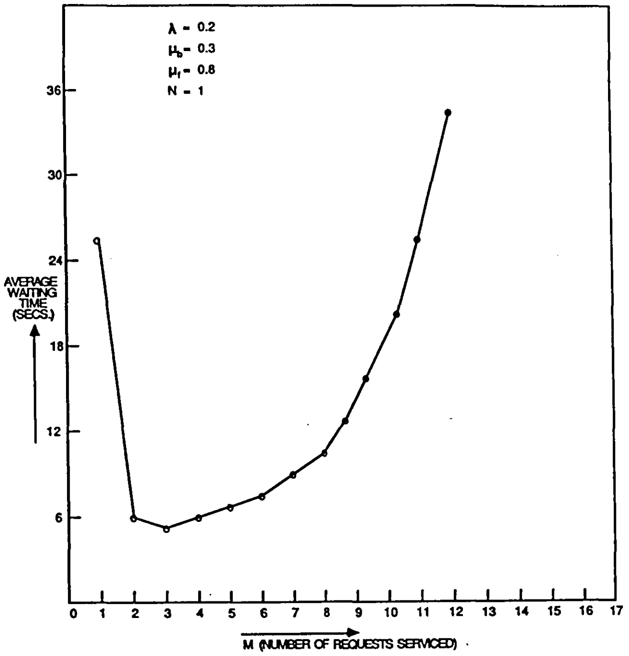

Figure 3. Performance of Policy I

POLICY II: In the second policy, the background process is run and is completed approximately every T seconds to update the data-structure. No preemption is permitted since it is costly in practical systems. The period T represents the time between the start of two consecutive updates performed by the background process. However, the actual period can be either equal to T if the cpu is idle (no foreground requests) or slightly different from T if the cpu is busy when it is time to run the background process. A decision is made whether to switch to the background process or handle one more client request depending on the arrival time of the request, on its service time which is known before hand, and on the time remaining in the current period of length T. In the period $(T-1.0/\mu_b)$ devoted to foreground requests, the system can serve a maximum of n customers such that

$$\sum_{i=0}^{n-1}[1 + \log_2(N+i)]/\mu_f \leq T - 1/\mu_b$$

Consider p(i) to be the probability that i requests will arrive and will be served in period T that starts when the background process is run (ignoring any old requests). Assuming poisson arrivals, the values of p(i) can be approximated by the following equations:

$$p(i) = [(\lambda T)^i/i!]e^{-\lambda T}, \text{ for } i < n;$$

$$p(i) = \sum_{i=n}^{\infty}[(\lambda T)^i/i!]e^{-\lambda T}, \text{ for } i \geq n.$$

The last equation assumes that that if more than n customers have arrived, the number of customers that are served is n. It should be clear that deciding if a request has been processed by the foreground process does not depend only on the number of arrivals and total time allotted for service in one period, but also on the detailed pattern of previous arrival times and service times in the underlying period and its predecessor periods as well. Hence, the above equations are an approximation of the complex real model. The mean number of customers $\underline{a}$ that are served every period T can be computed by the formula:

$$\underline{a} = \sum_{k=1}^{n} kp(k)$$

The average utilization of the cpu is equal to:

$$\rho = [\lambda/\underline{a}] \sum_{i=1}^{n} p(i)\{\sum_{k=0}^{i-1}[1.0+\log_2(k+N)]/\mu_f\} + 1.0/(\mu_b T).$$

The first term of the above equation represents the fraction of time in which the foreground requests are served and the second term represents the fraction of the time in which the background process is run. The above system can be modeled by an M/G/1 queue with adjusted rates. The average waiting time for the foreground requests are equal to the following:

$$W_{f2} = \{\lambda * E[X^2]\} / \{2 * (1 - \rho)\}$$

The average waiting time formula for the second scheduling policy is computed for $\mu_f = 0.8$, $\mu_b = 0.3$, and $\lambda = 0.2$ and several values of T and the results are shown in Figure 4. If T is very small, the system is unstable. Then, as T increases the average waiting time decreases because client requests have a larger probability of being served. This decrease continues until a minimum is reached (at T = 10.0 in this example). After this point, any increase in T will increase the average waiting time because of increasing system utilization and average service times.

The results of the analyses of the two policies agree quite well with the simulation predictions. The analytical models are found to be useful in providing the parameters for designing successful foreground/background operations.

2.3. STOCHASTIC CONTROL: In the following, we consider three policies reported in order of their effectiveness. We present some approximate analytical results along with some simulation results.

Case 1: Here, after every departure, the background process is invoked with probability (1-p). An approximate expression for the average service time is:

$$1/\mu_{avg} = \{1 + E[\log(d+N)]\}/\mu_f + (1-p)* \{(\lambda / \mu_{avg})/\mu_b + (1 - \lambda / \mu_{avg})[\lambda / (\lambda+\mu_b)]/\mu_b\}$$

The first term is the average service time and the second term is the delay due to the background process. There are two possibilities when the background process is invoked: If the system is not in the idle state (the probability of this event being λ / μ_{avg} in Figure 2 with $M_f(d) = \mu_{avg}$), then the delay is the full background service time. If the system is in the idle state (probability equal to $1 - \lambda / \mu_{avg}$), then the delay is only the

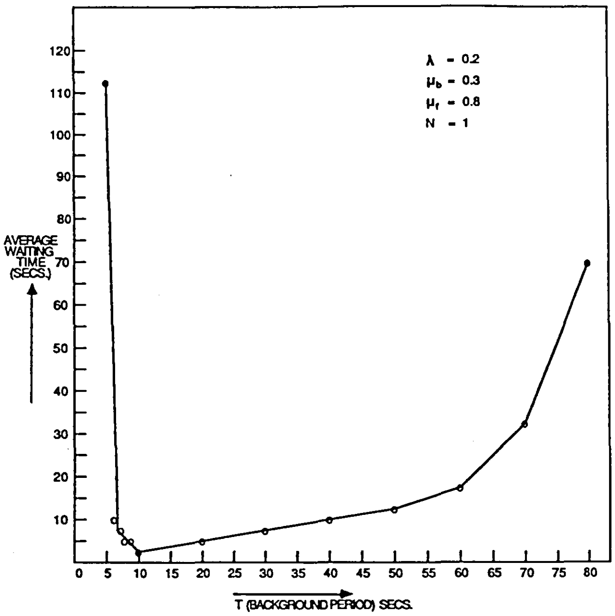

Figure 4. Performance of Policy II

residual time seen by the next arrival, i.e., $[\lambda / (\lambda + \mu_b)]/\mu_b$.

Table I shows the computed value of p which minimizes the average service time and the corresponding value found using simulation for some arbitrarily selected values of λ, μ_f, and μ_b. N = 1 in all the cases. The approximation ranges from medium to good.

Case 2: As in case 1, the background process is invoked to do a complete clean-up operation with probability (1-p′) after every departure. In addition, the background process is allowed to perform a partial clean-up during idle periods of the foreground process, i.e., it will upgrade the data structure as much as possible during the idle period. The value of p′ which minimizes the average service time should be greater than that in Case 1. An approximate result can be obtained by computing the value of p′ from the value of p for Case 1.

p = effective prob{do not clean up after
a departure}

= prob{do not clean up in Case 1 |
decide to clean up in Case 2}
* prob{decide to clean up in Case 2}

+ prob{do not clean up in Case 1 |
decide not to clean up in Case 2}
* prob{decide not to clean up in Case 2}

$$= 0 * (1-p') + \{P_0 * \lambda / (\lambda+\mu_b) + (1-P_0)*1\} * p'$$

where P_0 = prob{foreground process is idle}

$$\simeq 1 - \lambda / \mu_{avg}.$$

Hence, $p' = p/\{1 - (1 - \lambda / \mu_{avg}) \mu_b/(\lambda + \mu_b)\}$.

TABLE I

λ	μ_b	μ_f	CASE I			CASE II			CASE III	
			predicted P	observed P	Wmin	predicted P'	observed P'	Wmin	observed P"	Wmin
0.2	0.3	0.8	0.5	0.49	13.41	0.61	0.6	10.98	0.83	8.3
0.2	0.5	1.1	0.17	0.25	3.75	0.3	0.7	2.80	0.75	2.46
7.0	8.0	26.0	0.62	0.60	0.92	0.67	0.62	0.85	0.88	0.52
0.2	0.5	0.5	0.03	0.00	13.94	0.04	0.03	13.93	0.05	13.61
0.2	0.25	1.6	0.73	0.77	4.80	1.0	0.97	1.75	0.995	1.591

P, P', P" : Probabilities which minimize the average service time

Wmin : Waiting time corresponding to the tabulated values of P, P', P", respectively

Table I shows the computed value of p′ which minimizes $1/\mu_{avg}$ and the corresponding value found using simulation for the same set of values of λ, μ_b, μ_f as in Case 1. Again, N = 1. This is a very approximate calculation, and hence the agreement is worse than that in Case 1.

Case 3: In Cases 1 and 2, the decision to perform a complete clean-up is independent of the degradation level. Here, after every departure, the background process is invoked to do a complete clean-up with probability $(1-p''^{d})$, where d is the value of the degradation level. As in case 2, the background process is allowed to perform partial clean-ups during idle periods of the foreground process. The analysis of this case is complicated by the dependence of $1/\mu_{avg}$ on p′′ as well as on d. One possibility is to use an estimate of the average value of d. However, this double approximation renders a poor estimate. Nevertheless, we intuitively expect that the value of p′′ which minimizes $1/\mu_{avg}$ should be more than the corresponding ones of p and p′ for the same values of λ, μ_b, μ_f, and N. As shown in Table I, this is confirmed by simulation for the case where a complete clean-up is done with probability $(1-p''^{d})$.

A simulation study of these three cases appears in Figure 5. As can be seen, Case 3 yields the best results, i.e., the minimum average waiting time. Hence, we have adopted this strategy in the control of the relative priorities of the foreground and background processes in the experimental evaluation discussed in Section III.

III. AN EXPERIMENTAL EVALUATION OF CONCURRENT MAINTENANCE

In Section 3.1, a directory server for a hierarchical file system is presented to illustrate the foreground/background methodology in practice. The performance of an actual implementation of this system is presented in Section 3.2.

3.1 A DIRECTORY SERVER: The operations that the directory server can do are to create an entry for a new file, and to lookup, update or delete the entry for existing files. Files are identified by UNIX-like path names, e.g., /usr/xyz/filel. There

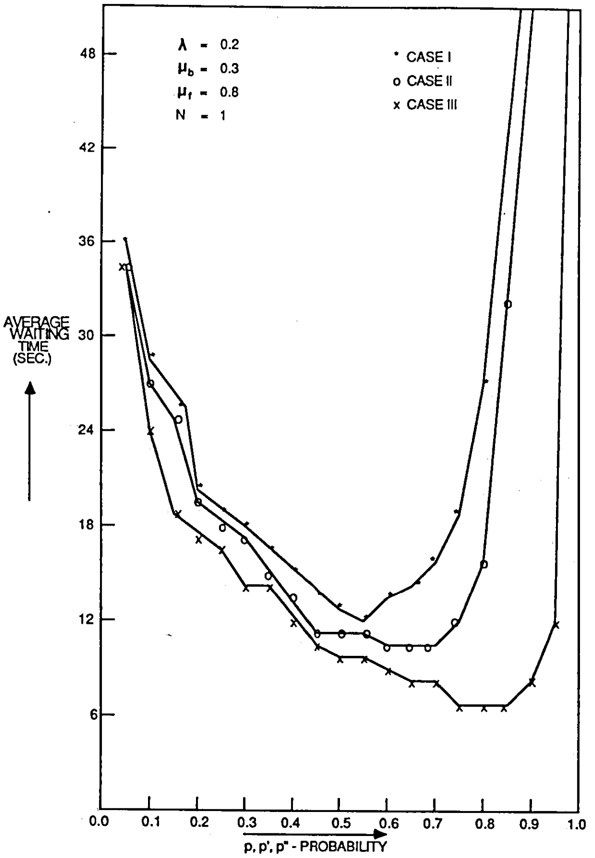

Figure 5. Comparison of Case I, II and III Using Simulation.

are two types of files, namely, directory and nondirectory files.

The data structure is a multiway tree in which the parent points to the first child and each child points to the next child. Since it is stored on secondary storage, performance can be improved by clustering the children of a node into as few pages as possible. In our case, the size of each entry is about 80 bytes, while each disk page consists of 512 bytes. Hence, six entries can reside in one page. The data structure diagram is shown in Figure 6 and the PASCAL declaration for the data structure is as follows:

```
const MaxEntriesPerPage = 6;

type address = ^page;
     entry = record
                status: (empty,occupied,deleted);
                info: . . .
                case type:
                    (directory,nondirectory) of
                  directory: (FirstChild: address);
                  nondirectory: ()
             end;
     page = record
               PreviousSibling,NextSibling: address;
               table: array [1..MaxEntriesPerPage]
                      of entry
            end;
```

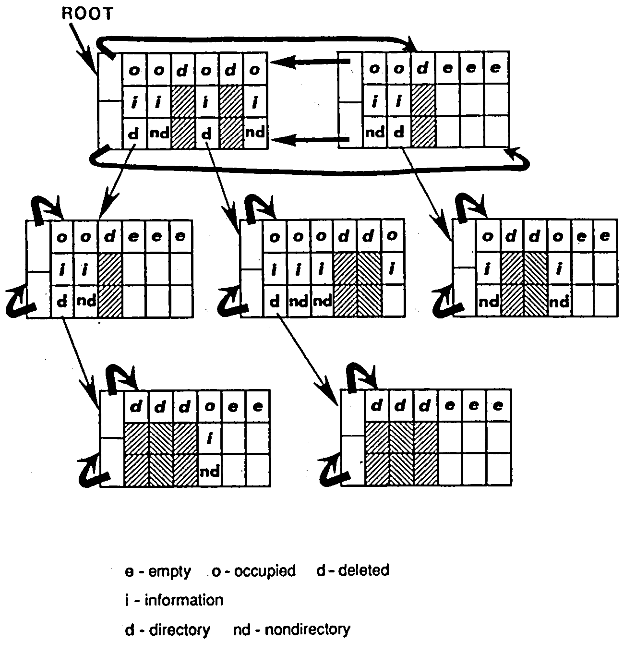

Figure 6. Data Structure Diagram for the Directory Server

```
var root: page;
```

The task of the foreground process is to carry out the client's request as fast as possible. It achieves this as follows:

(a) For create(a/b/.../j/k,type of file): If the file does not exist in the tree, and a/b/.../j exists and is of type directory, then k is added to an empty slot in the list of children of a/b/.../j. The status of the slot is changed to "occupied".

(b) For delete(a/b/.../j/k): If the file exists in the tree and it is a nondirectory file or there are no occupied slots in the list of children for the file, then the status of the slot containing the entry for k of children is changed to "deleted" in the list of children a/b/.../j.

(c) For LookUp(a/b/.../j/k) or update(a/b/.../j/k), the information corresponding to k in the list of children of a/b/.../j is either checked or modified depending on the operation. Pointers and status fields are not affected.

The background process removes slots which are marked deleted. In particular, it tries to bring the data structure into a state satisfying the following assertions:

(a) No page contains a slot marked "deleted";

(b) All slots marked "occupied" appear at the left most end of the table in each page;

(c) If a page contains a slot marked empty then it is the last page in this list.

The key procedure used by the foreground process is the following search function. It accepts a pathname and tries to locate it in the tree structure.

```
function search(root: page; s: path name)
returns found: boolean X depth: integer X p: page;

Precondition:

  root <> nil;

Postcondition:

  1) p is locked; all other pages locked by
     the procedure are unlocked;

  2) if the path specified by s exists
     in the tree then

     a) found = true
     b) depth = length(s)
     c) p <> nil; the path named by s
        leads to p

     else

     a) found = false
     b) 1 <= depth <= length(s)
     c) the path corresponding to the first
        "depth-1" names in s leads to the
        parent of p
     d) the path corresponding to the first
        "depth" names in s does not exist
        in the tree
     e) p <> nil; p is the last page
        in this list;
```

An example of its use is the following pseudocode for "create":

```
create(s,type) =>

found X depth X p:= search(s);
if found then
  error - file already exists
elsif depth < length(s) then
  error - parent does not exist
else
  {if there is no empty slot
        in p^.table then
    {q:= allocate and initialize a new page;
     lock q;
     add q to the list;
     unlock p;
     p:= q}
   add entry for the last name in s
    into an empty slot in p^.table,
    say p^.table[i];
  p^.table[i].status:= occupied;
  if type = directory then
    {r:= allocate and initialize a new page;
     p^.table[i].FirstChild:= r}
    }
unlock p
```

The background process does a breadth first traversal of the tree structure. If it finds a slot which is marked "deleted", it shifts everything in that chain of siblings to the left, deallocating all pages after the last page which contains an empty slot.

During the scanning phase, the background process does not lock any pages. In fact, it even ignores the locks of the foreground process. Once it finds an empty slot, it enters the cleanup phase. It then locks either 2 or 3 pages at a time in order to perform the cleanup operation. A detailed description of the implementation of these two processes appears in [CHE 85].

Noninterference of the foreground and the background processes is ensured by the following rely conditions:

(a) The foreground process relies on the condition that the tree structure formed by considering only occupied slots is left unchanged by the background process.

(b) The background process relies on the condition that the only actions of the foreground process with regard to the status of a slot is to change an "empty" slot to an "occupied" slot, or an "occupied" slot to a "deleted" slot.

(c) Absence of deadlocks can be guaranteed provided that each process locks pages in the left-to-right order along sibling chains.

(d) In order to ensure that some progress is made, each process relies on the other process to release a locked page within a finite time. In fact, maximum concurrency is possible provided that only the absolutely necessary pages are locked.

3.2 Implementation and Measurements:

The directory server discussed in Section III was implemented in C using UNIX interprocess communication primitives. It runs on a dedicated 3B2 computer [AT&T 84(A)] in a 3BNET local area network environment [AT&T 84(B)]. The server consists of five processes as shown in Figure 7.

(a) The "request receiver" accepts packets from the ethernet using UNIX 3BNET system calls. The packets are forwarded to the "foreground process".

(b) The "foreground process" executes the client's request by using UNIX file access and lock control facilities in order to search/update the tree structure. If it needs to allocate a page then it sends a request to the "file space manager" which, in turn, sends back the record number of a free page in the file containing the tree structure. The foreground process enqueues a response for the "request transmitter".

(c) The "response transmitter" sends a packet to the client via the ethernet.

(d) The "background process" removes slots which are marked "deleted". If any page becomes free then it informs the "file space manager".

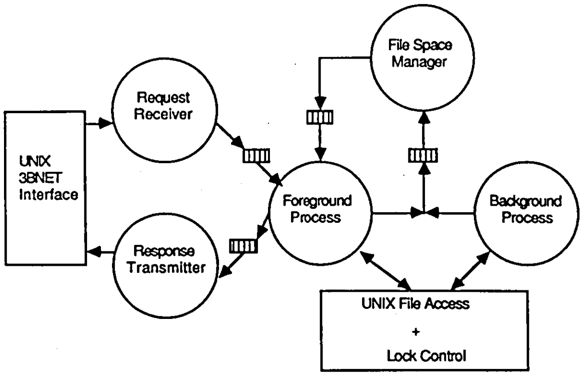

Figure 7. Structure of the Directory Server

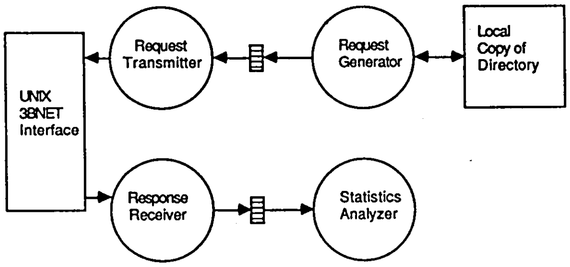

Figure 8. Structure of Clients

(e) The "file space manager" keeps a list of free file pages. It extends the size of the file only when the free list is empty and a new page must be allocated.

The experiment was conducted using a varying number of clients on a varying number of 3B2 computers. Each client consists of three processes as shown in Figure 8.

(a) The "request transmitter" is similar to the "response transmitter" in Figure 7.

(b) The "response receiver" accepts packets from the server. When the client generates a request it timestamps it. This timestamp is sent back with the response by the server. The "response receiver" can then compute the total time it has taken to process the request. This approach eliminates the need for a global clock.

(c) The "request generator" repeatedly executes the following code:

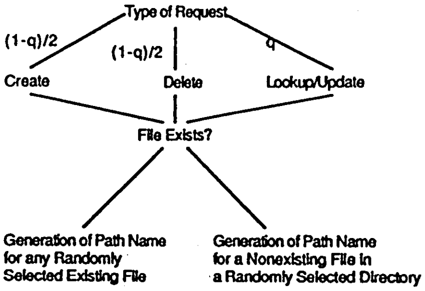
```
repeat

    generate a request

    update the local copy of the directory

    sleep for a period generated randomly using
    exponential distribution with mean ($\lambda$)

forever;
```



Type of Request
(1-q)/2
(1-q)/2
q
Create
Delete
Lookup/Update
File Exists?
Generation of Path Name for any Randomly Selected Existing File
Generation of Path Name for a Nonexisting File in a Randomly Selected Directory

Figure 9. Request Generator Program

It generates a request in two steps (see Figure 9). At first it determines the type of the request. It is "LookUp/update" with probability q, "create" with probability (1-q)/2, and "delete" with probability (1-q)/2. (If the probability that a request is "create" is not the same as the probability that it is "delete", then in the steady state either the directory will be empty or infinite. The steady state size of the directory, when the two probabilities are the same, is fixed by generating N "create" requests initially.)

Once the type of the request has been determined, the next step is to generate the full path name for either an existing file or a nonexisting file. This is done by consulting the local copy of the directory.

Thus, the parameters of the experiment are:

λ --> arrival rate

q --> LookUp/update probability

N --> steady state size of the directory

Figure 10 shows the results of the experiment. It also shows the measured response time for a server having no maintenance processes, but incorporating self-reorganizing data structures. Specifically, (a) during a search operation for the "create" request it keeps track of the first page containing an available slot, and (b) during a delete operation, it marks the slot as "deleted" and deallocates the page if it does not contain any "occupied" slots.

From Figure 10, we observe that self-reorganization has a significantly better performance than the implementation using a separate maintenance process. This is partly due to the system overhead in locking/unlocking pages and partly due to the contention with the background process. Since the code for the concurrent foreground/background processes is usually more complex than that for self-reorganization, careful study is required to determine situations where separate maintenance processes would be useful.

We have performed a series of experiments in

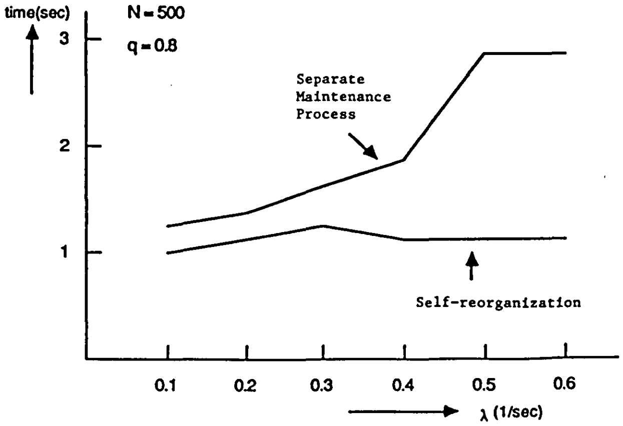


Figure 10. Experimental Results

order to compare the performance of stochastic control (a variant of case 2), deterministic control (policy I), and self-reorganization maintenance strategies. Because of time constraints, we were not able to include these experiments in this paper but they will reported in a forthcoming paper. The new results indicate that deterministic control has the best average case performance while stochastic control has the best worst case performance and the least variance among these three strategies. The performance of stochastic control can be improved significantly by using efficient synchronization primitives or coarser grained atomic actions. In general, concurrent foreground/background maintenance processes are competitive for real-time applications.

IV. SUMMARY

In this paper we have shown that the use of low priority maintenance processes for maintaining degradable data structures can result in unstable systems. This can be avoided by dynamically altering the relative priorities of the foreground and background processes. We have analyzed two control strategies for this purpose, namely. stochastic and deterministic policies. We have also presented the experimental evaluation of the performance of a concurrent directory server for a UNIX local area network environment and compared it with a server utilizing "on-the-fly" maintenance.

Some possible research areas include (1) refining the performance analysis of degradable systems, and extending it to cases where several foreground processes are active simultaneously, and (2) performing a comparative analysis of concurrent maintenance processes as opposed to the use of self-reorganizing data structures.

Abstract

Configuring N mutually non-attacking queens on an N-by-N chessboard is a classical problem that was first posed over a century ago. Over the past few decades, this problem has become important to computer scientists by serving as the standard example of a globally constrainted problem which is solvable using backtracking search methods. A related problem, placing the N queens on a toroidal board, has been discussed in detail by Polya and Chandra. Their work focused on characterizing the solvable cases and finding solutions which arrange the queens in a regular pattern.

This paper describes a new *divide-and-conquer* algorithm that solves both problems, investigates the relationship between them, and develops a partial ordering for the related enumeration problem. The connection between the solutions of the two problems illustrates an important, but frequently overlooked, method of algorithm design: detailed combinatorial analysis of an overconstrained variation can reveal solutions to the corresponding original problem.

> The problem of the eight queens is a well known example of the use of trial-and-error methods and of backtracking algorithms. It was investigated by C.F. Gauss in 1850, but he did not completely solve it. This should not surprise anyone. After all, the characteristic property of these problems is that they defy analytic solution. Instead, they require large amounts of exacting labor, patience and accuracy. Such algorithms have therefore gained relevance almost exclusively through the automatic computer, which possesses these properties to a much higher degree than people, even geniuses, do.

1. Introduction

The preceding quote typifies the prevalent view of the N-queens problem. First posed by Max Bezzel in 1848, the problem of placing eight queens on an eight-by-eight chessboard in mutually nonattacking positions was solved in 1850 by Franz Nauck, who used trial-and-error methods to find 12 solutions. In 1874, S. Gunther proved Nauck's list exhaustive and J.W.L. Glaisher generalized the problem to placing N queens on an N-by-N board. Gunther and Glaisher proposed the following solution: Represent the board as a symbolic N-by-N matrix. Certain easily recognizable terms in this matrix' determinant indicate solutions to the N-queens problem. This approach, although helpful in the 8-by-8 case, is actually a brute force search on the N! terms in the determinant which looks for all solutions. In the early 1950's, A.M. Yaglom and I.M. Yaglom [25] found a pair of patterns which yield one solution for each N. A sketch of their solution, which remains relatively unknown, can be found in the appendix. Their suggestion cannot be generalized to give more than a unique solution, and is not based on a general algorithmic technique. For more details of the problem's early history see [2] [8] [17].

The N-queens problem has three variants: finding one solution, finding a family of solutions, and finding all solutions. Yaglom and Yaglom's patterns solve the first problem while Gunther and Glaisher's exhaustive search solves the third. The inherent difficulty of the N-queens

[2] Supported in part by NSF grant MCS-8303139 and an I.B.M. fellowship

variants is generally accepted; recent work has followed one of two basic approaches. The first accepts the problem as intractable and uses it as an example of trial-and-error methods like backtracking, while the second modifies the problem to one that does not defy combinatorial analysis. Examples of the former approach abound. Various fields, including algorithm design [12] [24] [6], program development [5] [23], and artificial intelligence [19] [10] [11] have relied on the N-queens problem to illustrate issues related to systematic heuristic search. In Artificial Intelligence the problem is one of the classic constraint satisfaction problems. Another such A.I. problem, the labeling of polyhedral scenes [22], has recently been proven to be NP-Complete [14]. As for the latter approach, analytically solvable variations of the N-queens problem can be grouped into two broad categories: those that reduce constraints [21] and those that increase them [20] [4].

This paper addresses the "family of solutions" variant. The method used in constructing this family involves the divide-and-conquer technique which suggests splitting the input into distinct subsets. This splitting property generally appears to be inapplicable when global constraints are involved. The basis of the solution is a combinatorially analyzable related problem, placing N queens on a toroidal board. Previous work on this variation focused on classifying the solvable cases [20] and finding *regular solutions*, setups that are obtained by placing queens on the board in a regular pattern [4]. The family of regular solutions solves the planar problem for a large class of N, but leaves almost as many board sizes unsolved. A non-regular family of solutions to the toroidal problem is developed here. This non-regular family is then modified to yield a general family of solutions to the N-queens problem for almost all N. This solution clarifies the relation between the toroidal and planar cases.

Sections 2 and 3 consist mainly of background material: section 2 discusses the N-queens problem as an example of backtracking techniques and constraint satisfaction problems, while section 3 introduces and outlines previous work done on the combinatorialy solvable toroidal problem. Section 4 then introduces the non-regular family of solutions to the toroidal problem, which leads to the general solution to the planar problem in section 5. Some conclusions and directions for future work are discussed in section 6. Along the way, some light is shed on the enumeration problem: a lower bound and a partial ordering on the number of toroidal solutions are shown.

2. Solutions Based on Search Techniques

The N-queens problem is an example of *constraint satisfaction*, a family of problems that involves assigning values to variables subject to a set of binary constraints [7] [19]. The standard solution method applied to these problems is backtracking search [12], a worst case exponential method which is usually supported by heuristics [10] [19] [15]. For a recent complexity analysis of backtracking search and general heuristic techniques see [3]. The popularity of the N-queens and other chessboard puzzles can be attributed to two factors: the long history of the chessboard and the relative simplicity with which problems related to it can be stated. In the N-queens problem, rows can be regarded as variables and columns as values. Given the board size, N, as input, the <variable,value> pairs can be expressed as a permutation P of 0 to N-1, where P(i) is the column of the queen in the i^{th} row. This representation alone is enough to guarantee that no two queens will be in the same row or column, leaving only the diagonal constraints to be verified. Since the diagonals going from top left to bottom right can be characterized by (i-P(i))=constant, and those from top right to bottom left by (i+P(i))=constant, P is a solution if and only if for $i \neq j$, $(i-P(i)) \neq (j-P(j))$, and $(i+P(i)) \neq (j+P(j))$.

The general constraint satisfaction problem has been discussed in detail in [10] [19]. We have shown that the general problem (over the integers) is NP-complete [1]. Most problems of interest, however, are not random instances of general constraint satisfaction, but special, structured cases of it, in which the constraints follow specific patterns. Many of them are rather difficult, including relatives of several NP-complete problems [9] and various hard problems in computer vision and artificial intelligence [11] [10] [14]. The N-queens, for example, can be viewed as finding an independent set of a special graph. Simply view the board as a graph with a vertex for each square and an edge between any two vertices representing squares in the same row, column or diagonal. A solution to the N-queens problem is a set of N squares sharing neither row, column, nor diagonal, or a set of N independent vertices.

3. The Toroidal Problem and Regular Solutions

Several interesting variations to the N-queens problem have been proposed. One that has attracted a good deal of attention is the N-superqueens problem. A *superqueen*, introduced in [20], is a queen which upon reaching an edge of the board can wrap around to the opposite edge, in effect treating the board as a torus. The superqueen places additional constraints on the board by connecting previously separate diagonals. The resulting (toroidal) board has N rows, N columns, and two sets of N diagonals (characterized by {(row-column)=constant mod N} and {(row+column)=constant mod N}), each containing N squares. This symmetry makes the N-superqueens problem easier to analyze combinatorially than the N-queens. Polya [20] showed that an N-superqueens solution exists if and only if N is not divisible by 2 or 3. Since the N-superqueens is an overconstrained variation, any N-superqueens solution solves the N-queens as well.

Chandra [4] developed the theory of *independent permutations* which he used to characterize a family of solutions to the N-superqueens problem, the *regular solutions*. A regular solution is one in which the permutation P can be characterized by P(i)=Ai+B (mod N). The permutation P(i)=2i, for example, starts with a superqueen in the upper left hand corner and proceeds around the board placing queens one row down and two columns across. This solution is called the *knight-walk*. Chandra also built on the result of [20] by showing that for any N, if the N-superqueens problem is solvable and M is the smallest factor of N (M > 1), a family of regular solutions exists, and is characterized by P(i)=Ai, A=2,4,...2^k, where k= [$\log_2 M$] -1. Since P(0)=0, each member of this family has a superqueen in the upper left hand corner. Only regular solutions exist for N < 13. For N=13, however, the non-regular permutation P=(0 3 8 11 5 1 10 4 7 12 2 9 6) is a solution as well. Some regular extensions of the toroidal problem are discussed in [4] [13].

As an immediate extension of their existence for any solvable N-superqueens problem, the family of regular solutions described above solves the N-queens problem for 2/3 of the odd numbers. Furthermore, removing the top row and leftmost column from the N-by-N board deletes only the queen in the top left hand corner square. This leaves an (N-1)-by-(N-1) board with (N-1) mutually nonattacking queens, solving the (N-1)-queens problem, and thereby constructing solutions for 2/3 of the even numbers. No other simple board modifications are possible, since removal of any other row and column would either delete two queens, shift the diagonals, or both. Regular solutions and upper left hand corner-removal, then, constitute a solution scheme for 2/3 of all N.

4. The Decomposition Solution to the Superqueens Problem

This section shows how to construct a family of non-regular solutions to the N-superqueens problem, the decomposition solutions. The main idea is to use the factorization of N to apply a divide-and-conquer approach to the problem. Basically, if N can be factored as AB where both A and B are solvable, the N-superqueens problem can be reduced to solving A appropriately chosen copies of the B-superqueens problem.

Definition: Let N=AB, where there are solutions to the A-superqueens and B-superqueens problems. A decomposition solution breaks the N-by-N board into an A-by-A grid of B-by-B tiles. Tiles corresponding to an A-superqueens solution are filled with a B-superqueens solution; the same B-superqueens solution is used throughout.

In order to simplify further discussions, some additional definitions are necessary.

Definition: Let LR(N) refer to the set of diagonals running from top left to bottom right on an N-by-N board. Let OLR(N) refer to those members of LR(N) which are occupied by a queen. Similarly, let WLR(N) refer to the set of N wrapped diagonals on a planar representation of an N-by-N toroidal board running from top left to bottom right. Let OWLR(N) refer to those members of WLR(N) which are occupied by a superqueen. Let the diagonals from top right to bottom left be named correspondingly (that is, RL(N), ORL(N), WRL(N), and OWRL(N)).

As an illustration of the manner in which a decomposition solution solves the problem, look at the example in figure 1, where N=35, A=7, and B=5. The knight-walk is used as both the 5 and 7-superqueens solutions. A board set up according to the definition of decomposition clearly contains 35 superqueens, with no two in any one row or column. That no diagonal contains two superqueens, however, is a bit less obvious. The trick here is to realize that the diagonals that result from tiling a plane with 5-by-5 boards are equivalent to those resulting from placing a 5-by-5 board on a torus. As shown in the diagram, a diagonal in WLR(35) passes alternately through members of LR(5) of lengths 2 and 3. These are exactly the LR(5) diagonals which combine to form a single element of WLR(5). The use of a 5-superqueens solution guarantees that only one of these LR(5) diagonals contains a superqueen. This reduces the realm of possible conflicts to superqueens in the same position on different boards. Examination of the figure reveals that if a member of WLR(35) passes through corresponding LR(5) diagonals on two 5-by-5 tiles, the tiles lie along the same LR(7) diagonal. The use of a 7-superqueens solution precludes the possibility of two such boards being chosen, and thus no two superqueens can be in the same member of WLR(35). Thanks to the symmetry of the board, an identical argument can be used for WRL(35).

Theorem 1: A decomposition solution solves the N-superqueens problem.

In order to discuss the general case, some machinery must be developed for referring to individual squares on a decomposed board. Each square's location can be specified

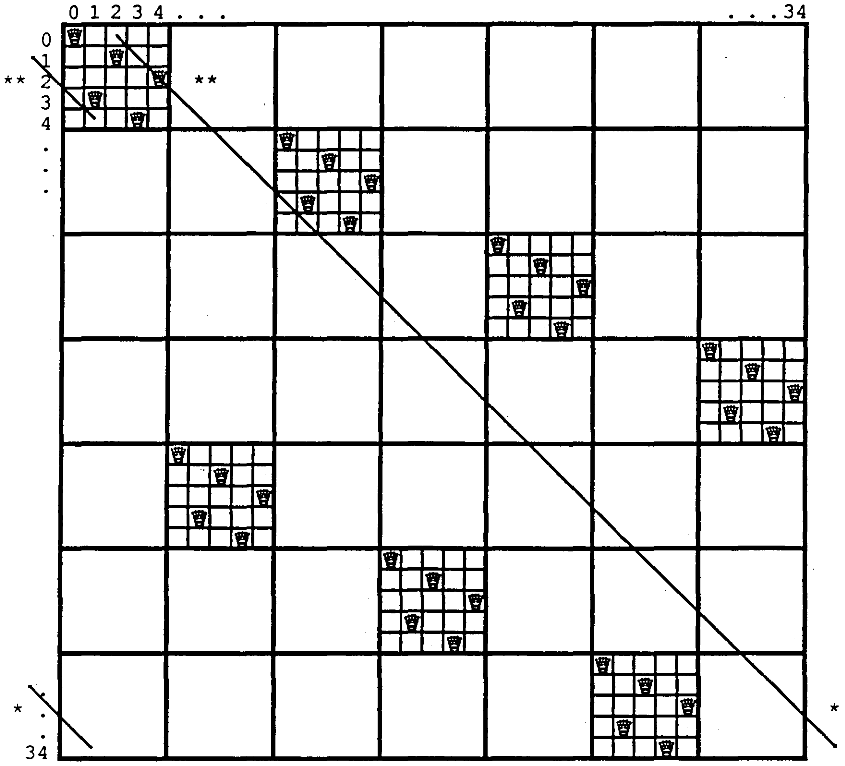

Figure 1: An example of a Decomposition Solution. N=35, A=7 and B=5. A diagonal is drawn, along with its continuations in both WLR(B) ** and WLR(N) *.

in two coordinate systems: the N-by-N system and the B-by-B system within the A-by-A grid. In converting between the systems, let $<i_N,j_N>$= tile $<i_A,j_A>$ square $<i_B,j_B>$, where i_N,j_N=0 to N-1, i_A,j_A=0 to A-1, i_B,j_B=0 to B-1. Since superqueens solutions are used throughout, all boards must be treated as tori, and therefore, all arithmetic is done modulo the subscripted number. The relationship between the systems is simple. Each tile contains B rows and B columns. Thus, $i_N=Bi_A+i_B$ and $j_N=Bj_A+j_B$. In other words, to determine the location of a square on the N-by-N board, find out which tile it is in, multiply each tile index by B to determine how many rows or columns preceded it, and add the number of rows or columns preceding it in its tile. Furthermore, since rows and columns within a tile are counted modulo B, the row following the (B-1)st in any tile is the 0th row of the following tile. The same is true of columns. In the example of figure 1, where N=35, A=7, and B=5, if $<i_N,j_N>$=<14,23>, the square in question is tile <2,4> square <4,3>. Moving one square to the right, <15,23> is tile <3,4> square <0,3>. Two squares *correspond* if they have the same B coordinates. In the example of figure 1, <7,4>= tile <2,1> square <2,4> and <12,14>= tile <3,3> square <2,4> correspond with each other. Using this notation, the proof of the theorem becomes a straightforward generalization of the case shown in figure 1.

One implication of theorem 1 is that every ordered split of N into its (not necessarily prime) factors corresponds to at least one decomposition solution. Given such a split, $N=f_1f_2...f_k$, the first factor plays the role of A, breaking the N-by-N board into a grid of (N/f_1)-by-(N/f_1) tiles. Any solution to the f_1-superqueens problem can be used to choose tiles. The rest of the factors are used recursively to fill the tiles specified by the chosen f_1-superqueens solution. Ergo, if M is a proper divisor of N, any M-superqueens solution gives rise to at least one N-superqueens solution. Since there is at least one N-superqueen solution that is not built up from any M-superqueen solution, namely the knight-walk, there are fewer M-superqueens solutions than N-superqueens solutions. This induces a partial order on the number of N-superqueens solutions.

Corollary 1: If there is a solution to the N-superqueens problem, and M is a proper divisor of N, there are fewer M-superqueens solutions than N-superqueens solutions.

The solution family introduced in this section also reveals a lower bound on the number of solutions for a given N. By the corrolary, each ordered split of N corresponds to at least one decomposition solution. Consider the sequence N={5^i}, where (i ≥ 1). There are 2^{i-1} different ordered splits of 5^i, corresponding to the number of ways to distribute i indistinguishable objects (the 5's) into j distinguishable cells (the positions in the ordered split) for j=1 to i, with at least one object in each cell. These ordered splits indicate that there are at least 2^{i-1} different solutions. In other words, this shows a lower bound of O($N^{\log_5 2}$). Further exploitation of properties of integer sequences and techniques of combinatorial enumeration may be helpful in finding a better lower bound for this problem.

5. A General Solution to the Queens Problem

This section develops a general solution scheme which connects the toroidal and planar problems. A simple modification of toroidal decomposition yields a family of solutions to the previously unsolved planar boards. The key to this modification lies in the major difference between the knight-walk and decomposition. The knight-walk uses individual superqueens as basic blocks. The interplay between these blocks severely limits the ways in which the solution can be modified. Thus, the knight-walk is of limited use in the construction of a general solution. Decomposition, on the other hand, relies on pre-solved boards as blocks. The size of these blocks offers a great deal of flexibility in terms of modifications to the solution, allowing decomposition to serve as the infrastructure of a general solution.

Consider a specific type of decomposition, a D-solution, in which the A-superqueens solution contains a superqueen in the upper left hand corner and the B-knight-walk is used. The scheme for constructing a general N-queens-solution consists of appropriately modifying a D-solution. This section can be divided into two parts. The first part shows that replacing the top leftmost tile of a D-solution with a smaller tile does not violate any of the problem's constraints. The second part proves that such modifications provide decomposable N-queens solutions for nearly all remaining cases.

Lemma 1: If there is a solution to N-superqueens and N=AB, there is a solution to the B(A-1)-queens problem.

Consider a D-solution. A simple removal of the top row and leftmost column from the A-superqueens board corresponds to removing the top B rows and B leftmost columns from the N-superqueens board. Just as a solution exists for (A-1)-queens, one exists for (N-B)=B(A-1)-queens.

This modification alone is not enough. In order to proceed with the discussion, one more definition is needed:

Definition: For all P ≤ N, call the bottom P rows of the P rightmost columns of an N-by-N board the lower right sub-board of order P.

The notion of a lower right sub-board is important in showing that replacing the top leftmost tile of a D-solution with a smaller tile does not violate any of the problem's constraints. Consider the example of figure 2, which shows a 7-by-7 board and its lower right sub-board of order 5. The numbers drawn represent the 5 and 7 knight-walks, respectively. Note that the first three superqueens placed on the 5-by-5 sub-board fall in members of OLR(7). The remainder of the 5-superqueens fall in squares containing 7-superqueens. Thus, OLR(5) is a subset of OLR(7). A similar argument holds in the general case, as well.

Lemma 2: Given the knight-walk solutions to the B-queens and C-queens problems (B-knight-walk and C-knight-walk, respectively), C ≤ B, replacing B's lower right sub-board of order C with the C-queens solution does not add new diagonals to OLR(B).

Lemma 3: If there are solutions to N-superqueens and C-superqueens, N=AB, and C ≤ B, then there is a solution to the B(A-1)+C-queens problem.

These lemmas enlarge the class of board sizes solved by the methods discussed here to all N=B(A-1)+C for some A,B,C not divisible by 2 or 3, and C ≤ B. Clearly, knight-walk and decomposition are subsumed by this scheme. For a decomposition set C=B, and for a knight-walk set C=B=1. As an informal proof of the validity of the lemmas, note that lemma 2 is simply a general extension of the case discussed above (figure 2). For lemma 3, consider a D-solution. Rather than removing the top B rows and leftmost B columns (as was done in lemma 1), remove only the top (B-C) rows and leftmost (B-C) columns, and replace the remainder of the top left corner tile with the C-knight-walk. By Lemma 2, no diagonal constraints are violated, leaving a solution to the B(A-1)+C queens problem. This is a *general solution.*

Definition: Let N=(A-1)B+C, where there are solutions to the A, B, and C-superqueens problems, and C ≤ B. A general solution starts with a D-solution to the AB-superqueens problem. The top B rows and B leftmost columns of the decomposition are replaced with C rows and C columns. The C-knight-walk is then placed in the newly created C-by-C tile in the upper left hand corner of the board.

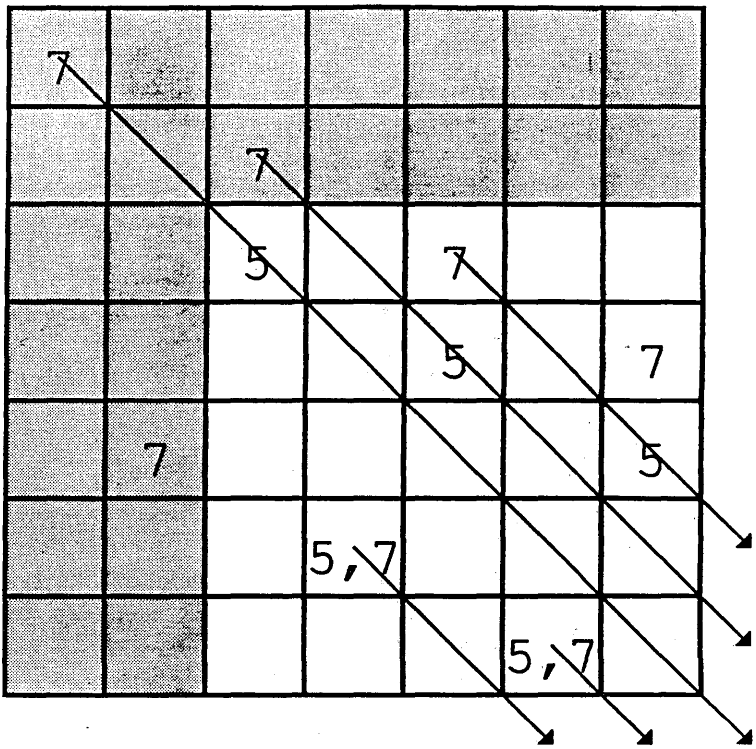

Figure 2: A 7-by-7 board and its lower right subboard of order 5. The knight-walk solutions have been drawn in.

The question remains, for which of the remaining board sizes does this general solution work? The following two lemmas provide the answer: (almost) all N. In order to find a general solution there must first be a D-solution that can be modified appropriately. The need for a D-solution, in turn, points to the importance of determining the conditions under which A and B exist such that $B(A-1) < N < BA$, and then finding an appropriate A and B.

Lemma 4: Let N be an odd number divisible by 3. If there exist odd numbers A and B, $A=2 \bmod 3$ and $B \neq 0 \bmod 3$, such that $B(A-1) < N < BA$, then there exists a solution to the N-queens problem.

Let $N=B(A-1)+C$. Then:

- $\{B(A-1)<N<BA\}$ implies $\{0<C<B\}$.
- $\{A=B=1 \bmod 2\}$ and $\{N=1 \bmod 2\}$ imply $\{B(A-1)=0 \bmod 2\}$, and thus $\{C=1 \bmod 2\}$.
- $\{A=2 \bmod 3\}$ and $\{B \neq 0 \bmod 3\}$ imply $\{B(A-1) \neq 0 \bmod 3\}$.
- $\{B(A-1) \neq 0 \bmod 3\}$ and $\{N=0 \bmod 3\}$ imply $\{C \neq 0 \bmod 3\}$.

In other words, if an appropriate D-solution can be found, a C that meets the requirements of lemma 3 can be found as well: odd, not divisible by 3, and no larger than B.

Lemma 4 characterizes the family of general solutions for a given N. In lemma 5, one member of the family is shown to be applied to almost all N. This solution is computable in linear time.

Lemma 5: For odd N divisible by 3, $N \neq 3,9,15,27,39$, setting $A=5$ guarantees the existence of a B that meets the specifications of lemma 4.

The proof of lemma 5 follows directly from the requirements of lemma 4. According to these specifications, B must be an odd number not divisible by 3, or a member of one of two equivalence classes, (i) $B=1 \bmod 6$ and (ii) $B=5 \bmod 6$. Let N be an odd number divisible by 3. Let B_1 be the largest B such that $4B_1 < N$. Since B_1 is well defined only for $N > 3$, the case of $N=3$ is ruled out of consideration. (In fact, there is no solution to the 3-queens problem). If $N < 5B_1$ then B_1 is as required by lemma 4 (set $C=N-4B_1$, and A,B, and C are all defined as explained above), so assume

$N > 5B_1$. Let B_2 be the smallest B larger than B_1, or the smallest B such that $4B_2 > N$. If B_1 is in equivalence class (i), $B_2=B_1+4$. Otherwise, B_1 is in equivalence class (ii), and $B_2=B_1+2$. In the first case, $5B_1 < N < 4B_2=4(B_1+4)$, which implies $B_1 \leq 14$. The only numbers which satisfy these conditions for B_1 are 1, 7, and 13. In the second case, $5B_1 < N < 4B_2=4(B_1+2)$, which implies $B_1 \leq 6$. The only number which satisfies these conditions for B_1 is 5. The intervals of candidates for N, then, are $5B_1 < N < 4B_2$, where B_1 is one of the aforementioned four numbers. In other words, one of the following is true: $\{5 < N < 20\}$, $\{25 < N < 28\}$, $\{35 < N < 44\}$, or $\{65 < N < 68\}$. The only odd numbers divisible by 3 in these intervals are 9, 15, 27, and 39.

Although a family of solutions is given by any triple (A-1,B,C) meeting the specifications of lemma 3, assigning A a value other than 5 does not solve any of the remaining cases. Since lemma 4 required that A=2 mod 3, the next value that A could be assigned is 11. The minimal non-trivial value for B, however, is 5, (recall B=1 yields the knight-walk), so the smallest board size that A=11 could solve is 50. This is larger than the largest unsolved board. As for the hitherto unsolved even numbers, the construction described in the general solution guarantees the existence of a queen in the upper left hand corner. Removing the top row and leftmost column gives solutions to all even numbers but 2,8,14,26 and 38. As far as these few cases are concerned, the N-queens problem is unsolvable if N=2 or 3. Lemmas 1 through 5 can be summarized as:

Theorem 2: The general scheme yields a non-empty family of solutions to the N-queens problem for all N, $N \neq 2,3,8,9,14,15,26,27,38,39$.

The algorithm in figure 3 gives one member of the general solution family for each N. In this algorithm, the number of arithmetic operations is constant. If bit operations are counted instead, when the input length is n ($n=\log_2 N$), the arithmetic calculations cost n. In either model, the dominant cost is the length of the output. When computing families of solutions, notice that decomposition relies on number factorization and arranging of ordered factorizations. The best well-known algorithm for factorization has an expected running time of $(\exp(\sqrt{n \log n}))$ [16], although a recent result has reduced the complexity to $(\exp(p \log p))$, where p is the length of the largest prime factor of N [18]. The family of general solutions for a given N can be found by considering all $O(N^2)$ potential triples <A,B,C>. Thus, any family can be computed in time bounded by $(N^2\, n^{1+\varepsilon})$.

6. Conclusions

This paper investigated and presented new families of solutions to two related problems, the N-queens and the N-superqueens. Both are examples of constraint satisfaction and both have been extensively studied in the past. The exact nature of the relationship between the two problems has not been well understood, and the belief that N-queens is in fact an intractable problem, best solved by backtracking, persists. This paper tries to provide possible resolutions to each of these difficulties by using the divide-and-conquer approach. A family of non-regular solutions to the N-superqueens problem is shown. These superqueen-decomposition solutions are then combined to form queens solutions. This is an example of lifting a result found for a special case (toroidal board) to a general case (planar board), and raises the question of whether other well understood algebraic or combinatorial problems can be used to solve their less well understood relatives.

Some open questions are raised by this work. Specifically, can other methods produce different N-queens solution families, or give more information about the enumeration problem? More generally, can the approach used here help solve other problems? We believe that many special cases of interesting intractable problems should be studied in the same fashion: take a new approach and investigate carefully the special properties of the structure of the problem in question.

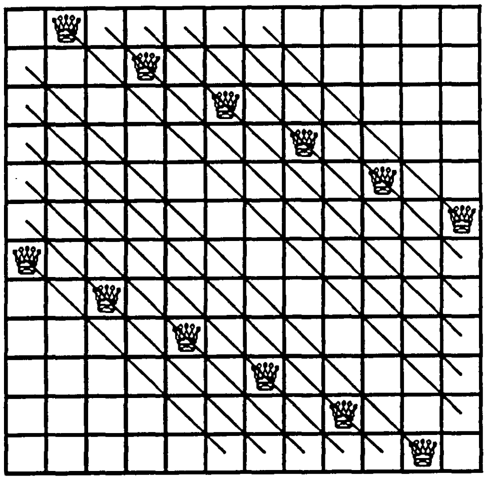

Figure 4a: An example of Yagloms' solution for N of the form N=6m or N=6m+4. Here N=12.

Acknowledgements

We would like to thank Zvi Galil and Richard Korf for their interest in our work and for their encouragement. Special thanks to Ashok Chandra and Martin Gardner who pointed out previous work done on the problem.

Appendix: The Yagloms' Solution

Yaglom and Yaglom described a solution to the N-queens problem for all N in [25]. They concentrated on giving one solution for even board sizes without placing queens in the main diagonal. That vacancy allowed the addition of a row, column, and queen to solve odd sized boards. For even N of the form N=6m or N=6m+4, the setup they describe is shown in figure 4a. It is basically the knight-walk of this paper (more accurately, the knight-walk minus the queen in the upper left hand corner). For board sizes of the form N=6m+2, however, a totally different setup is needed. They exhibited a pattern which works for these boards. Proceeding rightward from the leftmost column, placing successive queens in the diagonals specified by the following pattern (using the diagonal numbering scheme shown in figure 4b), solves the problem:

2n-4,n+1,n+2,n+3,...,3n/2-3,n/2+2,3n/2-1,n/2+1,3n/2-2, n/2+3,n/2+4,n/2+5,...,n-1,4

The example of N=14 is shown in figure 4b.

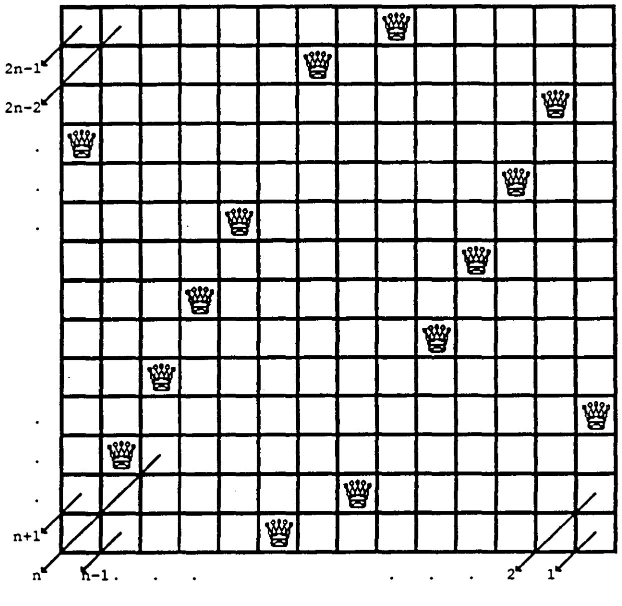

Figure 4b: An example of Yagloms' solution for N of the form N=6m+2. Here N=14. The diagonal numbers have been drawn in.

TWO FLOW ROUTING ALGORITHMS
FOR THE
MAXIMUM CONCURRENT FLOW PROBLEM

Jit Biswas* - David W. Matula**

ABSTRACT

We describe two heuristic flow routing algorithms and analyse their convergence to the solution of the Maximum Concurrent Flow Problem (MCFP) [Ma83], [Ma85]. Implementation results demonstrate the algorithms to be robust. Both algorithms provide a feasible concurrent flow along with a bound on the maximum concurrent flow. The greedy flow augmentation procedure is most efficient but can yield suboptimal results. The flow rerouting procedure can be shown to produce results within an arbitrary tolerance of optimality. These flow routing algorithms make feasible the solution of a larger MCFP than can be handled by linear programming techniques [Pa84]. The algorithms may be interpreted as state space search algorithms regarding artificial intelligence models and therefore generalize to allow non-linear constraints. Applications are in packet switching networks [At81] and cluster analysis [Ma83].

1. Introduction and Summary

Informally the Maximum Concurrent Flow Problem (MCFP) can be stated as follows: Let there be a network of entities (cities, neighborhoods, computers, etc.) in which there exists traffic or flow (passengers, messages, etc.) between all pairs of entities. The flow is sustained through channels (air links, roads, communication lines etc.) which are capacitated. We seek to assign flows in a manner such that the flow relative to demand between any pair of entities (throughput) is equal to the flow relative to demand between any other pair of entities. We then ask for the maximum throughput of such concurrent flow that can be attained in the network, respecting capacity constraints.

For example, consider the interconnection network with sixteen processors shown in Figure 1, which is representative of the structure of the ILLIAC IV. In this case it can be shown [MD82] that there exists a set of paths including at most two paths between any pair of processors (vertices) such that concurrently a total of two units of flow (concurrent flow throughput) can be transmitted between each of the one-hundred and twenty vertex pairs over the respective paths subject to a capacity limitation of sixteen units of total flow over each of the thirty-two linkages (edges) between processors. Our methods here provide routing solutions for concurrent flow throughput for non regular topologies as well as the regular topology of Figure 1.

Section 2 provides a brief background to the maximum concurrent flow problem, giving two linear programming (LP) formulations and their complexities. Section 3 considers algorithmic characteristics for the MCFP from the artificial intelligence point of view. Section 4 develops criteria that are used to simplify the problem formulation and provide convergence bounds. Sections 5 and 6 analyse, successively, a greedy flow augmentation algorithm, and a more sophisticated flow rerouting algorithm, for determining a concurrent flow. Both algorithms are illustrated by application to a set of test graphs.

2. Linear Programming Formulations of the Maximum Concurrent Flow Problem

There are two main formulations of the MCFP, the Node-Arc formulation and the Edge-Path formulation [Ma83], [Ma85], [Pa84]. In our formulation the terms edge and arc are synonymous as are the terms node and vertex. Notationally, we assume throughout this paper that the graph $G = (V,E)$ has vertex set $V = \{1,2,\dots,n\}$ and edge set E.

Node-Arc Formulation of the MCFP. Let the ordered pair (i,j) for $i<j$ denote the commodity flowing from vertex i to node j. In a graph on n vertices there are $\binom{n}{2}$ commodities. We impose conservation equations which set the sum of the incoming flow on edges equal to the outgoing flow on edges for each vertex. In addition there are demands for flow between each vertex pair and capacity constraints on each edge. Thus the MCFP can be formulated as:

Maximize the concurrent flow throughput z subject to the following constraints:

$$\sum_{k=1}^{n} f_{k\ell}^{(ij)} - \sum_{m=1}^{n} f_{\ell m}^{(ij)} = \begin{cases} -D_{ij}z & \text{if } \ell = i \\ +D_{ij}z & \text{if } \ell = j \\ 0 & \text{otherwise} \end{cases} \qquad (1)$$

for $1 \le \ell \le n$, $1 \le i < j \le n$,

$$\sum_{ij} f_e^{(ij)} \le c_e \qquad \text{for all } e \in E \qquad (2)$$

where E is the set of edges, c_e the capacity of edge e, and D_{ij} the demand for flow between vertices i and j. $f_{k\ell}^{(ij)}$ is the flow of commodity ij flowing on edge $k\ell$ from vertex k to vertex ℓ. If there is no such edge the corresponding flow is always zero. Also, $f_e^{(ij)} = f_{k\ell}^{(ij)} + f_{k\ell}^{(ij)}$ for e the edge between k and ℓ. We assume here that the constraints for non-negativity of individual flows always hold for a general LP formulation and do not state them explicitly.

Complexity. There are $n\binom{n}{2}$ constraints of the type (1) and $|E|$ constraints of the type (2). The number of variables is $2|E|\binom{n}{2} + 1$. The ellipsoid algorithm of Khachiyan [PS82] then assures us that the MCFP is solvable by a polynomially bounded algorithm, but the size of this LP formulation renders standard LP techniques practically ineffective on all but relatively small problems. Even if we reformulate this multiple commodity flow interpretation into n "single-source, multiple-destination" type flows [He84], we still have the formidable size of $O(n^2)$ constraints and $O(n|E|)$ variables.

Edge Path Formulation of the MCFP. Let P_{ij} denote the set of all paths between vertices i and j. For $p \in P_{ij}$ let f_p denote the amount of flow being hosted along the path p, and D_{ij} the demand between vertices i and j. A maximum concurrent flow function $f\colon \bigcup_{ij} P_{ij} \rightarrow \text{Reals}^+$ of throughput z must satisfy

$$\sum_{p \in P_{ij}} f_p - D_{ij}z = 0 \qquad \text{for all } 1 \le i < j \le n. \qquad (3)$$

Let P_e denote the set of all paths containing the edge e with c_e the capacity of e. Then any feasible concurrent flow must satisfy the following capacity constraints:

$$\sum_{p \in P_e} f_p - c_e \le 0 \quad \text{for all } e \in E. \qquad (4)$$

The objective as before is to maximize the concurrent flow throughput z.

Although this formulation is implicitly exponential in the number of variables, an LP solution exists for this edge-path formulation where an appropriate choice of $\binom{n}{2} + |E| - 1$ of the $\sum_{ij} |P_{ij}|$ paths is sufficent to achieve optimality. Note that this implies that some optimal solution employs flow on an average of less than two paths from each P_{ij}.

Our iterative algorithms approximate a solution through the use of heuristics which reduce the gap between the current solution and the optimal solution employing flows on paths as in this formulation. They do so in a manner such that only a reasonable number of paths are required to be explored. The concept of deviating flow [FG73] for telecommunication routing in store-and-forward packet-switched networks is one similar instance of such an approach. In the LP network literature generally, the edge path formulation has not been pursued to a great extent.

3. Viewing the MCFP as a search problem.

According to Rich [Ri83], a search problem can be analyzed along several key dimensions that dictate the choice of an appropriate efficiency criteria or heuristic. In this section, we categorize the MCFP along some of the dimensions considered by

Rich. This discussion, we hope, acts as a motivation for the algorithms to follow in Sections 4 and 5.

It is clear that we are dealing with a predictable universe in the sense used by Rich. States of the system are completely specified in terms of the node and arc capacities and their utilizations at a given instant of execution. Constraints are therefore static and the LP formulation completely specifies all possible constraints.

The problem is not decomposable. However, decompositions into minimally interacting components is possible. This is evident from the fact that each node must receive (and send) flow from (/to) every other node. Even if we decompose the problem into several instances of a "single-source, multiple-destination" type problem, we still have a decomposition where the components interact quite heavily. In particular, addition of flow of some commodity along an edge reduces the capacity of that edge for other commodities by a certain amount, thereby affecting all other paths that contend for use of that edge. In spite of this interaction our approach will be to decompose the graph with heuristic labelling. We attempt by suitable heuristics to keep the effects of interaction appropriately controlled. The net effect will be to improve time and space requirements for solving the problem as compared with alternative LP techniques.

If decomposition is our strategy then it follows that optimization is restricted to being local and we must be prepared to undo solution steps. This does not necessarily imply backtracking. The first of the two algorithms utilizes greedy flow augmentation and does not have a flow rerouting feature. Though it works very well in many of the cases, its performance can be greatly affected by certain aspects of the network topology. We show (in our second algorithm) how *bad* flow allocations in previous steps of the algorithm may be *undone* by appropriate flow rerouting in future steps.

Is a good solution obvious? If *good* is interpreted only as an exact optimal solution then the answer is no. If tolerances are acceptable, solutions can be efficiently developed with an indication of their maximum deviation from a provable bound on the maximum concurrent flow throughput. In practice, it turns out for our first algorithm that sometimes the upper bound is much higher than the maximum throughput value, but for our second algorithm the achieved throughputs and derived upper bounds on maximum throughput are convergent.

What is the role of knowledge? Not a great deal of explicit knowledge (in the sense used by Rich) is required to solve the problem. Demands between the vertex pairs, capacities of arcs, and the configuration of the graph are all that is needed for the solution. However, there is a lot of implicit knowledge that depends upon the structure of the graph. If this knowledge can be used to formulate heuristics, the algorithm can be guided much more effectively. A very simple heuristic is the degree of each vertex. If a vertex is of low degree we would not like to have many paths carry flow into and out of it because this will saturate the corresponding edges too rapidly. Our first algorithm (which does not undo) suffers from not necessarily recognizing this constraint. Before presenting the algorithms, we shall develop results concerning problem simplification and concurrent flow bounds.

4. Problem Simplification and Convergence Bounds

We shall henceforth investigate the MCFP only for the case where all demands and capacities are unity, as the extension to variable demands and capacities is then reasonably straightforward. The following lemma shows we can further simplify the problem to consider only demands and paths between non-adjacent vertices of the graph.

Lemma 1: For any graph $G = (V,E)$, if z' is the maximum throughput of concurrent flow between all non-adjacent vertex pairs and z is the maximum throughput of concurrent flow between all pairs of vertices, then $z = \frac{z'}{1+z'}$.

Proof. Let e be an edge between two vertices v_i and v_j. If some particular optimal solution to the all pairs MCFP has any flow from v_i to v_j not passing through the edge e, we can always swap this flow with an equivalent amount of flow passing through e and thereby restrict all flow between end vertices v_i and v_j to e alone. Since the optimal solution in the all pairs case is z, this will bring down the available capacity for non-adjacent flow along e to (1-z). The solution in the non-adjacent pairs case with all capacities (1-z) is then z'(1-z). But this is the same as z, since we have already allocated z units of flow between adjacent pairs. Thus $z = z'(1-z)$, from which the result follows. □

Our algorithms shall each identify a feasible concurrent flow, where the throughput is then implicitly a lower bound on the maximum throughput of concurrent flow. To provide a performance guarantee for an approximate solution, or perhaps confirm an optimal solution, we shall also compute certain upper bounds on the maximum concurrent flow [Ma85]. Noting that each of $|A||\bar{A}|$ vertex pairs must have z units of flow crossing the cut $(A,\bar{A})$ of capacity $|(A,\bar{A})|$ for any cut $(A,\bar{A})$, we obtain the following.

Lemma 2: The maximum concurrent flow throughput z for any graph G satisfies

$$z \le \min_{(A,\bar{A})} \frac{|(A,\bar{A})|}{|A||\bar{A}|} . \qquad (5)$$

Equality of a feasible z with the ratio $|(A,\bar{A})|/|A||\bar{A}|$ for some cut $(A,\bar{A})$ is sufficient to confirm optimality of the derived throughput, but not all graphs yield equality for (5) [Ma85]. Identification of a cut $(A,\bar{A})$ for which the ratio $|(A,A)|/|A||\bar{A}|$ is anticipated to be relatively small is incorporated in our greedy flow augmentation algorithm and will be seen to confirm an optimal solution for a number of test graphs.

A more general bound based on the principle underlying our flow rerouting algorithm is first motivated by a dual problem. Let us say that the graph G is actually a network of thoroughfares and that there is some authority placing tolls on each edge of G. The objective of this authority is to increase total revenue, however, regulations require a specified average toll on the edges. Obviously, if there is above average flow on a given edge with above average toll, it means increased toll collections for the authority. From the users' point of view, the objective is to minimize the toll paid. The user will therefore attempt to take the minimum cost (shortest) path to the destination given any set of toll specifications. These two objectives need to be reconciled by altering tolls until equilibrium is achieved. Our flow rerouting algorithm determines the tolls dynamically by a specified function associating larger edge tolls with larger existing flows through a given edge. This serves the dual purpose of making certain paths less attractive to the user and the total revenue more attractive to the authority. Minimum cost paths are determined and flows rerouted away from more expensive paths, followed by toll revisions, until a balance within tolerance is achieved.

Let T_{ij} denote the toll on the minimum cost path between vertices i and j given specified edge tolls T_e for all $e \in E$. For z units of flow between each vertex pair, the toll paid is at least z T_{ij} for each pair ij. Thus the total toll paid for z units of traffic throughput is at least $z \sum_{i,j} T_{ij}$. Note that T_e is the total revenue from edge e if it is saturated to unit capacity. So the maximum revenue received is at most $\sum_{e\in E} T_e$.

Thus $z \sum_{i,j} T_{ij} \le \sum_{e\in E} T_e$ which gives us an upper bound for any concurrent flow throughput,

$$z \le \frac{\sum_{e\in E} T_e}{\sum_{i,j} T_{ij}} . \qquad (6)$$

More formally, for the graph G let $d{:}E(G) \to R^+$ denote a non-negative valued distance function on the edges of G with d(i,j) the shortest distance between vertices i, j. We further assume the distance function satisfies the triangle inequality, so that d(i,j) = d(e) for e an edge between i and j, and also that d is not zero on all edges.

Theorem 3: Any concurrent flow throughput for the non trivial connected graph G satisfies

$$z \le \min_{d} \frac{\sum_{e\in E} d(e)}{\sum_{i<j} d(i,j)} . \qquad (7)$$

where the minimum is over all distance functions d.

It has been noted that Theorem 3 extends to yield an equality for the maximum concurrent flow throughput [Ma85], providing the basis for our flow rerouting algorithm to obtain an arbitrarily good approximation, but we do not prove that result here. Two corollaries are of immediate interest.

Corollary 3.1: Let $\{d_{ij}\}$ be the distance matrix for the connected graph G (corresponding to d(e) = 1 for all $e \in E$). Then the maximum concurrent flow throughput $\hat{z}$ satisfies

$$\hat{z} \le |E| / \sum_{i<j} d_{ij} . \qquad (8)$$

Corollary 3.2: The maximum concurrent flow throughput z for any connected $n \ge 2$ vertex graph G satisfies

$$\hat{z} \le |E|/[2\binom{n}{2} - |E|] . \qquad (9)$$

Our preceding Lemma 2 is also noted to follow as a corollary of Theorem 3 simply by taking d(e) = 1 for $e \in (A,\bar{A})$, and d(e) = 0 for e not in the cut $(A,\bar{A})$, providing great utility to the result of Theorem 3.

5. The Flow Augmentation Algorithm

The flow augmentation procedure is a greedy heuristic yielding a feasible concurrent flow and a saturated cut whose density provides an upper bound on the maximum concurrent flow throughput. The central idea for each cycle is to determine a set of shortest paths, one between each vertex pair, and to augment the concurrent flow equally on all these paths until at least one more edge is saturated. All additional saturated edges are removed and if the resulting graph is still connected, the residual capacities in the remaining edges are determined and the cycle repeated. When the graph becomes disconnected, a cut is determined and its density computed as an upper bound on concurrent flow throughput according to Lemma 2.

Algorithm Augment: Concurrent Flow Augmentation

Given a graph G = (V,E), this algorithm determines a feasible concurrent flow and a cut saturated by the concurrent flow whose density is an upper bound on the maximum concurrent flow. When the throughput of concurrent flow equals the cut density, a maximum concurrent flow has been found. When unequal, the concurrent flow throughput may or may not be maximum.

1. Set G_r = G and set residual capacities in all edges of G_r to unity.

2. Generate a shortest distance tree from vertex i spanning all vertices j > i for each $1 \leq i \leq |V(G_r)|$. From these trees identify a shortest path between each pair of non-adjacent vertices forming an augmenting set A of shortest paths of G_r.

3. Augment the concurrent flow by Δz on all paths of A, where Δz is determined by the minimum ratio over all edges, of the residual capacity divided by the number of paths of A through the edge.

4. Determine the residual capacity of each edge by $r(e) \leftarrow r(e) - |A_e|\Delta z$, where $A_e \subset A$ includes those paths of A through e. Then delete edges with residual capacity zero, determining a new G_r.

5. If G_r is connected, return to step 2.

6. Determine the vertex partition $A_1, A_2, \ldots, A_k$ for the components of G_r and determine the upper bound $u = \min\limits_{1 \leq i \leq k} \dfrac{|(A_i, V-A_i)|}{|A_i||V-A_i|}$.

7. Rescale the concurrent flow to the all pairs case as per Lemma 1. □

Step 2 is critical in determining the complexity of Algorithm Augment. Utilizing breath first search the shortest distance trees of step 2 can be found in time $O(|V||E|)$. As we are only guaranteed saturation of a single edge in each cycle, an overall time bound of $O(|V||E|^2)$ is obtained. Note that the vertex partition of step 6 can generally be expected to yield just two components. When k>2, all cuts between the k components could be investigated to determine which has minimum density to tighten the upper bound. However, such a computation would require testing up to 2^{k-1} cuts and still could result in an upper bound much greater than the achieved concurrent flow, so our algorithm suggests checking only the partitions A_i, $V-A_i$ to preserve the polynomial boundedness of the procedure. Clearly, considerable savings could be obtained by generating and saving (in step 2) spanning trees that are only a slight variation of preceding trees, or by initially computing and saving a directed acyclic graph (DAG) from each vertex. We have chosen to implement only a simple straightforward version of Algorithm Augment for comparison purposes, and as a suggested first phase for more sophisticated algorithms whose convergence, at least within tolerance, is guaranteed.

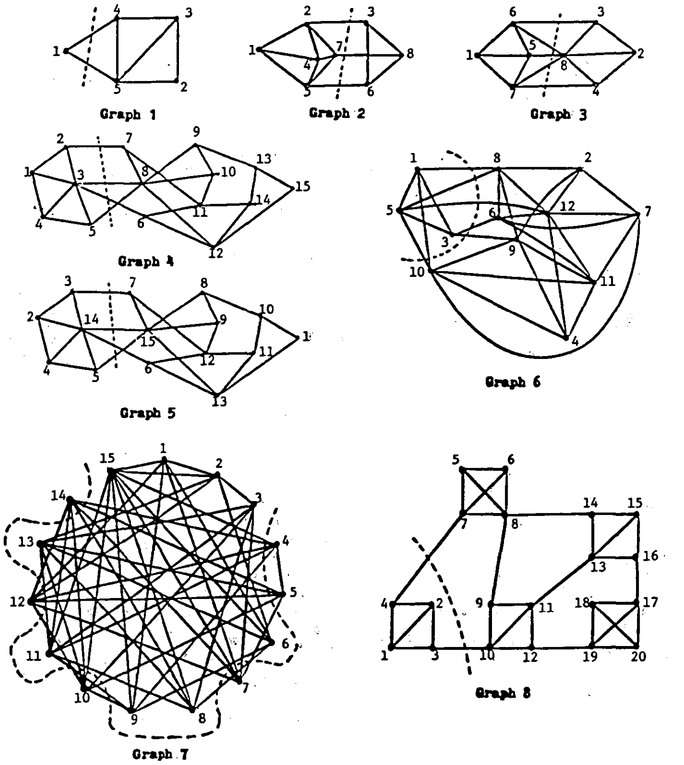

Figure 2: Eight graphs with sparsest cuts illustrated for each graph.

Eight example graphs are illustrated in Figure 2. The graphs have cuts illustrated whose density corresponds to the actual maximum concurrent flow throughput for the corresponding graph. The results of applying Algorithm Augment to these graphs are summarized in Table 1.

Table 1

Graph	|V|	|E|	Number Algorithm Cycles	Number Saturated Edges	Concurrent Flow Throughtput		Computed Cut Density Upper Bound on Throughput
					First Cycle	Final	
1	5	7	3	7	0.3333	0.5	$\frac{2}{4}$ = .5
2	8	14	4	4	0.1428	0.2	$\frac{3}{15}$ = .2
3	8	15	5	7	0.25	0.3125	$\frac{5}{16}$ = .3125
4	15	26	6	6	0.05	0.0761	$\frac{4}{50}$ = .08
5 (isomorphic to graph 4)	15	26	7	7	0.0666	0.0793	$\frac{4}{50}$ = .08
6	12	31	3	10	0.1666	0.2121	$\frac{4}{11}$ = .3636
7	15	49	24	25	0.125	0.2432	-
8	20	34	4	5	0.0222	0.0293	$\frac{3}{96}$ = .03125

Algorithm Augment finds a concurrent flow throughput which is confirmed to be maximum by the derived sparse cut bound for Graphs 1, 2 and 3. For Graphs 4, 5 and 8 the derived throughput of concurrent flow is only slightly less than the sparse cut bound determined, where in both cases the cut is the actual constraint on the maximum concurrent flow as verified by other methods. Note that a shortest path, such as 8, 3, 6 in Graph 4, can zigzag across the constraining sparse cut, and if chosen, an irreconcilable difference between the throughput achieved and the sparse cut bound will be obtained. The algorithm was applied to Graph 4 a second time after relabeling the vertices to obtain the isomorphic Graph 5. The results confirm, as expected, that selecting a different set of shortest paths in some cycle of Algorithm Augment can yield a different achieved concurrent flow throughput.

Graph 6 illustrates a wide disparity between throughput and the sparse cut bound. In this case the algorithm terminated by isolating vertex 3 yielding a bound of $\frac{4}{11}$ = .3636 rather than by separating the vertex set A = {1,3,5} for an achievable sparser cut upper bound of $\frac{7}{27}$ = .2592. The derived throughput is then actually 82% of the best possible throughput and considerably better than the obtained upper bound would indicate. For Graph 7 the bound of Corollary 3.2 indicates no more than $\frac{49}{161}$ = 0.3043 throughput is achievable. Further inspection of Graph 7 revealed the sparse cut illustrated in Figure 2, which was not found by Algorithm Augment. The cut illustrated yields an upper bound of $\frac{15}{54}$ = 0.2777 on throughput, so computed throughput was over 87% of optimum. It can be anticipated that the relatively slow convergence of Algorithm Augment illustrated for Graph 7 will prevail on such "near random" graphs, and other methods should be utilized for this class of graphs. Certainly the fact that all shortest paths have length one or two can be exploited by an alternative algorithm for the class of graphs of diameter two.

In summary, Algorithm Augment can be expected to generally determine the maximum concurrent flow when there exists a sufficiently sparse constraining cut with no shortest paths zigzaging across the cut. The main criticism of Augment is that the achieved throughput and derived bound can differ widely. The greedy method illustrated by Algorithm Augment is available to provide a quick and efficiently determined initial concurrent flow for input to other methods. The effectiveness is indicated, in particular, as the initial cycles alone determined a flow of between 45% and 85% of the optimum for the cases tested.

6. The Flow Rerouting Algorithm

The methodology of this algorithm is to first establish a unit of flow on some path between each vertex pair without regard to capacity constraints on edges. A "toll" is assigned to each edge by a specified function ascribing relatively large tolls to edges with relatively greater total flow. Iteratively, minimum cost paths are found and flows rescheduled off more costly paths with edge tolls dynamically updated. We prescribe a toll function that assigns considerably higher cost to an edge having only slightly higher flow than any other edge. As equilibrium is approached, the flow in those "critical" edges that must in theory be saturated by any maximum concurrent flow [Ma85] approach approximately the same flow (to avoid highly unbalanced costs). Normalization by dividing by the maximum flow observed in any edge yields a feasible concurrent flow where the critical edges should then each be nearly saturated. By appropriate parameter choice for our toll function and employing Theorem 3, it can be shown that a solution with throughput in any arbitrary tolerance of optimality can be determined.

Algorithm Reroute: Concurrent Flow Rerouting

Given a graph G, tolerance ε, and parameter c, this algorithm determines a concurrent flow and a set of edge tariffs such that (for sufficiently large c) the throughput of concurrent flow is within the specified tolerance of an upper bound on the maximum concurrent flow throughput, utilizing the tariff bound of Theorem 3.

1. Assuming edge tolls of unity, allocate a flow of 1 unit on one shortest path $p \in P_{ij}$ between every pair of vertices in the graph, disregarding capacity constraints. Set the flow through each edge, f(e), equal to the number of paths using that edge.

2. Determine the toll placed on each edge $e \in E(G)$ by the following non-linear function:

$$T_e = 2^{c(f(e)-f^*)} \qquad \text{where } f^* = \max_e f(e) \text{ .}$$

3. Proceeding in turn through each pair of vertices $1 \leq i < j \leq |V(G)|$ determine a minimum cost path $p' \in P_{ij}$. If a highest cost path p currently carrying flow from i to j has cost larger than that of p', reroute δ units of flow from p to p', dynamically updating the tolls on the edges affected as per the function of step 2. Determine δ so that the resulting costs as per the adjusted tolls for paths p and p' are identical where p has residual flow greater than zero, or otherwise set δ so as to reroute all flow off p and onto p'.

4. Calculate the concurrent flow throughput realized by this solution: $z = 1/\max_e f(e)$ gives the proper normalization. Calculate the upper bound $z_u = \sum_e T_e / \sum_{i<j} T_{ij}$, and if the difference between z and z_u satisfies the tolerance specified by ε, terminate. Otherwise return to step 3.

The choice of the toll function in step 2 is critical to the success of this procedure. Note that when an amount of flow δ is rerouted from p to an edge disjoint path p', the cost of path p is decreased by the factor $2^{c\delta}$ and p' increased by the factor $2^{c\delta}$. Thus the sum of the tolls on all edges, $\sum_e T_e$ strictly decreases and no cycling is possible. However, if the maximum amount of flow rerouted in any pass through all pairs in step 3 falls below some stipulated minimum, convergence should be considered too slow and the process terminated, or reinitiated with a larger value of the parameter c (e.g. c ← 2c).

The choice of c clearly effects the speed of convergence, but caution is necessary. In theory, for any desired tolerance ε, the algorithm can be shown to terminate with convergence for any sufficiently large c, but large values of c can cause erroneous behavior in finite precision computation. Our approach in the results following applying Algorithm Reroute is to utilize several convenient values of c. Further algorithm refinement incorporating internal determination of c with possible updating in a major cycle is under investigation, as is the application of the algorithm to larger graphs and networks of varying capacities with non uniform pairwise flow demands.

The following table summarizes the results of application of Algorithm Reroute to the test graphs of Figure 2. The data of Table 2 is from an implementation of a version of Algorithm Reroute developed by B. Thompson [TM86]. The version differs only slightly in that in step 3, paths p and p' are determined as indicated for each pair i,j, and the pair with largest difference in cost is chosen for flow rerouting in each iteration. In the table the bound z_u from inequality (6) is termed the elongation (elong.) upper bound, and the cut upper bound is also given for reference corresponding to the cuts illustrated in Figure 2. Note that convergence within 1% of maximum throughput is confirmed for Graphs 1-6, and within 2-1/2% for Graphs 7 and 8.

Acknowledgment: We would like to thank Vipin Kumar and R. V. Helgason for numerous discussions during the preparation of this paper, and Byron Thompson for the version and results of Algorithm Reroute given as Table 2.

A LEAST COST PARTITION ALGORITHM

Thomas J. Marlowe, Jr.

Department of Mathematics and Computer Science

Seton Hall University

The least-cost/greatest-profit integer partition problem have a natural formulations by recursive definition, closely related to the knapsack problem. Beginning with the obvious O (n^2) dynamic programming algorithm for least-cost partition, we present modifications illustrating themes in algorithm and data st-ucture design. One results in a lower average-case complexity of order O $(n^{3/2})$, a second in an efficient print algorithm for the resultant partition, and a third is a prepass particularly effective when unit costs are close to monotone. We show worst-case and average-case complexity for the revised algorithm, and argue that the 'real-world complexity' may be even less. We show each of these as a modification of the underlying system of equations or its data-structure representation. Finally, we show that no algorithm with similar primitives can have better worst-case performance.

The breadth of design and analysis concepts illustrated, their direct connection to data structure modification, and the variety of mathematical tools employed, render this problem an excellent example fc demonstrating these principles in instruction or other contexts.

1. THE LEAST-COST PARTITION PROBLEM

1.1 Definitions

Combinatorial objects such as permutations, selections, and partitions give rise to natural formulations in recursive definitions [15, 21]. Attaching cost functions, such as to edges in a graph, and looking for minima over sets of these objects, leads to interesting problems with significant applications [9, 15]. Such problems frequently have a recursive, dynamic programming formulation [2, 13] as an nXn equation set.

A **partition of an integer n** is a multiset of integers whose elements sum to n. Partitions have significant mathematical interest [7, 21], and can be enumerated in a natural way [17]. The **least-cost partition problem**, closely related to the integer knapsack problem, is clearly susceptible to recursive and/or dynamic programming formulation. (Compare [13, 14].)

We modify the definition of partition slightly, to insist on a particular ordering of its elements:

Definition 1.1.1: A **partition** P of an integer n is a non-decreasing finite sequence of positive integers whose sum is n.

Definition 1.1.2: The set of **summands** of P is the multiset of integers appearing in P; the set of **partisands** of P is the underlying set of *distinct* integers. The **height** of P, h(P), is the number of its summands; the **reduced height**, r(P), is the number of its partisands.

Definition 1.1.3: Let **C** be a cost function (a function from the non-negative integers to the non-negative reals, for which **C**(0) = 0). For a partition P, let the cost of P, **S**(P), be $\sum_{j \in P}$ **C**(*j*), and let **S(k)** = min {**S**(P) | P a partition of k} = **S(LCP(k))**, where **LCP(k)** is the *least-cost partition* of k. (Note that this partition is not necessarily unique. We will, however, give a deterministic algorithm for both **S**(n) and **LCP**(n).)

1.2 A Dynamic Programming Formulation

An obvious worst-case Θ (n^2) algorithm exists for finding **S(n)**, by building **S**(k) from the **S**'s of smaller integers:

Definition 1.2.1: Initial Algorithm for least-cost partitions:

$$S(k) = C(1) \qquad , k=1$$

$$= \min \{C(k), \min \{C(i) + S(k-i)\}_{i=1}^{k-1}\} \qquad , k > 1.$$

For such an integer-programming equation-set, the principal solution techniques are dynamic programming and branch-and-bound. Branch-and-bound is usually faster (Chvatal [3] claims it to be 50% faster for integer knapsack problems), requires less storage space, and proceeds from a reasonable initial approximate solution via heuristically directed search. For knapsack-type problems these heuristics frequently employ the list of candidates sorted in unit-cost order. Although the integer knapsack problem is known to be NP-complete (but pseudo-polynomial) [6], there do exist polynomial-time algorithms for various special cases (compare [4]).

For the least-cost partition problem, however, there are several factors which suggest consideration of dynamic programming: First, the greedy algorithm does not necessarily reach a good approximate solution, and early exact solutions found by branch-and-bound may be arbitrarily bad, so that less pruning will occur; second, the corresponding search space may be exponentially large; and

CH2345-7/86/0000/0637$01.00 © 1986 IEEE

third, dynamic programming lends itself to incremental and parallel application, in particular, the return of least-cost partitions of several distinct integers at essentially no additional cost. This algorithm provides a solution to one special case of the integer knapsack problem for which no good approximate algorithm exists, and can be modified to give an O (p^3) algorithm (polynomial in the O $(2p)$ length of the input)[1] for the problem of least-cost (greatest-profit) partition of n using only the integers {1,2,3, . . . ,p}. [11, 10].

We will, however, use certain features common to branch-and-bound algorithms: We sort the integers in *unit-cost* order, and use a pruning technique to reduce average complexity.

Definition 1.2.2: The **unit cost** of an integer k, relative to a cost function **C**, is given by

$$U(k) = \frac{C(k)}{k}.$$

We show that the solution for **S(n)**, including the print of the resulting partition, is possible in average time substantially less than O (n^2), in fact, in O $(n^{3/2})$. This improvement depends on the elimination (dynamically) of terms from the individual equations. We will show that, on average, fewer than $k^{1/2}$ terms are considered in the equation for S(k). These considerations motivate the following definition:

Definition 1.2.3: Call an integer j <u>simple</u> with respect to the given cost function **C** if its only least-cost partition is itself.

> **Proposition 1.2.1:** 1 is always *simple*, and if j is not *simple*, then
>
> 1. every integer in **LCP(j)** is *simple*, and
> 2. for some integer i in **LCP(j)**, $i \leq \lfloor \frac{j}{2} \rfloor$,
> 3. for some i in **LCP(j)**, $U(i) \leq U(j)$.

Since 1 is always *simple*, we have the algorithm:

Definition 1.2.4: Least-cost partition algorithm using simplicity.

$$S(k) = C(1) \qquad , k=1$$

$$= \min \{C(k), \min \{C(i) + S(k-i) \mid i \textbf{ simple}\}_{i=1}^{\lfloor \frac{k}{2} \rfloor}\} \qquad , k > 1.$$

The restriction to $i \leq \lfloor \frac{k}{2} \rfloor$ is immediate; the restriction to i **simple** justifies elimination of **C(i)** + **S(j)** whenever **C(i)** is not itself the best choice for expressing i.

It is however clear that every integer could be *simple* for a particular **C** [consider **C(k)** = $k^{1/2}$], so that the worst-case cost of the modified algorithm will still be O (n^2).

On the other hand, introducing a prepass 'PREMARK', we can show that, for **U** a monotone (non-increasing or non-decreasing) function of n, worst-case performance also improves significantly. PREMARK also leads to improved worst-case performance under reasonable assumptions related, but not equivalent, to monotonicity. PREMARK may be viewed as the application of an inexpensive prepass to eliminate a number of equations from the equation set; this idea is discussed more fully in section 3.3.

1.3 Description of the algorithm

OVERVIEW OF THE LCP ALGORITHM

0. Input is n and costs for integers 1 to n.
1. Compute *unit costs.* Sort the integers 1 to n in unit-cost order.
2. Apply PREMARK to eliminate some equations.
3. Apply modified definition; condense results.
4. Print resulting least cost and partition.

1.3.1 The LCP Data Structure

We now give an overall description of the basic LCP partition algorithm to compute **S(n)**. We discuss the algorithm as modifying the entries of an array A[1. .n] of the following data structure:

```
| IND | CST | MRK | SET | NXM | FRS | NUM | NXT | ,
```

Figure 1-1: DATA STRUCTURE FOR PARTITION ALGS

where for 1≤k≤n:

- IND = INDEX is simply k itself,
- A[k].CST (COST) = S[k] when generated,
- MRK = MARK is a flag; 1 = {k is *simple*},
- SET is a flag; 1 = {S[k] has been found},
- NXM = NEXTMARK points to the next largest *(simple)* integer MARKed, or to 0,
- FRS = FIRST is the smallest integer in **LCP(k)**,
- NUM = multiplicity of FIRST in **LCP(k)**,
- and NXT = NEXT = k - FIRST*NUM.

We also need the costs **C[k]** and unit costs **U[k]**; we keep the former in A[k].CST until needed.

1.3.2 Statement of the algorithm

Algorithm 1.3.1: The LCP algorithm:

The algorithm consists of five phases:

1. a SORT of U into an array **USORT** of records (INDEX,UNIT_COST), which SORT is stable and
   (1) worst-case O $(n \log n)$, and
   (2) O (n) if **U** is monotone;
2. an INITIALIZE of the data structure;
3. the PREMARK phase discussed below;
4. the PART phase, to invoke dynamic

[1] Counting bit lengths, input has length O(2p log p + log n); running time and output is O$(p^3 \log p + \log n)$.

programming on the recursive definition;

5. and a phase PRINT, to print the resulting least-cost partition in sorted increasing order.

Figure 1-2: OUTLINE OF THE LCP ALGORITHM

1.3.2.1 The algorithm PREMARK

Given the array **USORT**, we consider the permutation of [1. .n] induced by **USORT**.INDEX. It is clear that the integer j_0 = **USORT**[1].INDEX – the integer with the least unit cost – must be *simple*, and that none of its multiples can be. (The **LCP** of each of those multiples must be precisely a set of j_0's.) In fact, if we proceed through the list **USORT** maintaining an integer LEAST = the least integer found to be *simple* so far (initialized at n+1), then

- the first smaller integer, S, encountered in **USORT** must be *simple* (so MARK it),
- each of its multiples less than LEAST has a known least-cost partition (by S's), so can be SET, and finally
- LEAST now has the value S.

The algorithm continues until LEAST = 1.

Ex. 1.3.1: Use of the PREMARK algorithm:
For instance, if the permutation of [1. .23] induced by **USORT** were

17 21 18 5 9 19 13 15 22 7 6 2
10 19 11 4 14 23 20 1 8 12 3,

then j_0 = 17 would be *simple* (independent of other values of **C**), and 17 would be MARKed. Continuing, neither 21 nor 18 are less than 17, but 5 is, so 5 must be *simple*, (since no other partition could have lower average unit cost), and neither 10 nor 15 could be (further, their least-cost partitions are({5,5} and {5,5,5}. Note that we know that 20 cannot be simple, but cannot know whether its least-cost partition is {5,5,5,5} or perhaps {3,17}. Thus 5 would be MARKed, 10 and 15 (but not 20) SET, and LEAST set equal to 5. Continuing, neither 9, 16, 13, 15, 22, nor 7 is less than LEAST = 5, but 2 < 5, so 2 is *simple*, and 4 is not – 2 is MARKed and 4 is SET. Finally, 1 is encountered and MARKed as *simple*, but this time no other integer is SET.

PREMARK uses specific knowledge to solve certain equations before invocation of the recursive procedure (see section 3.3). We note that **our average-case complexity results do not depend on the use of PREMARK**; it has been introduced to guarantee that a unit-cost function close to monotone (more likely in real-world problem contexts) will produce close-to-optimum (linear-complexity) algorithm behavior.

1.3.2.2 PART, the dynamic programming phase of the LCP algorithm

PART proceeds as for definition 1.2.4 with the following modifications: **(1)** we do not expand integers already partitioned in PREMARK, **(2)** if i can be partitioned non-simply, we do so, (e.g., if **C**(8) = **C**(2) + **S**(6) = S(8), then 8 has two least-cost partitions: {8} and {2}∪**LCP**(6); we use the partition containing 2), **(3)** we use the smallest possible new partisand (these two conditions specify a tie-breaking mechanism, always selecting the leftmost expression of minimal cost in each row of the equations set), **(4)** if an integer i is *simple* (whether found in PREMARK or not), we link i into a linked list of *simple* integers. (Insuring that the scan for *simple* integers at level i depends only on the number of *simple* integers.), **(5)** we modify the listed solution (for use by PRINT) in the manner indicated below.

1.3.2.3 Condensation of equations and the PRINT phase

Ordinarily, to print the solution to a set of equations, we would maintain the solution chosen at each level i, e.g.,

$$\mathbf{S}(11) = \mathbf{C}(1) + \mathbf{S}(10)$$
$$\mathbf{S}(10) = \mathbf{C}(2) + \mathbf{S}(8)$$
$$\cdots$$
$$\mathbf{S}(8) = \mathbf{C}(2) + \mathbf{S}(6)$$
$$\cdots$$
$$\mathbf{S}(6) = \mathbf{C}(6),$$

etc.; from which we could expand

$$\mathbf{S}(11) = \mathbf{C}(1) + \mathbf{S}(10) = \mathbf{C}(1) + \mathbf{C}(2) + \mathbf{S}(8)$$
$$= \mathbf{C}(1) + \mathbf{C}(2) + \mathbf{C}(2) + \mathbf{S}(6) = \mathbf{C}(1) + 2\mathbf{C}(2) + \mathbf{C}(6).$$

However, repetition of partisands is characteristic of the partition problem, and the list of these in order a feature of the algorithm. This allows us to reduce the number of calls to other equations: if the j in

$$\mathbf{S}(i) = \mathbf{C}(j) + \mathbf{S}(i-j)$$

is the same as that in the expansion of **S**(i–j), we condense this information (in the FIRST, NUM, and NEXT fields of the data structure). If

$$\mathbf{S}(i-j) = a\mathbf{C}(j) + \mathbf{S}(r),$$

(where r = (i – j) – a•j), then we store at i the equation

$$\mathbf{S}(i) = (a + 1)\mathbf{C}(j) + \mathbf{S}(r);$$

if the j's are different, we will, of course, not attempt condensation.

Descent through this 'condensed' set of equations will make the PRINT routine function efficiently – its complexity is now determined by the *reduced height*, rather than the full *height*, of the partition. We will see in section 2.3 that PRINT actually does return the partition in sorted increasing order.

The next three sections discuss the complexity and effectiveness of the several phases of this algorithm. Section 2.1 covers the initial phases of the algorithm, through invocation of PREMARK. Section 2.2 shows that the average-case complexity of the LCP algorithm is lowered to O $(n^{3/2})$ from O (n^2) by use of simplicity. Finally, section 2.3 shows that the resulting least-cost partitions can be printed efficiently, and that the least-cost partitions of all integers less than n can be generated and printed with essentially no cost beyond that needed for n alone.

1.3.2.4 Assumptions for average-case analysis

Our average-case analysis assumes that all **n!** permutations of {1,2,. . .,n}, induced by sorting unit costs into increasing order, are equally likely. Although this is not entirely satisfactory, it almost certainly underestimates the actual savings by comparison to other reasonable and feasible models. Further, as we shall see, our analysis very likely further overestimates the number of remaining terms in the k^{th} equation, and we can show that the same average complexity would result from a stochastic process in which each term considered in equation k . qually likely to be chosen. Therefore, average-case savings demonstrated will almost certainly remain valid in most other models, or in likely real-world situations.

2. ELEMENTARY ANALYSIS OF THE LCP ALGORITHM

We assume all arithmetic operations are constant-cost, rather than depending on bit length. (We may also assume all operations are additions and multiplications if costs are integral and we substitute comparison of iC(j) with jC(i) for determination and comparison of unit costs.)

2.1 Analysis of PREMARK

The cost of determining the array of unit costs, $U[k] = \frac{C[k]}{k}$, is clearly $O(n)$; the subsequent sorting cost in creating **USORT** is $O(n \log n)$ (by assumption), and remaining initialization cost is $O(n)$. PREMARK now scans USORT.INDEX, MARKing each subsequent LEAST integer as *simple*, and SETting certain of its multiples. PREMARK will see each integer at most twice (once if SET, and once on the scan), so its complexity is also $O(n)$, and the issue of interest is:

How effective is PREMARK? How many integers have **LCP**'s determined during PREMARK, and how many of those will be *simple*? The probability that a particular integer is SET as non-simple in PREMARK is strongly influenced by the number of its divisors; elementary number theory and the divisibility lattice of the integers play a major role in the analysis of this phase.

If $k = j_0$ = **USORT**[1].INDEX, then k itself will be MARKed and SET, and $\lfloor \frac{n}{k} \rfloor$ integers in total will be SET at that point. With respect to the number of integers MARKed or SET, further application of PREMARK is in effect equivalent to the application of PREMARK to the induced permutation of {1,2,3,...,k−1}. This leads directly to recursive definitions for the average and worst-case number of integers MARKed and SET in PREMARK. Using number theory and the theory of recurrence relations, we find:

Proposition 2.1.1:

1. At least one integer larger than $\lfloor \frac{n}{2} \rfloor$ is SET in PREMARK(n).
2. The average number of integers MARKed as *simple* in PREMARK(n) is $\Theta(\log n)$.
3. The average number of integers SET in PREMARK(n) is $\Theta((\log n)^2)$.
4. In the worst case, only the integer 1 is MARKed as *simple* in PREMARK(n).
5. As few as $\Theta(\log n)$ integers could be SET in PREMARK(n)

Proof:

1. j_0 = **USORT**[1].INDEX is MARKed. If $j_0 \le \lfloor \frac{n}{2} \rfloor$, then at least one multiple kj_0 has $\lfloor \frac{n}{2} \rfloor < kj_0 \le n$.

2. Let PA(n) = the average number of integers found to be *simple* in {1,2,3, . . . ,n}. Then

$$PA(n) = \begin{cases} 1 & , n=1 \\ 1 + \frac{1}{n} \cdot \sum_{k=1}^{n-1} PA(k) & , n > 1. \end{cases}$$

whence, reasonably directly,

$$PA(n) = \sum_{k=1}^{n} \frac{1}{k} = O(\log n).$$

3. Let SA = the average number of integers in {1,2,3, . . . ,n} SET during PREMARK. Then

$$SA(n) = \begin{cases} n & , n=0,1 \\ \frac{1}{n} \cdot \sum_{k=1}^{n} \left(\lfloor \frac{n}{k} \rfloor + SA(k-1) \right) & , n > 1. \end{cases}$$

Exchanging double summations, we have

$$SA(n) = \sum_{k=1}^{n} \frac{d(k)}{k},$$

where d(k) = the number of divisors of k. Another double-summation argument shows that

$$\sum_{k=1}^{n} \lfloor \frac{n}{k} \rfloor = \sum_{k=1}^{n} d(k).$$

Finally, from Hardy and Wright [7], we have that

$$\sum_{i=1}^{n} d(i) = n \log n + O(n),$$

whence the average value of d(i), $1 \le i \le n$, is $\log n$. Replacing d(i) by $\log n$ for each i gives $\sum_{i=1}^{n} \frac{\log i}{i} = \Theta((\log n)^2)$.

4. Clear.

5. Let SW(n) = the fewest integers SET in execution of PREMARK on {1,2,3, . . . ,n}. Then

$$SW(n) = \begin{cases} n & , n=0,1 \\ \min \{ \lfloor \frac{n}{k} \rfloor + SW(k-1) \}_{k=1}^{n} & , n > 1 \end{cases}$$

which is minimized for $k = \lfloor \frac{n}{2} \rfloor + 1$. Iteration gives $SW(n) = \Theta(\log n)$.

Ex. 2.1.1: An example of worst-case behavior for PREMARK:
Consider the **USORT**.INDEX permutation for n = 31:

(16 30 29 28 27 26 25 24 23 22 21 20 19 18 17
8 15 14 13 12 11 10 9 4 7 6 5 2 3 1 31)

for which only 16 8 4 2 1 will be MARKed, and no other integer SET.

2.1.0.1 The work done by PREMARK

The total cost of PREMARK is O $(n \log n)$, since **USORT** is not otherwise needed. But how much work does PREMARK save? That is, how much work would have been required in PART to solve equations solved in PREMARK? Assume that evaluation of a term in an equation, and comparison of its value with the current min value of the equation is O (1); the question then reduces to: How many evaluations of terms are rendered unnecessary by PREMARK?

The previous example shows that the worst case is Θ (n), since the number of evaluations saved is $\sum_{k=1}^{\lfloor \log_2 n \rfloor} 2^k$, which is between n and 2n. But what is saved on average? If the index of the first entry of **USORT** is k, then no searching is required for $k, 2k, 3k, \ldots, \lfloor \frac{n}{k} \rfloor * k$, which, compared to original O (n^2) algorithm accounts for

$$k * \sum_{i=1}^{\lfloor \frac{n}{k} \rfloor} i = k * \lfloor \tfrac{n}{k} \rfloor * (\lfloor \tfrac{n}{k} \rfloor + 1) / 2;$$

together with any saved work from the induced permutation on {1,2,3,...,k−1}. Thus:

Definition 2.1.1: Recursive definition for average work done by PREMARK:

$$WORK\,(n) = \begin{cases} 1 & , n=1 \\ \frac{1}{n} \cdot \sum_{k=1}^{n} \frac{k}{2} * \lfloor \frac{n}{k} \rfloor * (\lfloor \frac{n}{k} \rfloor + 1) + WORK\,(k-1) & , n > 1. \end{cases}$$

Proposition 2.1.2: $\mathrm{WORK(n)} = \sum_{k=1}^{n} d\,(k) = \Theta\,(n \log n)$.

Proof: We first show by calculus of sums and differences that

$$\sum_{k=1}^{n} k * \lfloor \tfrac{n}{k} \rfloor * (\lfloor \tfrac{n}{k} \rfloor + 1) = \sum_{k=1}^{n} 2k * d\,(k).$$

(Clearly equal when n = 1, and manipulation of sums shows Δ(left−hand side) = Δ(right−hand side) for n > 1.)

Induction then establishes that $\mathrm{WORK(n)} = \sum_{k=1}^{n} d\,(k)$, which is O $(n \log n)$ by the previously cited result of Hardy and Wright [7].

Since the average work saved by PREMARK is only Θ $(n \log n)$ even in comparison to the original algorithm, and this is also its worst-case cost complexity, what are the reasons for its introduction?
First, it is more efficient and somewhat helpful in constructing an incremental algorithm [11];
second, as we shall see in section 3.1, PREMARK handles monotone and nearly monotone cost functions well. Its own complexity will frequently be less than O $(n \log n)$ (in fact, O (n) if **USORT** is monotone, when PREMARK itself will be more productive);
and, third, analysis of its properties provides an interesting application of certain techniques for determining average complexity.

Some final comments:

- First, if we are only concerned with the generation of **LCP(n)** for some fixed n, then:
  1. If n has been SET in PREMARK, do not invoke procedure PART; this occurs with probability $\frac{d(n)}{n}$.
  2. If **C** is not an increasing function, then any integer i < n whose cost **C(i)** is greater than or equal to **C(n)** can be eliminated from **U** before sorting.
- Second, if **U(i)** ≤ **U(j)** for $i | j$, then j can be partitioned by i's, and cannot be *simple*; a modification of SORT could eliminate j from **USORT**.

2.2 Analysis of PART

For each i not SET during PREMARK, PART selects the best decomposition of i by examining the partition **C(j) + S(i-j)** for each *simple* integer, j, less than or equal to $\frac{i}{2}$. The complexity of the procedure is therefore determined by the number of integers SET in PREMARK and the sum for all integers not SET of the number of *simple* integers less than or equal to half that integer. We have seen that as few as $\log n$ integers may have been SET even though every integer may in fact be *simple* (the partition of 31 in example 2.1.1). Thus worst-case complexity is still O $((n - \log n) * n)$ = O (n^2).

In the given worst-case example, significant improvement may be realized by using the observation that some partisand in the partition of j must have unit cost no greater than j's (otherwise, j would be *simple*.) We could thus use an alternate set of equations:

$$S\,(j) = \min\,\{C\,(i) + S\,(j-i)\},$$

where the min is taken over all i < j preceding j in **USORT**. However, the use of such an approach in general requires traversal of **USORT** for each i, and is clearly O (n^2), not only in worst-case, but on average. We will in fact show that any algorithm using only the **USORT** permutation and pairwise comparison of partition costs must have worst-case complexity O (n^2) (see Section 3.2).

The interesting consideration, therefore, is the average complexity of the algorithm, which relies on the determination of the average number of *simple* integers. We will average on the (equally-likely) permutations of {1,2,3,...,n} induced by **USORT.INDEX**, and we will assume that every integer which could be *simple* based on that information will be, although this need not in general be the case. (Such *combinatorial averaging* techniques [22] have been used for complexity analysis in other, sharper settings; the bibliography by Slominski [20] cites 70 references.)

Ex. 2.2.1: Simplicity not fully determined by **USORT.INDEX**:
If (2 7 3 6 5) are the first five entries of **USORT.INDEX**, then 2 must be *simple*, 6 (= 3·2) and 5 (= 2 + 3) cannot be, but 3 and 7 might or might not be, depending on the particular values of **C**.

Generalizing, for a given **USORT**.INDEX permutation (independent of the particular cost function C), the integers MARKed in PREMARK must be *simple*, an integer j following one of its partisand sets cannot be, and others are undetermined: they may be *simple* for some cost functions for the permutation, and non-simple for others. In fact, it seems probable that for any integer k not MARKed in the PREMARK phase there is a cost function with the given permutation for which k is not *simple*, though this will not be possible for every subset of such integers.

Ex. 2.2.2: Restrictions on non-simple subset:
Suppose 5 has the **USORT.INDEX** permutation (3 5 4 1 2) and 4 is *simple*. Since any non-simple partition of 5 must involve 3, the only alternatives are 3+2 and 3+1+1. But 3+1+1 is clearly less costly than 3+2, and if **LCP**(5) = 3+1+1 then **LCP**(4) = 3+1. CONTRADICTION. Thus 5 must also be *simple*.

Note that for any permutation 1 must be *simple*, and 2 cannot be undetermined. Note also that if there are at least two *simple* integers the second smallest (i.e., other than 1) must also be identified in PREMARK. Otherwise, essentially any behavior can occur: Given two disjoint subsets A and B of {2,3,...,n}, there is a permutation of [1. .n] so that every integer in A and no integer in B is *simple*.

The heart of the improvement in average-case performance lies, as mentioned earlier, in determination of the expected number of *simple* integers less than a given $\frac{k}{2}$, which in turn depends on the probability that each given integer j will be *simple*. Note that we also assume that "any integer which might be *simple* for the given **USORT** permutation will be". We then need to determine an estimate for the probability that k might be *simple*, i.e., that it has not been preceded by a set of partisands which, possibly with repetitions, sums to k.

In particular, we note:

> **Proposition 2.2.1:** k will not be *simple* if preceded in USORT.INDEX by:
>
> 1. any divisor d of k
> 2. any pair of primes m and n $< k^{1/2}$
> 3. any pair of numbers i and k−i.
>
> **Proof:** (2) Given any pair of relatively prime integers m and n, every integer larger than mn − m − n can be written as a positive integral combination of m and n [7, 19].

We model only the third constraint, which appears to dominate in practice. Let f(m) = the probability that a distinguished element * occurs before both elements of any of m pairs (a_j, b_j) in a random permutation of those 2m+1 elements; and let **Simp**(n) be the probability that n may be *simple* for a random permutation (i.e., that there is some cost function **C** with the given **USORT**.INDEX permutation for which n is *simple*). Then:

$$Simp(n) \le f(\lfloor \frac{n}{2} \rfloor).$$

This follows directly if n is odd; for n even, if $\frac{n}{2}$ occurs before n, then n is clearly not *simple*, so that Simp(n) is even less than it would be if $\frac{n}{2}$ had to match a paired element. Our main theorem then follows from the following combinatorial lemma, related to Chernov's inequality:

> **Lemma 2.2.1:** $f(n) \le \frac{c}{n^{1/2}}$.
>
> **Proof:** See [11].
>
> **Theorem 2.2.1:** The PART algorithm has average complexity between O ($n \log n$) and O ($n^{3/2}$).
>
> **Proof:** The average number of *simple* integers less than i is at least $\log i$, since the PREMARK phase MARKs an average of $\log i$ integers, and is certainly no greater than
>
> $$\sum_{j=1}^{i} Simp(j) < \sum_{j=1}^{i} (\lfloor \frac{2\pi}{j} \rfloor)^{1/2} \approx 2\cdot(\pi i)^{1/2}$$
>
> by the integral test.
>
> Thus the average complexity of the algorithm lies between
>
> $$\sum_{i=1}^{n} \log i \text{ and } \sum_{i=1}^{n} 2\cdot(\pi \lfloor \frac{i}{2} \rfloor)^{1/2},$$
>
> which are O ($n \log n$) and O ($n^{3/2}$) respectively.

Also note that each integer i will be *simple* with probability no less than $\frac{1}{i}$ (since that is the probability that, in the induced permutation on [1. .i], **USORT**[1].INDEX = i). Thus, at least

$$\sum_{i=1}^{k} \frac{1}{i} = O(\log k)$$

integers less than k will be *simple* on average, which would also show a minimum average complexity of O ($n \log n$).

Note that this ignores the contribution of the PREMARK algorithm, but section 2.1 shows that PREMARK will not make a significant improvement on average. Nonetheless, the approximation of Simp(k) by $f(\lfloor \frac{k}{2} \rfloor)$ can be seen numerically to be a large overestimate.

2.3 Analysis of PRINT

We first show that **LCP(n)** will be printed in non-decreasing order. Consider the data structure (Fig. 1−1): If the condensed equation for k is **S(k)** = a**C(j)** + **S(r)**, then A[k].FIRST = j, A[k].NUM = a, and A[k].NEXT = r. Since, for j be an element of **LCP(k)** we must have that **LCP(k)** − {j} is a least-cost partition of k − j, we have:

Proposition 2.3.1: At the end of the LCP algorithm, A[k].FIRST is the smallest integer in **LCP(k)**.

Proof: If A[k].NEXT = 0, then only one integer occurs in **LCP(k)**, and the result is clear. (In particular, this occurs if k is *simple* or if k was SET in PREMARK).

So assume at least two distinct j occur in **LCP(k)**. For each distinct j in **LCP(k)**, j is *simple* and **LCP(k)** − {j} is a least-cost partition of k−j. However, the recursive line of the definition of **LCP** must have been invoked for k, and must have selected some integer less than k (since k is not *simple*), and so must certainly have considered the smallest integer actually occurring in **LCP(k)**. But if the smallest was considered, it must have been selcted, since LCP chooses the smallest at each step.

Corollary 2.3.1.1: **LCP(k)** is generated in non-decreasing order. In particular, all occurrences of a given integer are consecutive, and therefore condensed.

In fact, this demonstrates that:

Corollary 2.3.1.2: Among partitions of n with equal and least cost, the LCP algorithm chooses the first in lexicographic order (when listed in sorted increasing order).

However, any partition of n, given in non-decreasing order, whether a least-cost partition or not, can be printed by the PRINT procedure outlined in time proportional to the number of distinct integers (partisands) therein, i.e., to its reduced height. We therefore have:

Proposition 2.3.2:

1. No partition of n, whether a least-cost partition or not, has reduced height $\geq (2n)^{1/2}$.
2. If S and T are two sub-multisets of **LCP(k)**, disjoint as sets of partisands, then $\Sigma_{s \in S} s \neq \Sigma_{t \in T} t$
3. If a_1, a_2, a_3, and a_4 are distinct elements of **LCP(k)**, then $a_1 - a_2 \neq a_3 - a_4$. In particular, differences between consecutive distinct integers in **LCP(k)** cannot take on the same value more than twice.
4. The reduced height of **LCP(k)** is at most $\log_2(k+1)$. Thus the complexity of PRINT(k) is O (log *k*).

Proof:

1. Let P be a partition of n, in which each of k distinct integers a_i, $1 \leq i \leq k$, is repeated $n_i \geq 1$ times. Then

$$n = \sum_{i=1}^{k} n_i a_i \geq \sum_{i=1}^{k} a_i \geq \sum_{i=1}^{k} i = \frac{k(k+1)}{2}.$$

   But then $k < (2n)^{1/2}$.
2. If the total cost of S ≠ the total cost of T, then the cost of **LCP(k)** could be lowered by replacing the more costly with the other. If total costs are equal, then by Proposition 2.3.1, the one with the smaller least entry would have been chosen.
3. Else $a_1 + a_4 = a_2 + a_3$.
4. Let r(**LCP(k)**) = R.

   Then each of the $2^R - 1$ non-empty subsets of $\{a_i\}_{i=1}^{R}$ must sum to distinct integers, of which $k \geq \sum_{i=1}^{R} a_i$ is the largest, whence $k \geq 2^R - 1$.

   Thus the number of distinct integers in **LCP(k)** is at worst O (log *k*), whence likewise the complexity of PRINT(k). On the other hand, it is clear that

$$C(a) = \begin{cases} 1, a = 2^i & \text{for some } i \\ \infty & \text{, otherwise} \end{cases}$$

   gives **LCP**$(2^r - 1) = 1, 2, 4, 8, \ldots, 2^{r-1}$, which has $R = \log_2(k+1)$.

Corollary 2.3.2.1: Determination and printing of the **LCP**'s of all integers from 1 to n is of worst-case complexity $O(n^2)$, and average complexity at worst $O(n^{3/2})$.

Proof: Determination of **LCP(n)** determines in the process the **LCP** of all smaller integers. Printing these **LCP**'s has complexity

$$\sum_{k=1}^{n} O(\log k) = O(n \log n) < O(n^{3/2}).$$

Thus **LCP(n)**, seen as an algorithm determining and printing the **LCP**'s of all integers between 1 and n, determines n 'pieces of information' and outputs them in no worse than $O(n^2)$ time.

3. FURTHER ANALYSIS OF THE ALGORITHM

3.1 The effect of monotonicity assumptions

When unit costs are monotonic or nearly monotonic, PREMARK becomes important, and the order of complexity of the LCP algorithm is lowered significantly. This occurs most dramatically if strict monotonicity holds, in which case this follows directly:

Proposition 3.1.1: If **U** is monotone increasing, then only 1 is MARKed, and everything is SET in PREMARK, and the complexity is thus O (*n*). If **U** is monotone decreasing, then everything is MARKed in PREMARK, and the complexity is likewise O (*n*).

What if U is monotonic except for essentially 'random' fluctuations? We show most of the savings available from monotonicity still apply in many cases.

Definition 3.1.1: A function f is **nearly monotonic** if there exist positive real constants **a** and **b** so that $f(m) \geq f(n)$ for all $m \geq a \cdot n + b$ (or $f(m) \leq f(n)$) for all such pairs m and n. f is **almost monotonic** if a can be taken as 1. We will use terms such as 'almost increasing' and 'nearly decreasing' in the obvious sense.

Proposition 3.1.2: If U is *almost increasing* with constant c, then

1. no more than the first **c** integers can be *simple*,
2. on average, fewer than $c^{1/2}$ will be,
3. at least $\lfloor \frac{n}{c} \rfloor$. integers, and an average of
$$\frac{1}{c} \cdot \sum_{k=1}^{c} \lfloor \frac{n}{c} \rfloor = O\left(\frac{n \log c}{c}\right),$$
integers will be SET during PREMARK.

Proposition 3.1.3: If U is *almost increasing* with constant **c**, then the average complexity of the entire LCP algorithm is at most
$$O\left(\max\left(n \log n, c^{1/2} \cdot n\left(1 - \frac{\log c}{c}\right)\right)\right).$$

Proposition 3.1.4: If **U** is known to be *almost increasing a priori*, and **c** is known, then, then the complexity of the SORT phase can be reduced from $O(n \log n)$ to $O(c \log c)$. Thus the complexity of the LCP algorithm is $O(nc)$ at worst, and $O(nc^{1/2})$ on average.

The situation for *nearly increasing* functions is almost as good:

Proposition 3.1.5: If U is *nearly increasing* with constants **a** and **b**, then **LCP(n)** has average complexity at most $O(\max(n \log n, (a+b)^{1/2} \cdot n))$

Functions which are essentially decreasing, however, are in most cases not so well-behaved: If **U** is *almost decreasing* with constant c, then $U(m) \leq U(1)$ for all $m > c$, and, for any m, at least one of {m,m+1,m+2,...,m+c−1} must be MARKed in PREMARK. However, the only non-simple integers which could possibly be SET in PREMARK are integers less than 2c.

Proposition 3.1.6: If **U** is *almost decreasing* with constant c then:

1. If PREMARK always leaves at least one integer between m and m + c unMARKed for each m ≥ c, then PART(n) has complexity between $O\left(\left(\frac{n}{c}\right)^2\right)$ and $O\left((n)^2\right)$
2. In such a case, PREMARK saves at least $O\left(\left(\frac{n}{c}\right)^2\right)$ work over the efficient implementation of PART without PREMARK.

Consideration of Example 2.1.1, restricted to n = 30, shows that *nearly decreasing* functions with $a \geq 2$ can exhibit very nearly worst-case behavior. However, if **a** and **b** are known *a priori*, and $a < 2$, then the algorithm suggested for that example at the beginning of section 2.1 will be more efficient than PART; a related algorithm may in fact be more efficient for many cases in which all that is known is that **U** is *nearly decreasing*. The corresponding set of equations formulation for an *almost decreasing* example with known **c** would be:

Definition 3.1.2: Least-cost algorithm for *almost decreasing* functions:

$$\begin{aligned} S(k) &= C(k) && , k=1 \\ &= \min\{\min\{C(i)+S(k-i)\}_{i=1}^{\lfloor \frac{k}{2} \rfloor}, C(k)\} && , 2 \leq k \leq 2c \\ &= \min\{\min\{C(k-i)+S(i)\}_{i=1}^{c}, C(k)\} && , 2c < k. \end{aligned}$$

Proposition 3.1.7: Assume **U** is *almost decreasing* with known constant **c**. Then the algorithm of definition 3.1.2 gives a least-cost partition for each integer k and has worst-case complexity $O(O(\text{PREMARK}) + nc)$.

Two final comments:

- First, the initial phases of the algorithm need not be used, if SORT is not required to discover monotonicity;
- Second, we still need not consider non-simple trial partisands.

Further, there exists an elementary $O(n)$ algorithm for determining whether a sorted list of unit costs is *almost monotone* with an arbitrarily specified parameter **c**.

3.2 Minimum complexity of an LCP algorithm

It is clear that any LCP algorithm will have to examine all of the input at least some of the time, since any one integer, and any pair of integers less than $\frac{n}{2}$, can occur in **LCP(n)** for some cost function **C**, whence any LCP algorithm is at least $O(n)$.

Further general analysis is difficult (since, for example, there exist sorting algorithms in restricted domains more efficient than $O(n \log n)$, if operations are not restricted to key comparison and swapping [9]). We can however show a lower bound on minimum complexity for any algorithm which proceeds by computing and comparing the costs of partitions in order to attain least-cost partitions for integers $1 \leq k \leq n$, even if the array **USORT.INDEX** can also be used.

Ex. 3.2.1: $O(n^2)$ best-case partition.
Let n = 4m + 1, and **USORT.INDEX** =

2m, 2m-1, 2m-2,...,3,2,1,2m+1,2m+2,...,4m,4m+1.

Then each integer from 1 to 2m is *simple*, but only 4m is otherwise SET by a PREMARK-type prepass (actually 4m-1 = 2m + (2m-1) is also known, but this is irrelevant, as we will show that no other **LCP** could be).

$$S(2m+1) = \min\{C(i) + C(2m+1-i)\}_{i=1}^{m},$$

where each of the alternatives must be considered. Suppose the partition selected is (1,2m). Then

$$S(2m+2) = \min\{C(i) + C(2m+2-i)\}_{i=2}^{m+1},$$

and again each of the possibilities must be considered. Again suppose (2,2m) is selected. Continuing in this fashion, we must consider

$$m + m + (m-1) + (m-1) + (m-2) + \dots + 2 + 2 + 1$$

$$= m(m+1) - 1 = O\left(\frac{n^2}{16}\right) \text{ different terms}$$

to determine **LCP**'s of integers 2m+1 through 4m.

But determination of **LCP**(4m+1) requires consideration of each possible decomposition

$$C(j) + S(4m+1-j), \text{ for } 1 \le j \le 2m,$$

so that all these $O(m^2)$ possibilities are considered by the algorithm.

To establish the lower bound, the possibility of a cutoff in the evaluation of the **S**(j) must be ruled out. We can however show:

Proposition 3.2.1: Given any pair of integers i and j with $0 < j \le i \le \lfloor\frac{2m+j}{2}\rfloor$, there is a cost function $\mathbf{C}_{i,j}$ with the **USORT**.INDEX permutation of the example above for which the **LCP** of each 2m+k, k ≠ j, is {k,2m}, and for which **LCP**(2m+j) is {i,2m+j−i}.

Theorem 3.2.1: Let **AP** be an algorithm which determines least-cost partitions for each integer from 1 to n, using only ranking of the costs or unit costs of using integers, and comparison of the cost of partitions with each other or with a current minimum. Then the worst-case complexity of **AP** is at least $\Omega(n^2)$

Proof: For n = 4m+1 fixed, each of the cost functions of proposition 3.2.1 has exactly the same **USORT**.INDEX permutation and the same COST permutation. But if any of the $O\left(\frac{n^2}{16}\right)$ terms of the example is not examined by **AP**, say **C**(i) + **C**(2m+j−1), there is a cost function $\mathbf{C}_{i,j}$ for which that would have yielded the least cost partition of 2m+j.

The example appears also to demonstrate a minimum $O(n^2)$ bound on the complexity of an algorithm which finds the **LCP** of n alone.

3.3 The LCP algorithm and the least-cost partition equation set

The techniques used to achieve reduced complexity in the LCP algorithm of definition 1.2.4 are most easily understood through consideration of the dependency graph and equation set [15] of the least-cost partition problem. The direct implementation of the initial algorithm of definition 1.2.1, instantiates the solution of an equation set with acyclic dependency graph [12, 15]. The savings of the LCP algorithm are threefold, namely:

1. the use of PREMARK,
2. the restriction to simplicity, and
3. the condensation of the equations as created for PRINT;

the use of the data structure (Fig. 1−1) makes possible the incorporation of all three improvements.

3.3.0.1 The use of PREMARK

Consider a system of "linear" equations in the form:

$$Q(k) = (R(i_1)+Q(j_1)) \downarrow (R(i_2)+Q(j_2)) \dots \downarrow C(k),$$

in which all R values are non-negative and whose dependency graph is acyclic. We call such a system an **acyclic min-sum equation set**. We can prune the equation set by dynamically determining the minimum constant and setting the corresponding value equal to that constant. The difficulty lies in the cost of updating information. Note, however, that any term in an equation of this type whose coefficient *R* is larger than the current constant (the updated *C*) of that equation can be discarded.

The work done by PREMARK can be seen, in some sense, as related to the above; it too discards equations based on constant and coefficient terms; it is also related to the minimum constant principle [15] and the solution procedure for triangular matrices/acyclic dependency graphs. However, PREMARK does not attempt to solve the entire system, but merely applies an initial step, with some additional dividends: Not only are the equations in which the initial constant dominates eliminated, but also some of those in which substitution of those initial constants will yield solved equations. PREMARK can thus be viewed as a standard technique for solution of equation sets, slightly extended, or as a technique applicable to min-sum equations, significantly restricted.

The resulting simplification of the equation set, though sometimes of small value, is sometimes very significant, at the cost merely of an inexpensive single $O(n \log n)$ sort of the data, without any updating of numerical values. Both this efficiency, and the extension to the integers SET, appear to depend heavily on domain structure, namely, the divisibility structure of the integers. Further, PREMARK is not quite an instance of the minimum-constant solution technique, relying on *unit cost* rather than *cost*. Integers marked *simple* in PREMARK need not have minimum *cost*, and PREMARK does not involve direct application of a min-op equation solution principle. Rather, the operation used by PREMARK is convex combination:

$$U(i+j) = \frac{i}{i+j}U(i) + \frac{j}{i+j}U(j),$$

and simplification relies on the fact that in **S**(k), the term **C**(i) + **S**(j) has j = k− i.

The utility of similar techniques would appear restricted to situations in which domain knowledge makes such a prepass or solution method as cheap to apply as in the least-cost partition problem, or as effective as we have seen it to be in the case of nearly-monotone unit cost functions. In general, we would like the cost of the prepass to be less than the average cost achievable by the algorithm without prepass, and to save on average an amount of work at least comparable to its cost, or else to be of particular use in situations actually likely to occur; three tests we have seen to be met by PREMARK in the least-cost partition problem.

3.3.0.2 The restriction to simplicity

The restriction of terms of the min operator to *simple* values, on the other hand, corresponds to the elimination of columns (corresponding to non-simple integers) in the equation-set 'coefficient' matrix. This is related to the elimination of terms whose coefficient is dominated by the corresponding constant, but does not appear to follow directly from such a procedure. In effect, it proposes elimination of terms whose eventual value will certainly be dominated by the eventual value of some other term, whose identity and value however may still be uncertain; perhaps it is most satisfactorily viewed as a use of *comparability* [15]. The availability of this refinement appears to depend highly on the nature of the partition problem and on properties of the integers; related refinements would also appear to be strongly conditioned on detailed domain knowledge.

3.3.0.3 Condensation of equations

Finally, condensation for PRINT can be viewed as partial solution of equations set aside for back-substitution; the economy arises from the propagation of these partial results and the assurance that a significant amount of such condensation will occur. Similar complexity savings from partially solving equations, though occurring differently and at a different point in the solution procedure, underlie improvements on Gaussian elimination and Allen-Cocke interval analysis in program data-flow analysis [1, 5, 8, 16, 18]. Although such saving too is domain-dependent, its applicability appears fairly wide, and some consideration of the possibility of such condensation of partial solutions may frequently repay investigation.

3.3.0.4 The data structure of the LCP algorithm

The data structure created can be viewed as a multiply-threaded list, linked not only by the integer-successor relation, but with each k linked to some i [with **LCP**(k) = FIRST•NUM + **LCP**(i)], and each *simple* j linked to the *simple* integers preceding and following it.

The INDEX and COST fields are inherent in any dynamic programming algorithm for a knapsack-type problem, although the INDEX field simply repeats address information. PREMARK initializes some portions of this data structure, and the MARK and SET fields allow for the graceful merge of PREMARK information with information being developed by PART. NXTMK allows access to the *simple list* at a cost proprtional to its length, and is needed for average-case improvement. The FIRST, NUM and NEXT fields are used for condensation and thereafter by PRINT (although any one of them could be computed on the fly from the other two), and their presence is responsible for the improvement in the efficiency of the PRINT routine.

I. Example of the execution of algorithm LCP

Ex. I.0.1: Let n = 13, and the input **C** array be
(9, 14, 24, 30, 33, 42, 46.9,
64, 67.5, 72, 75.9, 87.6, 92.3).
Computing the **U(k)** = $\frac{C(k)}{k}$, **U** =
(9, 7, 8, 7.5, 6.6, 7, 6.7,
8, 7.5, 7.2, 6.9, 7.3, 7.1),
and the stable SORT procedure gives **USORT.INDEX** =
(5, 7, 11, 2, 6, 13, 10, 12, 4, 9, 3, 8, 1).

Applying PREMARK:
Initially, LEAST = 14, and j_0 = 5. Thus 5 is MARKed and 10 is SET, and LEAST set to 5.
Then neither 7 nor 11 is less than 5, but 2 is, so s is MARKed and 4 SET, and LEAST set to 2.
Finally, none of 6, 13, 10, 12, 4, 9, 3, or 8 are less than 2, but 1 is, so it is MARKed.
See Fig. I-3 for the appearance of the array A at this point, and Fig. I-4 for the appearance of array A at the end of the algorithm.

Figure I-1: Execution of PREMARK

A POLYNOMIAL DETERMINATION OF THE MOST RECENT PROPERTY IN PASCAL-LIKE PROGRAMS

Dieter Armbruster

University of Stuttgart, Institut für Informatik
Azenbergstr. 12, D-7000 STUTTGART 1
West-Germany

0. ABSTRACT.

If a compiler knew which procedures (or functions) of a program fulfill the most recent property it could produce more adequate code. This stands in contrast to the prevailing tacit worst case assumption on the non-most-recent behavior of those procedures being passed as parameters (for all other procedures this property holds trivially). This old and well known phenomenon will attract new attention with the development of new computer architectures - such as RISC.

We present a method which is polynomial in the program length for deciding this property in Wirth-Pascal-like programs by exploiting the inherent restriction concerning formal procedures. It is this restriction that enables us to

1. reduce (polynomially) the most-recent problem to a reachabiltiy problem for certain procedures and
2. solve this reachability problem with the polynomial algorithm which we present.

This polynomial result for such programs is rather unexpected since for programs in slightly less restricted languages like ISO-Pascal the problem is still decidable but with a complexity as bad as P-space complete.

1. INTRODUCTION

As new computer architectures emerge, especially those with reduced but faster instruction sets (RISC [PA85]), the use of knowledge about the run time behavior of procedures (and functions) in block structered languages like Pascal attracts new attention. While for the present comfortable (but slow) microprogrammed machine instructions (e.g. for a subroutine call) it does not seem to be promising to distinguish between most recent (mr) and non-mr or recursive and non-recursive procedures, this situation changes for reduced, uncomfortable (but considerably faster) instruction sets, since these call for very sophisticated code optimizers. This means that a general worst case assumption on the run time behaviour of procedures (i.e. being non-mr resp. recursive) can no longer be afforded.

Now, we give (informal) definitions of the necessary notions: We say that a procedure P is actually mr (i.e. it fulfills the most recent property) iff

- P is declared locally within procedure Q (Q is the static predecessor of P, Q=SP(P)) and
- in the run time stack which consists of the frames (=activation records) of the called but not yet terminated procedures the static pointer of P's frame always refers to the downwards closest - i.e. most recent - frame of Q.

A program is said to be mr iff every (nested) procedure in it is so.

The non-mr-ness of the following Pascal-like program fragment is revealed by looking at P's static chain in the snapshot of the run time stack which was taken after the execution of several recursive calls of Q and during the subsequent call z(), (i.e., Some_Cond was false). If P now referenced some variables local to Q, they would be located in the second frame of Q (from top), not in the most recent one.

```
program PROG;    ...
 procedure Q( z: proc() )
  begin
  procedure P()  begin ... end
  if Some_Cond then Q(P);
  z();
  end
 Q(A);  ...
```

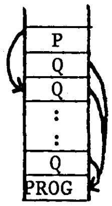

Fig. 1.a: A non-mr program fragment with snapshot of run time stack.

Unfortunately this actual property is in general unsolvable - even for I/O-free programs (because of the ability of such programs to simulate any Turing machine). We thus have to be content with an approximation called formal most recent property which is defined on the formal execution tree of a program schemes [WI82, LA73] rather than on the runtime stack (see below).

In such a scheme (we will call it nevertheless a "program") all data, labels, and the related statements are removed (to provide a better decidability basis) leaving only (arbitrarily nested) procedure declarations with parameters of type procedure and statement parts (body minus local procedure declarations) with zero or more call statements (see Fig.1.b).

If Q = SP(P) (P local in Q) then every call to Q generates a modified copy of the declaration of P by replacing those global formals in the body of P which are in Q's parameter list by the actuals of this call, according to the copy rule of block structured languages. We will distinguish among those copies by appending a superscript s≥0 to P. Now, s can be interpreted as a static pointer to the call of that copy of Q that generated this copy P^s of P.

The static sequence of the call statements within a procedure is made irrelevant by considering them simultaneously, i.e. each call in the statement part of procedure A creates node α_{i+1} on level i+1 as successor of node α_i=A(..) on level i. The label of this successor node is formed by replacing all formals in the call statement by non-formal

CH2345-7/86/0000/0648$01.00 © 1986 IEEE

names of copies of procedures - according to the semantics of Algol or Pascal. Starting this construction with the outermost parameterless procedure α_1=PROG (mainprogram) we end up with a (possibly infinite) formal execution tree E(PROG) of our program(-scheme) PROG:

```
PROG:
{ procedure A()  {  }
  procedure Q(z: proc())
     { procedure P()  {  }
       Q(P)
       z()
     }
  Q(A)
}
```

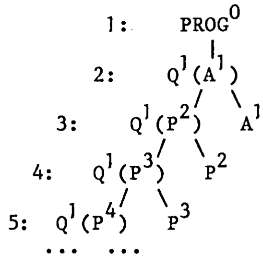

Fig.1b: The non-mr program(-scheme) of Fig.1a and its formal execution tree.

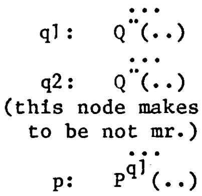
We say further that a procedure P in PROG is formally reachable (recursive) iff there is a branch in E(PROG) which begins at PROG and along which an arbitrary copy $P^{''}$ of P is called at least once (twice). ($^{''}$ denotes a "don't care" static pointer.)

A procedure P formally calls procedure Q iff there exists a subbranch (.., $P^{''}$(..), .., $Q^{''}$(..), ..) in E(PROG).

Now, P is formally mr iff the subbranch between each call to P^{q1} on level p and its static predecessor $Q^{''}$ on level q1 contains no other call to a copy $Q^{''}$. Obviously, P in fig.1b is not mr.



It should be clear by now that formal mr-ness implies the actual but not vice versa (the call that destroys formal mr-ness may never get actually executed!).

By ressorting to this approximation, what do we win as to decidability?

The answer depends on the mode depth MD (type depth) of the procedure names. In fig.1, MD(z)=1, because the call "z()" has no procedure as parameter. If the call would have read "z(P)", then MD(z) would be 2, since MD(P)=1. The specifier of z would then look like "z:proc(proc))". In general:

The mode depth of a formal or non-formal name x which has no parameters when being called is defined to be 1. Then, inductively, the mode depth of a name y which is called as y(..x_i..) is MD(y) = max(MD(x_i))+1, and MD of a program PROG is MD(PROG) = max(MD(P_i)), with P_i being the procedure names.

For finite mode (=FM, e.g. ISO-Pascal [ISO81]) programs MD(P_i) is finite, whereas for FM2 (e.g. Wirth-Pascal) programs MD(P_i) $\leq$ 2.

Note that in FM-programs all formal parameters can therefore be specified completely, as is done, for example, in ISO-Pascal. Thus, a call like P(P) which is legal in an infinite mode allowing language (e.g. Algol60) would be syntactically illegal in a finite mode language, since the formal parameter of P cannot be specified completely (without resorting to recursive types).

We can now give a brief survey of the history of the mr-phenomenon, thereby answering our still open question on the decidability:

In the sixties it was widely (erroneously) believed (at least by Dijkstra) that the static link of an activation record points "to the most recent ... activation of the first block that lexicographically encloses the subroutine" [DI67], i.e., that every block-structured program is mr.

In 1972, McGowan pointed out this "most recent error" and showed the advantages of a mr-based runtime stack organization with all static pointers being redundant. Furthermore he gave a rather coarse sufficient condition for a compiler to determine whether a program is actually mr [MG72].

In [KA74] it was shown that formal mr-ness of a program is decidable - even for infinite mode programs - which is astonishing if contrasted with the negative result for formal reachability of procedures in infinite mode programs [LA73]. (For finite modes formal termination and hence both, formal reachability and recursivity is decidable [DF79,AH85] - though with complexity "complete in deterministic exponential time" [ME85].)

As a consequence, formal mr-ness of a particular procedure P which is based on the reachability of copies of P is also undecidable in infinite mode programs. The positive result for programs is quantified in [WI83] to be unfortunately no better than P-Space complete for both finite and infinite mode programs.

However, we obtain a more encouraging result - namely a polynomial one - as shown in the sequel, if we restrict ourselves to MD $\leq$ 2, e.g. to Wirth-Pascal, where a formal procedure call can no more have actual parameters (remember, the only parameters we deal with are of type procedure) whereas a non-formal call can have formal and non-formal actual parameters - as before.

Now, what is our problem?

If we want to know whether P local to Q is mr we have to check the formal execution tree for a non-mr situation as in the definition. But how deep do we have to search for it? FM2-programs reward us with a pleasant property which we will call "permeability" (section 2), that allows us to call off the search on a branch after having encountered P^q, where q is the level of the first call to a copy of Q on that branch. In section 3 we present a transformation that reduces the question for mr-ness of P to a reachability problem, which is solved in section 4 by an O(n^3) algorithm. (Whenever possible we omit the attribute "formal".)

2. PERMEABLE PROGRAMS

Consider the following figure with MD(EXAMPLE2)=3:

```
EXAMPLE2:
{ procedure Q(x,y: proc(proc(),proc()), z:proc())
    { procedure P()  {  }
      x(P,z)
      Q(y,x,P)
    }
  procedure A(t,u: proc())  { u() }
  procedure B(v,w: proc())  { v() }
  procedure C()  {  }
  Q(A,B,C)
}
```

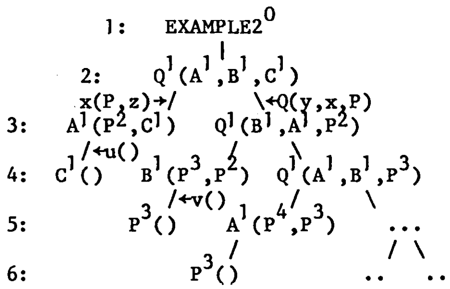


Fig.2: A non-permeable program with MD(EXAMPLE2)=3.

While call node 2: $Q^1(..,C^1)$ has $C^1()$, its third actual, as successor this is not true for 3: $Q^1(...,P^2)$. This possible "constipation" for MD≥3 is the reason for the exorbitant intractability of all interesting calling behavior problems. Therefore we exclude it for permeable programs:

Definition: If the i-th actual of a call to an arbitraray copy of a procedure Q is applied (i.e. either called or passed on as parameter) further down on a branch of the tree, then in a permeable program the i-th actual of any other (possibly different) copy of Q is applied as well.

This – at first glance – exotic and arbitrarily defined property is inherent to all FM2 programs – as can be proven by means of the following lemma which says that if we reach P^t, which has its static link passing via α_q (we write $t{=}{\rightarrow}q$), after a call to an arbitrary copy of Q at level q ($\alpha_q=Q^{\cdot\cdot}(..)$), then we have an analogous situation for any other call $\alpha_r=Q^{\cdot\cdot}(..)$ elsewhere in the whole tree:

Lemma 1: Let P and Q be procedures in program PROG with MD(PROG)≤2. If there exists in E(PROG) a subbranch (omitting parameter lists)

$$B = (\alpha_q=Q^{\cdot\cdot}=A_0{}^{a0}, ..., \alpha_{q+i}=A_i{}^{ai}, ..., \alpha_{q+n}=A_n{}^{an}, \alpha_p=P^{\rightarrow q})$$

with $p=q+(n+1)$, $n\geq 0$, and there exists further a node $\alpha_r=Q^{\cdot\cdot}$, then

(1) there also exists a subbranch

$$B' = (\alpha_r=Q^{\cdot\cdot}=B_0{}^{b0}, ..., \alpha_{r+i}=B_i{}^{bi}, ..., \alpha_{r+n}=B_n{}^{bn}, \alpha_{p'}=P^{\rightarrow r})$$

with $p'=r+(n+1)$,

(2) $A_i = B_i$, i=0..n, and

(3) if $aj{=}{\rightarrow}q$, then $bj{=}{\rightarrow}r$, j=1..n.

Note: The existence of α_p and α_q implies:

q: $Q^{\cdot\cdot}(..) = SP^k(P^{\rightarrow q})$, $k=p-q$, and hence $Q = SP^k(P)$.

The proof is a lengthy induction on the procedures A_1, .., A_n between Q and P, following the construction rules for the tree. (The complete proofs of the lemmata and theorems would not fit into this paper; they should appear elsewhere).

Lemma 1 is used in Theorem 1 and in the next lemma:

Lemma 2: Each program PROG with MD(PROG) ≤ 2 is permeable.

Proof: We are given

$$(\alpha_q=Q^t(..A^a..), ..., \alpha_p = P^s(..), \alpha_{p+1} =..A^a..), p\geq q,$$
and $\alpha_r = Q^{t'}(..B^b..)$ in E(PROG), MD(PROG) ≤ 2.

We show that

$$(\alpha_r=Q^{t'}(..B^b..), .., \alpha_{p'}= P^{s'}(..), \alpha_{p'+1}=..B^b..)$$ exists.

Let w be the formal being replaced by A^a and B^b in α_q and α_p resp. Then α_{p+1} and $\alpha_{p'+1}$ are created by the statement ..w.. in P according the two cases:

- If w is locally formal then P=Q, and w is simply replaced by B^b to build α_{p+1}.
- If w is globally formal then $s{=}{\rightarrow}q$ together with α_r form the hypothesis of lemma 1 giving us $\alpha_{p'+1}$ = ..B^b.. .

We will make extensive use of this lemma in the correctness proof of our algorithm in section 4 (of the complete paper).

Now, let's look back to EXAMPLE2 in fig.2 which shows us that for programs with MD=3 the non-mr-ness of a procedure (here P) is not necessarily revealed by the first call to Q (in fact, here it is the second on level 3, the fourth on level 5, etc. on the subbranches ..–Q–Q–A–P. Of course, by enlarging the rotating parameter list of Q this event could be placed anywhere down the tree).

This messy situation is cleared by the following theorem which assures that in FM2 programs non-mr-ness is detected using the first call to Q as reference:

Theorem 1: Let P and Q be procedures of program PROG with MD(PROG)≤2 and Q=SP(P). P is not mr iff there exists a subbranch in E(PROG)

(1) $B = (..., \alpha_i=A_i{}^{\cdot\cdot}, ..., \alpha_{q1}=Q^{\cdot\cdot}, ..., \alpha_{q2}=Q^{\cdot\cdot}, ..., \alpha_p=P^{q1}, ...)$,

(2) and $A_i\neq Q$, $0\leq i<q1<q2$, A_0 = PROG.

Proof: The right-to-left direction is trivial (definition of mr-ness). For the other direction we only have to show (2) which is an application of lemma 1.

It is this theorem that crunches the intractable (P-space-complete) complexity of the decision problem and makes it managable by means of the following sections.

3. TRANSFORMATIONS

As a result of the previous section we can concentrate on the first call to a copy of Q in, say, $\alpha_q = Q^{\cdot\cdot}(..)$ in each branch during our nondeterministic search for a non-mr situation. From α_q on we look for a second (recursive) call to $Q^{\cdot\cdot}$. It's only after such subsequent calls to $Q^{\cdot\cdot}$ that we are interested in the reachability of P^{q1} – a copy of P the static predecessor of which is α_{q1}.

Now, P is mr iff such a P^{q1} is unreachable.

3.1 Reducing calling to reachability

The key tool to achieve this is a reduction of the problem "does A call B?" to "is B' reachable?", since for reachability we have a polynomial algorithm.

The reduction idea is simple:

After having encountered a call to a copy of procedure A in a branch during a nondeterministic search through the tree we have to change some "state" in order to memorize this event and to be ready for any subsequent call to a copy of B (which would have beeen ignored up to now). To implement this state of change we duplicate each declaration of a procedure Q(..x..) to get the pair: procedure Q1(..x1.., ..x2..) and Q2(..x1.., ..x2..) on the same nesting level as Q. The call ids in the statement parts of Q1 and Q2 receive the suffix 1 and 2 resp., except for A1 which has only call ids with suffix 2. The actual parameterlists get duplicated analogously to the formal ones. Note that the mode depths are not changed by this transformation.

Now, let's follow a branch BR and its transformed BR1, starting at PROG resp. PROG1: On our way to reach the first $A^{\cdot\cdot}$ and $A1^{\cdot\cdot}$ all ids in BR1 have suffix 1. It is directly after $A1^{\cdot\cdot}$ that the suffix switches to 2 and remains 2 for all successors of $A1^{\cdot\cdot}$. So, iff there is a call to $B^{\cdot\cdot}$ in BR1 we must reach $B2^{\cdot\cdot}$. Now the function of the duplicated parameterlists becomes clear: they make the ..2-procedures statically available when needed. This transformation T_A is specified as an attributed grammar in the final paper; here we demonstrate it by applying it to procedure P (i.e. T_P) in a didactical modification of the program in fig.1b:

```
PROG:                           PROG1:
 { procedure A(x)                { procedure A1(x1,x2)
     { A() }                          { A1() }
                                   procedure A2(x2)
                                      { A2() }

   procedure Q(z)                  procedure Q1(z1,z2)
     { procedure P()                  { procedure P1()
          { P(z) }                         { P2(z2) }
                                        procedure P2()
                                           { P2(z2) }

        Q(P)                            Q1(P1,P2)
        z()                             z1()
                                      }
                                   procedure Q2(z2)
                                      { procedure P2()
                                           { P2(z2) }
                                        Q2(P2)
                                        z2()
     }                                }
   Q(A)                            Q1(A1,A2)
 }                               }
```

Fig.3: PROG1 = T_P(PROG)

Note: 1. We realize that within ..2-procedures we do not need any ..1-names since they can never be used. Therefore we simplified the transformation which now yields a worst case (all n procedures in PROG nested in each other) of $O(n^2)$ procedures in PROG1 – as opposed to $O(2^n)$.

2. Sometimes we want to distinguish (for didactical reasons) between procedures bearing the same name (as a result of the transformation). We do this by appending to them – seperated by dots – the names of their surrounding procedures (inside out) until they become unique.

We are now ready to make a theorem out of it:

Theorem 2: Procedure A in program PROG (indirectly) calls procedure B iff
B2 in PROG1 = T_A(PROG) is reachable.

Proof: The proof is a formalization of the mechanism: it takes an arbitrary branch BR and analogously constructs its transformed BR1 by induction on the different cases that may arise: a successor may be called by a nonformal, local formal, or global formal statement. Then, if we are about to construct a node in BR with a call to a copy of B – after having previously constructed a node with a call to a copy of A, we are in BR1 within a ..2-procedure and about to construct the node $B2^{\cdot\cdot}(..)$.

For the other direction, a branch BR1 containing $B2^{\cdot\cdot}(..)$ is transformed back to BR with the inverse transformation and, again by induction, it is shown that BR then must contain both, a call to a copy of A and B.

3.2 Reducing mr-ness to reachability

In order to look for the first occurence of some copy of Q=SP(P), we apply T_Q to the program to be analyzed: If then Q2 is reachable, we know there exists (at least) a second (recursive) call to Q on some branch in the original tree.

Now, we want to know whether this Q2 (indirectly) calls P2.Q1, i.e. SP(P2)=Q1, which would violate the mr-ness of P. This is accomplished by a second application of the transformation with respect to Q2, i.e. T_{Q2}, which takes P2.Q1 into P22.Q11 – if it shows up (the second "2" in the suffix stems from the fact that P2 is called after the suffix switching Q2 whereas the call to Q11=SP(P22) occurs before Q2 which explains the second "1").

It should be clear by now, that and why the following theorem holds (s. fig.5):

Theorem 3: Let P and Q be procedures in PROG, with MD(PROG)≤2 and Q=SP(P).
P is mr iff P22.Q11 in PROG11 = $T_{Q2} \circ T_Q$(PROG) is unreachable.

	q1:		q2:		q3:	p:	p1:	p2:	
	.. Q	.. A	.. Q	.. B	.. Q	.. P^{q1}	.. P^{q2}	.. P^{q3}	..
T_Q:	.. Q1	.. A2	.. Q2	.. B2	.. Q2	.. $P2.Q1^{q1}$	.. $P2.Q2^{q2}$	.. $P2.Q2^{q3}$	..
T_{Q2}:	.. Q11	.. A21	.. Q21	.. B22	.. Q22	.. $P22.Q11^{q1}$	.. $P22.Q21^{q2}$	.. $P22.Q22^{q3}$	..

Fig.5: Transformation of a non-mr situation in an execution tree (to be read from left to right).

4. THE ALGORITHM FOR CALCULATING REACHABILITY

We now need an efficient method to calculate the reachability of a specific procedure, preferably only by inspecting the program text - without constructing the execution tree. Such a method is well known and it computes what is sometimes called the "potentially" reachable procedures. But unfortunately they form only a (less exact) superset of the formal reachable ones [*KL*74, *WA*76].

The method keeps a set of actuals for each formal parameter x, being continuously updated during (in general several) passes through the program: wherever a new actual is found on the position of x it is simply added to the set.

Since no static information is used it is little surprising that this method is less accurate than one operating on the tree. However, the following algorithm is based on the above described method, and yet it yields exactly the formal reachable procedures if applied to FM2-(Wirth-Pascal-)programs (in fact it is only applicable to such programs).

This means: for FM2-programs formal and potential reachability coincide!

Let P be the set of procedures in program PROG, and
X the set of all formal parameters in PROG,

then $I \subseteq P \times X$ is the <u>insertion relation:</u>
A I x <==> A is inserted for x.

$R \subseteq P$ is the <u>reachability relation:</u>
R(A) <==> A is reachable.

```
Step 1: Initialization ($I$ and $R$ viewed as boolean
        arrays): $I$, $R$ := "false"; $R$(PROG) := "true".
Step 2: For all reachable procedures A, i.e. those for
        which $R$(A)="true", do:
  Step 3: For all statements stm in the statementpart of
          A do one of the following three cases depending
          on the form of stm:
    Step 4a: stm = B(..D..), with the nonformal actual D
             on the position of y:
             $R$(B) := D$I$y := "true".
         4b: stm = B(..z..), with the formal actual z on
             the position of y:
             $R$(B) := "true".
             Q$I$y := Q$I$y $\vee$ Q$I$z, for all Q $\in$ $P$.
         4c: stm = y():
             $R$(Q) := $R$(Q) $\vee$ Q$I$y, for all Q $\in$ $P$.
Step 5: If $R$ or $I$ has been changed in step 2 then go back
        to step 2.
Step 6: Halt.
```

Complexity considerations:

If n is the number of procedures in the program (= $|P|$),
s the number of statements of the longest statement part, and
f the number of formal names in the program (= $|X|$),
This yields an overall complexity of $O(s*f^2*n^3)$.

The correctness of this algorithm is stated in our last theorem:

<u>Theorem 4:</u> P is formally reachable iff R(P) holds.

<u>Proof:</u> The left-to-right direction is shown with an induction over a branch containing P''(..). While constructing this branch, we observe the changes that occur to I and R. The other direction uses an induction over the passes through step 4, where R and I are affected.

Now we are ready for our final result combining theorem 3 and 4:

<u>Theorem 5:</u> Let P and Q be procedures of a (FM2-)program PROG, with MD(PROG)≤2, Q=SP(P) and PROG11 = $T_{Q2} \circ T_Q$(PROG). Then
P is not mr iff R_{PROG11}(P22.Q11) holds.

Note: If an original program has n procedures, then PROG11 has at worst $O(n^{2*2})$ procedures. Since the transformation itself is essentially a parsing mechanism with output (the transformation is implemented by means of solely synthesized attributes) it can certainly be done in O(n*f*s). Then R is calculated in $O(s*f^2*n^{4*3})$, i.e. polynomial.

However, if we restrict the nesting depth of procedures (to an arbitrarily high limit), our transformation will then yield only O(n) new procedures; a further restriction on the length of parameter lists and statement parts then allows to compute R in $O(n^3)$.

5. CONCLUSION

We presented a polynomial method that determines whether or not a procedure P behaves most-recently and - applied to all nested procedures - whether the whole program behaves so. Strictly speaking, we were dealing with the weak mr-property; an extension to the strong one (where mr-ness is required not only for the static predecessor but rather for all procedures in the whole static chain) is straightforward but didactically less useful.

We do hope that these results stimulate a reconsideration of an old phenomenon.

FRAME CACHING IN MENU-DRIVEN VIDEOTEX SYSTEMS

Seetha Lakshmi, Seraphin Calo and Piyush Gupta

IBM T.J. Watson Research Center
Yorktown Heights, N.Y. 10598

Abstract

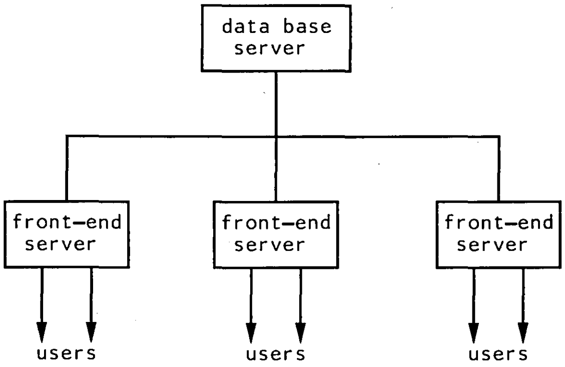
The concept of frame caching in Videotex systems is explored. Caching of frames is expected to improve the response time for retrieval requests. The level of improvement, however, is a function of the cache hit ratio. In this paper, by modelling the user activities on the data base frames, we obtain an analytic expression for cache hit ratio. The analytic solution provides exact results for simple user models, and a tight upper bound for complex models of user behavior. In addition, we use a simulation methodology to study the impact of different parameters on the hit ratio. Our studies reveal that a considerable amount of locality of reference exists among menu-driven videotex users.

1. Introduction

A Videotex system is a medium for delivering information in an effective, user friendly, and relatively inexpensive manner to a large user population. It combines color, graphics, and text to present information in an attractive manner. It provides a unified interface between multiple data bases and a wide variety of user terminals. The interface is simple enough to enable naive users (non-dp professionals) to easily use the services offered. These services range from retrieval services for information such as general news, entertainment listings, financial news, airline schedules, etc., to transactional services such as banking and home shopping.

The back bone of a Videotex system is a powerful data base management system (DBMS). The users access the DBMS through a high level, user friendly interface rather than a traditional data base query language[2,16,18]. An important factor, besides user interface, that must be considered in designing a successful Videotex system is its ability to provide very fast responses to user requests, and to support a large number of users. One of the design strategies that is expected to improve the response time is frame caching.

A Videotex frame is defined as a logical unit of information that can be displayed on a user terminal. A Videotex data base is a collection of frames pertaining to a specific topic. The Videotex system maintains several such data bases. Frame caching is a mechanism by which a subset of the most frequently accessed frames (across all users) is stored in a cache external to the DBMS. For caching to be effective, the cost of retrieving the frame from the cache should be less than the cost of retrieving it from the DBMS.



A Videotex System

Figure 1

Figure 1 represents a conceptual architecture for a Videotex system that supports a large number of users. It consists of a data base server which maintains the Videotex data bases, and a set of front-end communication/distribution servers, which connect the user terminals and the data base server. The front-ends act as terminal concentrators, provide session and terminal management functions, and perform simple user commands which do not require access to the data base server.

Typically, when a front-end receives a frame retrieval command from a user, it performs some preprocessing (to resolve the frame id, data base id, etc., if possible) and then sends a message to the data base server to retrieve the appropriate frame. When frame caching is in effect, frames retrieved from the data base server are retained in a cache maintained by the front-end. Retrieval commands from the users are sent to the data base server only if the required frame is not already present in the cache. Since, for some requests, this scheme avoids the communication delay and processing delay involved in accessing the data base server, it is expected to enhance the average response time perceived by the users. Also, by sending only some of the requests to the data base server, the load on the data base server is reduced. This, in turn, enables the data base server to support more users, thus increasing the overall

CH2345-7/86/0000/0655$01.00 © 1986 IEEE

capacity of the system. The expected performance of a Videotex system with frame caching is evaluated in [7].

The performance improvement is proportional to the cache hit ratio (ratio of the number of requests that found the required frame in the cache to the total number of requests served by the front-end processor). This paper attempts to determine the range of hit ratios that is achievable in real Videotex systems.

In Section 2, we discuss the related work on caching in conventional programming environments and data base transaction processing environments. In Section 3, we describe the access mechanisms prevalent in Videotex systems; we also elaborate on possible organizations of frames in the data base, and the user behavior. In Section 4, we develop an analytical model to evaluate the cache hit ratio. Numerical results based on the analytical model are compared with simulation results. The simulation methodology used to study the impact of various parameters on cache hit ratio is described in Section 5. The results are presented in Section 6.

2. Previous Work

No previous work has been reported on cache studies in Videotex systems. Exhaustive studies of cache memory performance in conventional programming environments can be found in [3,14,15]. Program behavior, which influences the effectiveness of cache memory, has been well studied and understood. It has been established that programs exhibit strong locality, i.e., over a short period of time most accesses tend to reference only a few pages, and these pages constitute a very small subset of the program's total set of pages. Such strong locality enables one to achieve very high hit ratios with very small cache memory sizes. Techniques such as structured programming and loop constructs help achieve this strong locality.

The analog of program behavior in the realm of conventional DBMS is transaction behavior. There has been very little work done in modelling the behavior of data base transactions. Authors [4,9] have studied data reference traces from specific IMS (a hierarchical DBMS) applications and characterized the transaction behavior. An interesting observation made from these studies is that within a single transaction there is very little rereferencing of data; however, data referenced by one transaction is often referenced by other transactions as well. It appears, therefore, that in a DBMS such as IMS, locality is mostly due to inter-transaction rereferencing. Whether inter-transaction locality will improve cache hit ratio will depend, among other things, on the cache management policy, and the scheduling of the transactions. Discussions on alternate cache management schemes for DBMS are found in [10].

3. Videotex Data Bases and Users

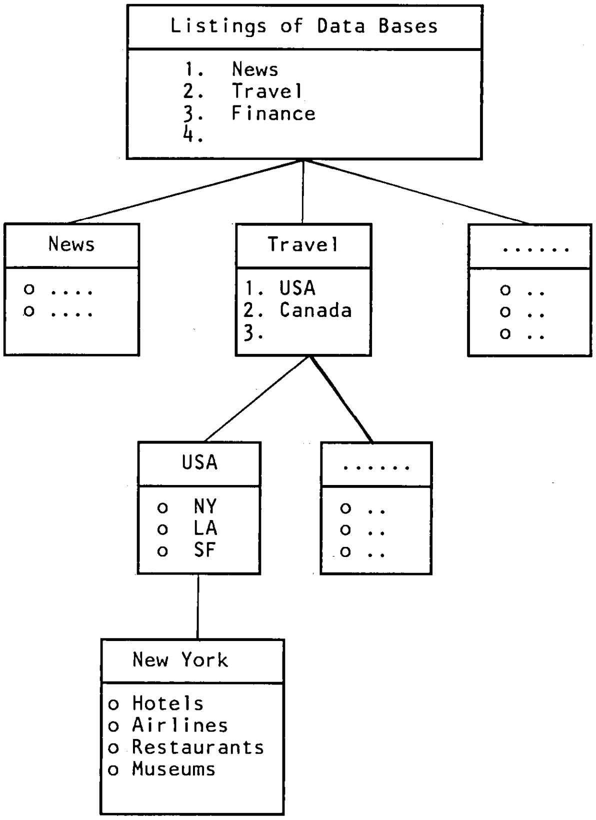
In this section, we characterize the organizational structure of frames and the behavior of users in Videotex systems. Such a characterization enables us to systematically study cache performance.

3.1 Data Base

As mentioned in Section 1, Videotex data bases consist of a collection of frames. The organization of these frames within the data bases and the types of retrieval commands to be supported are interdependent. These are key issues in designing a successful Videotex system. Studies by Videotex researchers are underway to establish the types of retrieval requests that are efficient and powerful, yet easy to learn/use by non-dp professionals [11,17]. Currently, two types of retrieval commands, menu-driven and key word based, are widely supported.

In a menu-driven system, the data base is organized as a tree with one frame at each node. The frames which guide the users are known as *menu frames*. The frames which contain the information sought by the users are called *information frames*. Information frames are located at the leaf nodes of the tree while menu frames are located at the intermediate nodes. Users traverse the tree to view the various frames. They are presented with a series of menu frames which guide them to the information frame of interest. Let us consider an example where a user is interested in some travel related information. The first frame displayed to the user will be a menu frame that resides at the root of the tree. This frame lists the various categories of information available on the system (see Figure 2). Suppose the user selects a menu choice corresponding to travel service. In response, another menu frame containing the information providers logo, categories like domestic travel, foreign travel, etc., will appear on the user's terminal. The user can make further selections based on city, hotel, airlines, etc. Thus, with very few key strokes, the user is guided towards the information of interest.

In a key word based retrieval system, tree traversal by the user is avoided. The users specify key words which succinctly describe the information required. The system searches the whole data base and displays the frames containing the specified key words. While key word based systems may be convenient to use (for experienced users) they have some inherent drawbacks with today's technology. First, a list of key words has to be distributed to the users (perhaps akin to telephone directory distribution). When the list gets frequently updated, distributing most recent versions could become a problem. Second, although it is a simple matter to search the data base for the occurrences of the key words, as the number of data bases and their sizes get larger, the search can consume most of the processor's capacity. A poor choice of key words will also result in wasted processor capacity. On the other hand, the processing requirement in a menu-driven system, which lists only a limited number of selections, will be significantly less. Therefore, while the experienced users may profit from the use of key word



A Tree Structured Data Base

Figure 2

based retrieval commands, inexperienced users may actually achieve a higher level of productivity with menu-driven commands. Efficient methods of structuring the data bases and providing both types of commands are still open research problems[5,13].

In this paper, we study frame caching in the context of menu-driven retrievals. We further limit our attention to tree structured data bases. In reality, the data bases may not have a pure tree structure; there may be multiple links to a given frame. We conjecture that data base structures containing multiple links to a frame will provide better hit ratio than pure tree structures because the probability of several requests fetching the same frame increases. Hence, compared to other structures, our results based on tree structure can be interpreted as a lower bound on cache performance.

In our model, each data base is characterized by two parameters: N, the number of levels in the data base tree and K, the number of choices in each menu frame. The information frames are located at the leaf nodes (level N) and the menu frames are located at the intermediate nodes (levels 1 to $N-1$). The level 0 frame corresponds to the root node which lists the available data bases in the system. Each node representing a menu frame has K children. The parameters N and K completely describe the data base organization. The total number of frames in the system is M.

3.2 User Behavior

Users are assumed to have independent identical behavior, i.e., a user's entry into the system and subsequent frame selections do not depend on the behavior of other users; however, the frame retrieval patterns of all the users are statistically identical. By statistically identical we mean: if several users retrieve a large number of frames, the probability p_{ij} of selecting frame j while viewing frame i (for all i and j) has the same distribution for all users. (It is possible to have models of user behavior where different groups of users have different p_{ij} values. Such models are not considered here.) Users traverse the Videotex data base tree as discussed in Section 3.1. While viewing any of the frames, a user leaves the system with probability p_0 , and views another frame with probability $(1 - p_o)$. The next frame chosen depends on the probability matrix p_{ij}. In Sections 4 and 5 we consider different p_{ij} matrices.

4. Analytical Model

In this section, we develop analytical models to evaluate cache performance. For simple user behavior patterns, the analytical model provides closed form expressions for cache hit ratio. As the user behavior becomes more complex, a closed form expression is no longer possible; instead, it requires an algorithmic evaluation. One of the limitations of the analytical model is that it does not explicitly consider the dynamics of cache management policies. It assumes the existence of a perfect replacement policy that retains the optimal set of frames in the cache. i.e., the replacement policy is considered to have absolute knowledge of future frame references. In reality, replacement decisions are not necessarily optimal since they are based on the past history of user references. Hence, the results from the analytical model should be considered an upper bound on the cache performance. Comparison with simulation models (which capture the dynamics of cache behavior) shows that this is indeed true, and that the analytical model can be confidently used for establishing bounds on cache performance. In the remainder of this section a general formula for hit ratio is obtained and the hit ratios for different user behavior patterns are evaluated. The analytical results are validated through a simulation.

To obtain an analytic expression for cache hit ratio, we model each frame in the data base as a separate service center. Thus, there are M service centers labelled $1, \ldots, M$. Users enter the system according to a Poisson process with rate Λ. Upon entering the system, the users first visit service center i, $(i = 1,2,..,M)$, with probability

p_{oi}. Note that $\sum_{i=1}^{M} p_{oi} = 1$. The residence time at each center is assumed to have a general distribution with a mean of $1/\mu$. The sequence of frames referenced by the users is governed by a first order Markov chain $\{p_{ij}\}$, $1 \leq i,j \leq M$. p_{ij} is the probability that the next frame to be referenced is j, given that the frame being viewed is i. Let p_{i0} denote the probability of a user departing from the system after referencing frame i. The Markov chain whose states are labeled by i is shown in figure 3.

Let λ_i be the aggregate rate at which frame i is requested by the users. The following set of linear equations hold good for the system.

$$\lambda_i = \Lambda\, p_{oi} + \sum_{j=1}^{M} p_{ji}\, \lambda_j \qquad i = 1, \ldots ,M \quad (4.1)$$

If the probability of leaving the system is independent of the current frame being viewed, i.e., $p_{io} = p_o$, for all i, then $\sum_{i=1}^{M} \lambda_i = \Lambda / p_o$. In the following discussions, unless otherwise stated, we assume that $p_{io} = p_o$.

In the Videotex system, it is possible for several users to view the same frame simultaneously. Hence, the occupancy process at each service center is that of a center with infinite number of servers. Such a network of M service centers clearly belongs to the class of product form networks [1]. Let us define the aggregate state of the system by the vector $X = [x_1, x_2, \ldots , x_M]$ where x_i represents the number of references to frame i. Let $P[X]$ denote the steady state probability of the system being in state X. Knowing the rate at which frames are being referenced (λ_i), and the mean viewing time of each frame ($1/\mu$), we can compute $P[X]$ using the closed form expression given in references [1,6]. The equilibrium state probabilities are given by

$$P[X = x_1, x_2, \ldots , x_M] \quad = \quad \prod_{i=1}^{M} e^{-\rho_i} \frac{\rho_i^{x_i}}{x_i!}$$

where $\rho_i = \lambda_i / \mu$

The marginal probability distribution $P[x_i]$ is obtained by summing $P[X]$ over all feasible states with fixed x_i, i.e.,

$P[x_i]$, Prob. that x_i references are made to frame i

$$= \quad \frac{e^{-\rho_i}}{x_i!} \left(\frac{\lambda_i}{\mu}\right)^{x_i}$$

The expected number of references to frame i is given by

$$\sum_{x_i=0}^{\infty} x_i P[x_i] \quad = \quad \rho_i$$

And, the expected number of overall references in the system is given by

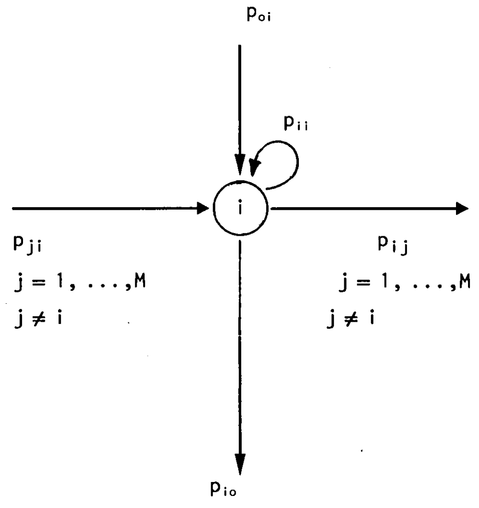


Figure 3

$$\sum_{i=1}^{M} \sum_{x_i=0}^{\infty} x_i P[x_i] \quad = \quad \frac{\rho}{p_o}$$

where $\rho = \Lambda / \mu$

In a cached system, a subset ζ of the M frames is captured in the cache. The subset ζ retained in the cache is determined by the cache management policy. Efficient cache management policies attempt to retain the most frequently accessed frames in the cache. If the next frame referenced is already present in the cache, then a cache hit is said to occur. The steady state probability of cache hit (also known as hit ratio) is defined as the ratio of the number of references to frames in ζ over the total number of references to the system.

Expected value of number of references to frames in ζ

$$= \quad E\left[\sum_{i\in\zeta} \rho_i\right]$$

Expected value of number of references to all M frames

$$= \quad E\left[\sum_{i=1}^{M} \rho_i\right]$$

$$\mathcal{H}\text{, cache hit ratio} \quad = \quad p_o \sum_{i\in\zeta} \lambda_i \,/\, \Lambda \qquad (4.2)$$

Let $|\zeta|$ be the cardinality of the set ζ. Since the cache retains the $|\zeta|$ most frequently referenced frames, the summation in the expression (4.2) is over those frames which have the highest request arrival rate (i.e., the λ_i's are sorted in ascending order, and the first $|\zeta|$ elements are summed).

In the following sections, we compute the cache hit ratio for different user behavior patterns. Each pattern leads to a different Markov chain.

Case 1: Random Entry and Uniform Transitions

Users, upon entering the system, choose to view any of the M frames in the system with equal probability; and after viewing frame i, choose any frame j with equal probability. i.e.,

$$p_{ij} = \begin{cases} 1/M & i = 0,\ j = 1, \ldots, M \\ p_o & j = 0,\ i = 1, \ldots, M \\ (1 - p_o)/M & i,\ j = 1, \ldots, M \end{cases}$$

Substituting these in equation (4.1) the arrival rate for each frame is given by

$$\lambda_i = \frac{\Lambda}{M p_o} \qquad i = 1, \ldots, M \qquad (4.3)$$

Since the request arrival rates are equal, the first $|\zeta|$ frames can be considered to be in the cache. From equations (4.2) and (4.3), the cache hit ratio is derived as

$$\mathcal{H} = p_o\, |\zeta|\, \lambda_i/\Lambda \qquad = \frac{|\zeta|}{M}$$

Case 2: Unique Entry and Uniform Transitions

There is a designated frame f that is viewed by all the users upon entering the system. After viewing frame f, the subsequent frames viewed by the users are as described under case 1. Thus, the arrival rate to each frame is given as

$$\lambda_f = \Lambda + \frac{1 - p_o}{M} \sum_{j=1}^{M} \lambda_j$$

$$\lambda_i = \frac{1 - p_o}{M} \sum_{j=1}^{M} \lambda_j \qquad i = 1, \ldots, M; \quad i \neq f$$

i.e.,

$$\lambda_f = \Lambda \left(1 + \frac{1 - p_o}{p_o M}\right)$$

$$\lambda_i = \frac{(1 - p_o)\, \Lambda}{p_o M} \qquad i = 1, \ldots, M, \quad i \neq f$$

Substituting the above expressions in equations in (4.2), the cache hit ratio is derived as

$$\mathcal{H} = p_o + (1 - p_o) \frac{|\zeta|}{M}$$

When p_o (the probability of leaving the system) is small, case 2 degenerates to case 1 and the hit ratio approaches $|\zeta|/M$. (i.e., unique entry does not have any significance in the long run.) On the other hand, when p_o approaches 1, users reference only a few frames before leaving the system; and these frames are found in the cache. This results in a high hit ratio (approaching 1).

Case 3: Strict Tree Traversal

Here, users enter the Videotex database tree at the root and traverse the tree by selecting the menu choices available at each level in the tree. When they reach the leaf nodes, they return to the root node and traverse the tree again.

For this analysis, a balanced tree with N levels (level 0 corresponds to the root node) and degree K is considered. Let $\{S_\nu\}$ be the set of frames located in the tree at levels 0 through ν. Now,

M, the total number of frames in the system

$$= \frac{K^{N+1} - 1}{K - 1}$$

$|S_\nu|$, the sum of all the frames up to level ν

$$= \frac{K^{\nu+1} - 1}{K - 1}$$

The number of frames cached $|\zeta|$ is such that, $|S_\nu| < |\zeta| \leq |S_{\nu+1}|$ for some νin the range $0 \ldots N - 1$ Let λ_n denote the rate of arrival to any frame at level n in the tree and let $q_o = (1 - p_o)$. Then,

$$\lambda_o = \Lambda + K^N \lambda_N q_o$$

$$\lambda_n = \frac{q_o}{K} \lambda_{n-1} = \left(\frac{q_o}{K}\right)^n \lambda_o \qquad n = 1, \ldots, N$$

Solving for λ_o from the above equations

$$\lambda_o = \frac{\Lambda}{1 - q_o^{N+1}}$$

Let R_ν denote the expected number of references to frames in the set $\{S_\nu\}$.

$$R_\nu = \sum_{n=0}^{\nu} K^n \frac{\lambda_n}{\mu} = \frac{\rho}{p_o} \frac{1 - q_o^{\nu+1}}{1 - q_o^{N+1}}$$

The cache hit ratio is given by

$$\mathcal{H} = \frac{R_\nu + \#\text{ of references to frames in } \{\zeta - S_\nu\}}{R_N} \qquad (4.4)$$

Equation (4.4) will lead to the following expressions, based on the cache size.

$$\text{when } |\zeta| = 1, \qquad \mathcal{H} = \frac{p_o}{1 - q_o^{N+1}}$$

And, when $|S_\nu| < |\zeta| \leq |S_{\nu+1}|$, $\nu = 0, \ldots, N - 1$

$$\mathcal{H} = \frac{p_o}{1 - q_o^{N+1}} \left[\frac{1 - q_o^{\nu+1}}{p_o} + \left(\frac{q_o}{K}\right)^{\nu+1} \left(|\zeta| - |S_\nu| \right) \right] \qquad (4.5)$$

4.1 Validation

In this section, the cache hit ratio is computed using the expression (4.5) and compared with that obtained from a simulation study (described in Section 5). Two different trees are being considered. The users are assumed to perform a strict tree traversal as discussed under Case 3. The probability of leaving the system, p_0 is assumed to be 0.0125. The results are presented in Table I. One can observe, as expected, that the simulation results are always lower than the analytical results.

Table I

Analytic Vs Simulation Comparison of Hit Ratios

cache size	M = 66,430
	K = 9, N = 5
			M = 9331
			K = 6, N = 5	

	anal	sim	anal	sim
2K frames	0.704	0.690	0.84	0.79
4K	0.754	0.760	0.89	0.88
6K	0.804	0.802	0.93	0.93
8K	0.840	0.803	0.97	0.95
10K	0.846	0.804	1.00	1.00

The analytic solution is also used to obtain a general understanding of the effectiveness of frame caching. Table II illustrates the cache hit ratio as a function of cache size for various data base sizes. Interestingly enough, it appears that hit ratios higher than 60% can be achieved with cache sizes which are merely 1% of the data base size, irrespective of the depth or degree of the tree. The actual hit ratio in a real system may, however, be slightly less. These results are corroborated by the simulation study presented in Section 5.

5. The Simulator

While the analytic model developed in the last section can be further extended to model more complex user behavior, it has the limitation of providing only a bound on the performance. In this section, the results from the analytical model are augmented with a simulation study. For this purpose, we constructed a two part simulator. The first part, a reference string generator, generates a sequence of frame ids referenced by the active users. These synthetic frame reference strings are processed by the second part, the cache simulator. While processing the reference strings the cache simulator also collects statistics on the cache performance and displays them at the end of the run. The design of the traffic generator and the cache simulator allows the data base related, user related, and cache related parameters to be easily varied, and their effects observed. We first describe the different parameters that are being varied.

Table II

Cache Hit Ratio for Strict Traversal in a Balanced Tree

cache size
(as % of
db size M)
	K = 3
	N = 10
	M =
	88,573
		K = 5
		N = 7
		M =
		97656
			K = 10
			N = 5
			M =
			11111
				K = 18
				N = 4
				M =
				11151

1 %	0.63	0.64	0.67	0.63
5 %	0.76	0.77	0.75	0.78
10 %	0.82	0.80	0.83	0.81
20 %	0.86	0.88	0.86	0.84
50 %	0.94	0.93	0.91	0.90
90 %	0.98	0.98	0.98	0.98

5.1 DB-Related

It is assumed that there are 9 data bases; i.e., there are 9 choices at level 0. The depth N and the degree K of the tree depend on which of the 9 data bases is selected at level 0. For example, if data base i is chosen, the depth along that path will be N_i and the degree will be K_i. Thus, the Videotex tree used in the simulator need not be a balanced tree. N_i and K_i are randomly chosen (from a uniform distribution between 5 and 9), such that the total number of frames M in the system ranges from 10 thousand to 10 million. From a ***human factors*** view point, traversing more than 9 levels of a tree or choosing among more than 9 choices may not be tolerated by the users, hence, the choice of values for N_i and K_i.

5.2 User-Related

User behavior is characterized by the following probability measures:

p_0 probability of leaving the system

$p_r(l)$ probability of retrace, i.e., probability of backing up to level $l - 1$ while viewing a level l frame $(0 < l < N)$; $p_r(0) = 0$

$p_d(l)$ probability of descending to level $l + 1$ while viewing a level l frame, $(0 \leq l < N)$; $p_d(N) = 0$

$p_b(n)$ probability of backing up to level n while viewing a level N (leaf) frame, $(0 \leq n < N)$

A typical user enters the system through the level 0 frame (the root node) which lists the data bases on available topics. While at level 0, he chooses to view any of the 9 data bases with equal probability. When the user is viewing a level l frame, $(0 < l < N)$, he decides to retrace (back up one level on the tree) with probability $p_r(l)$; or decides to select a menu choice and traverse down the tree with probability $p_d(l)$. When the user is viewing any of the leaf nodes (level N), he backs up to level n, $(0 \leq n < N)$, with probability $p_b(n)$. The probabilities defined above satisfy the following invariants:

$$p_0 + p_r(l) + p_d(l) = 1; \qquad (0 \leq l < N)$$

$$p_0 + \sum_{n=0}^{N-1} p_b(n) = 1$$

The various parameter values considered in the simulation study are listed below:

1. $p_0 = 0$; i.e., the users do not leave the system. In a real system, $p_0 = 0$ implies that when an active user leaves the system, he is immediately replaced by another user entering the system. This is true when the total user population is much larger than the number of active users. The fixed number of active users model has been successfully used in evaluating the performance of time sharing computer systems [8,12]. In the simulation, number of active users = 1, 2, 50, 100.
2. $p_r(l) = 0, 0.1,$ or 0.2. A higher value for $p_r(l)$ implies that the user will be rereferencing a frame more frequently.
3. $p_d(l) = 1 - p_r(l)$, since the invariant has to be maintained.
4. Menu choice selection: Let j be a menu frame at some level l, $(0 \leq l < N)$, containing K choices. If a user decides to traverse down the tree, one of these K choices has to be chosen. Let p_{jk} be the probability of selecting menu choice k,$(1 \leq k \leq K)$. Two different probability distributions for menu choice selection are used in the simulation.

   Case 1: The menu selection is based on a uniform probability distribution, i.e., each menu choice is equally likely to be selected. $p_{jk} = \frac{1}{K}$, for all k.

   Case2: The menu selection is based on a geometric probability distribution. Here, the probability of selecting choice k is less than the probability of selecting choice k-1. With a geometric distribution it is possible to model the fact that some choices have a higher probability of being selected than others. In a geometric distribution with parameter g, $(0 < g \leq 1)$

$$p_{jk} = \begin{cases} g(1-g)^{k-1} & 1 \leq k < K \\ (1-g)^{K-1} & k = K \end{cases}$$

   By assigning different values to g we can model different degrees of locality in frame references. Results for g =0.3 and 0.5 are reported in Section 6.

5. The probability of backing up to level n after viewing a leaf node is assumed to be uniformly distributed. i.e.,

   $p_b(n) = \frac{1}{N}$ for $0 \leq n < N$

5.3 Cache-Related

The following cache related parameters are varied:

1. cache size, also referred to as the number of frames cached (.125K, .25K, .5K, 1K, 2K, 4K, 8K, and 10K)
2. replacement policy (Least Recently Used vs First In First Out)
3. caching policy (any frame can be cached vs only menu frames can be cached)

6. Results

The base parameters for the following experiments are assumed to be

DB size = 100K frames
Number of users = 100
Uniform distribution for menu choice selection
Retrace prob. = 0.1;
Replacement policy = LRU; (menu frames and information frames cached)

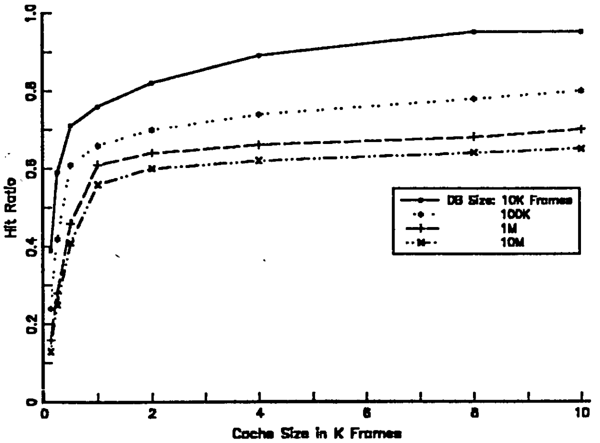
In each experiment, one of these parameters and the cache size are varied, and the effect observed.

6.1 Impact of Data Base Size and Cache Size

In this experiment, the dependence of the hit ratio on data base size (total number of frames in the system) and cache size are studied. The data base size is varied from 10K to 10M frames. For each data base size setting the cache size is varied from 125 to 10K frames. Plots of hit ratio against the cache size, as a function of data base size, are given in Figure 4. These plots show that it is possible to achieve a high hit ratio with a relatively small cache size. In fact, a cache size of 2K frames, which can only hold a very small fraction of the (10M frames) data bases, is able to provide a hit ratio as high as 0.6. This supports the analytical results.

6.2. Impact of Number of Active Users

In order to investigate how the number of concurrently active users affects the cache hit ratio, the cache behavior is studied while the number of users is varied from 1 to 100. The total number of frames in the system is held constant at 100K frames. The menu choice selection probability is assumed to be uniformly distributed; the probability of retrace is assumed to be 0.1. The hit ratios achieved for different cache sizes are listed in Table III. Interesting observations can be made from Table III. The high hit ratios observed in the single user experiments suggest that there is strong intra-user locality of reference. Even when the number of active users in the system increases, the hit ratio remains high. This suggests that there is also considerable inter-user locality of reference.



Hit Ratio vs Cache size and Data Base size

Figure 4

Based on the 10K cache size experiment, one can conclude that a single user is interested in only 10% of the frames available in the data base. Also, when there are multiple users active in the system, 80% of the references (across all users) are for only 10% of the data base. These observations suggest that more detailed studies should be undertaken to establish some rules of thumb for locality of reference in Videotex systems (similar to the 80-20 or 90-10 rules in conventional programming environments).

Table III

Hit Ratio Vs. Active Users

cache size	active users			
	1	2	50	100
.125K frames	0.58	0.58	0.34	0.24
.25K	0.60	0.60	0.55	0.42
.5K	0.63	0.62	0.63	0.61
1K	0.66	0.66	0.61	0.66
2K	0.70	0.70	0.70	0.70
4K	0.74	0.74	0.74	0.74
8K	0.78	0.78	0.78	0.78
10K	1.00	0.80	0.80	0.80

6.3. Impact of Menu Selection Probability Distribution

In this and the next experiment, the effect of changing user related parameters is studied. As discussed in section 5.2, two different probability distributions (uniform and geometric) are considered for menu choice selection. In the geometric distribution, two different values are assigned for the parameter g ($g = 0.5$ and 0.3). The parameter g is the probability of selecting the first choice in the menu frame. A high value for g implies a high degree of commonality of interest among all the users. Clearly, it should be possible to achieve better hit ratios with a geometric distribution rather than a uniform distribution. The simulation results, shown in Table IV strongly support the above conjecture. For a given cache size and data base size, uniform distribution provides the lowest hit ratio while geometric distribution (with g approaching 1) provides hit ratios very close to one.

Table IV

Hit Ratios with Different Distributions of Menu Selection Probability

cache size	Prob. Distribution		
	uniform	geometric	
		g = 0.3	g = 0.5
.125K frames	0.24	0.26	0.34
.25K	0.42	0.44	0.56
.5K	0.61	0.63	0.72
1K	0.66	0.68	0.78
2K	0.70	0.72	0.83
4K	0.74	0.76	0.89
8K	0.78	0.82	0.92
10K	0.80	0.84	0.94

6.4 Impact of Probability of Retrace

In this experiment, $p_r(i)$, the probability of retrace (backing up one level in the tree) is varied from 0 to 0.2, and the hit ratio is observed. This models the situation where the users tend to rereference a frame within a short period of time. The hit ratios achieved for different retrace probabilities and cache sizes are listed in Table V. As expected, when users retrace their path often, higher hit ratios are observed.

Table. V

Impact of Probability of Retrace

cache size	Prob. of Retrace		
	0	0.1	0.2
.125K frames	0.23	0.24	0.28
.25K	0.39	0.42	0.45
.5K	0.59	0.61	0.63
1K	0.65	0.66	0.68
2K	0.69	0.70	0.72
4K	0.72	0.74	0.76
8K	0.77	0.78	0.80
10K	0.79	0.80	0.82

6.5 Impact of Caching Only Menu Frames

The locality of reference observed in all the above experiments can be attributed to the tree structure of the data bases. Since the users are constrained to traverse the tree, the frames in the top few levels of the tree are more likely to be rereferenced. In this experiment, the cache hit ratios are determined when only the menu frames (non-leaf nodes) are cached. The hit ratios from this experiment along with those obtained when any frame is allowed to be cached are listed in Table VI. As expected, for the same cache size, higher hit ratios can be achieved by caching menu frames alone. However, the improvement is not that appreciable. An alternate way to interpret this improvement in hit ratio is as follows: if only the menu frames are cached, a given hit ratio can be achieved with a smaller cache.

Table VI

Hit Ratio When Only Menu Frames Are Cached

cache size	any frame is cached	only menu frame is cached
.125K frames	0.24	0.27
.25K	0.42	0.47
.5K	0.61	0.64
1K	0.66	0.67
2K	0.70	0.71
4K	0.74	0.76
8K	0.78	0.81
10K	0.80	0.82

6.6 *Impact of Replacement Policy*

The choice of cache replacement policy may have an impact on the cache performance. Here, hit ratio is studied under two different cache replacement policies, LRU (least recently used) and FIFO (first in first out). When a frame is to be inserted in the cache and the cache is already full, it replaces another frame. In the case of LRU, the frame that has been used least recently is replaced while in the case of FIFO, the frame that has been in the cache for the longest time is replaced. The hit ratios are determined for different cache sizes. The results are given in Table VII. Although there is no dramatic difference in performance, LRU replacement policy tends to provide better performance than FIFO policy.

7. Conclusion

In this paper, we have considered a caching mechanism for Videotex systems, wherein, a dynamic subset of the information is moved closer to the users. The subset that is moved is dependent on the users' behavior. Since the data base functions and the front-end functions are not implemented within the same processor, moving a subset of the information closer to the users reduces the communication and processing delays involved in accessing the data base server. Therefore, users perceive better response times and the data base server is able to support more users. The effectiveness of this scheme, measured by cache hit ratio, is a function of the locality of references.

Table VII

Hit Ratio Vs. Active Users

cache size	replacement policy	
	LRU	FIFO
cache any frame		
2K frames	0.70	0.67
4K	0.74	0.71
8K	0.78	0.76
10K	0.80	0.77
cache only menu		
2K frames	0.71	0.69
4K	0.76	0.74
8K	0.81	0.80

Through an analytic model and a simulation method, we have explored the performance of frame caching in Videotex systems. We find that when the frames are organized as a tree structure, and the users traverse the tree (as in a menu driven retrieval service), it is possible to achieve hit ratios in the 60% to 80% range, with very small cache size. Because of the tree structure, a single user tends to rereference the frames often and exhibits strong locality (only 10% of the data base is referenced). When there are multiple users, there are several frames that are shared by them, resulting in a high degree of inter-user locality (80% of references across all users are observed to be for only 10% of the data base). We feel that more detailed studies should be conducted to establish rules of thumb for locality of reference in Videotex systems. Varying user related parameters like menu selection probability distribution and retrace probability influences the hit ratio in an expected manner. Cache replacement policy does not have a major impact on the hit ratio.

The simulation methodology discussed in this paper is very general and can be used for detailed studies. However, it is computationally expensive. On the other hand, the analytic model developed in this paper is computationally inexpensive; but it is useful only in establishing a tight upper bound. We believe the two approaches complement each other.

THE CONTRIBUTION TO PERFORMANCE OF INSTRUCTION SET USAGE IN SYSTEM/370

O. R. LaMaire and W. W. White

IBM Thomas J. Watson Research Center
Yorktown Hts., New York 10598

Abstract

The actual usage of instructions in the different environments in which a processor must run reflects both architectural and workload considerations, while the achieved overall internal processor performance reflects these as well as processor implementation considerations. The most frequently used instructions are not necessarily those which the processor spends the most time executing, either totally or on a per instruction basis. Furthermore, focusing on the effects of instruction usage in one environment may provide an inadequate basis for projecting the effects in other environments. This is illustrated by measurements of production systems executing on large IBM mainframe processors. A significant aspect is the differentiation between supervisor and problem program instruction usage, and the extent of their commonality across environments.

1. Introduction

The internal performance of modern, high end computers is heavily affected by both architectural and implementation considerations. However, the nature of the workload actually being executed on the machines is itself a major factor. It is not hard to find cases where one workload running on a machine executes up to twice as fast as a different workload running on the same machine. In an earlier paper [7], we examined the effect of a major implementation factor, the cache (high speed buffer memory), on processor performance in different workload environments. In this paper we will explore a possibly more direct workload effect, the instruction mix of the workload itself. However, implementation considerations (including the cache itself) come into play when considering overall performance, as it is the time spent executing the instructions which is then important. Examples drawn from real processing environments will be used to illustrate these points.

One of the major aspects of instruction usage is the amount of system code being executed. In some sense, as we shall see, the system code provides a degree of commonality between different workloads, while the problem code may be more different since it is more specialized towards solving a particular problem or performing a particular function. Thus, environments which have a higher supervisor content will tend to look more alike than environments in which the supervisor content is low. From a user's perspective, this is important for two reasons: (1) neglecting the system code may be misleading in terms of processor evaluation, and (2) system code is usually not under the control of the user. From a designer's perspective, this is important because it provides a "core" set of instructions which should occur with some degree of regularity, and then another set of instructions, more workload specific, which will provide the variability which must be addressed in order to design an effective, general purpose machine. With special purpose machines, of course, one can be much more specific as to one's design points, with a corresponding loss of performance if the machine is not used for what it was designed.

In any case, however, instruction set usage should be tracked in real environments. Often this will provide the necessary feedback to designers on what the real life problems are, which should be driving systems design. And this information can be used to calibrate benchmarks which can then be used to provide deeper, laboratory studies of processor performance. For these purposes, it is necessary to look at all the instructions executed in order to see the effects on processor performance, and not just on application characteristics.

The processors with which we will be concerned will be the large mainframes on which businesses run their major production work, including commercial and scientific programs, large corporate data bases, program development, etc. While the implications of much of the material presented below is applicable to such machines offered by many different manufacturers, our focus is on machines using the IBM System 370 instruction set (see [6]), or its variants, and the examples will come from IBM processors such as the 3081K.

In Section 2 below we will discuss internal processor performance, noting the dependence on workload, and how instruction set usage contributes to the overall internal performance. A measurement technology for obtaining instruction mixes using a hardware monitor is discussed in Section 3, and in Section 4 we go into more detail on the measurements themselves. In Section 5 we explore some of the supervisor and problem program content considerations, and a general discussion of the implications, as well as some possible extensions, is given in Section 6. Section 7 presents a short summary of the major points made.

2. Internal Processor Performance

As noted above, the actual use of instructions delineates the work done from an internal processor viewpoint. If all instructions executed in the same amount of time, for example in one machine cycle, a RISC architecture-like feature (see Colwell et. al., [4]), then one could evaluate the internal speed of the processor directly from knowing the total number of instructions executed. If, however, even just a subset of the instructions executes in a different number of machine cycles, then one must know the number of cycles each instruction will take to execute in order to evaluate performance, as well as the instruction mix itself.

CH2345-7/86/0000/0665$01.00 © 1986 IEEE

This is generally more complicated than looking up some nominal value supplied by instruction timing formulas. While such an approach can be workable, e.g., for base timing of particular instructions dependent on operand length, it may have little connection with actual execution as experienced within a full system context. In this case, the interaction of the instructions with other aspects of the workload behavior may dominate the 'kernel-like' characteristics. In particular, many machine implementation considerations will have an effect, especially in high-performance processors. These include pipeline breakage due to branching, holding off of instruction execution due to lack of operands (or of the instruction itself) being present, memory interference, and so forth.

To do a full performance evaluation from first principles, one needs to get at more information than just instruction mix and instruction timing formulas (see, for example, Peuto and Shustek [10]). However, one can do a characterization of the performance impact of instruction usage by measurement 'after the fact', i.e., by actually measuring code execution, as in Clark and Levy [2], although the focus there is more specific rather than at system level behavior across environments. Depending on what data one collects, one can gain insight into how the instructions of a particular workload drive performance.

To provide a somewhat more specific basis for our discussions, let us call f_i the fraction of occurrence, i.e., the normalized frequency, of the i^{th} instruction, so that

$$1 = \sum f_i$$

In the following, we will also sometimes refer to f_i as a percent instead of a fraction, but the context will make it clear which is which.

It is generally convenient to assume an order to the instructions. In particular, one that we shall use will be the frequency of occurrence itself with respect to a given workload, so that, for that workload, $f_i \geq f_{i+1}$ for all i. For other workloads ordered according to the given workload, this relationship need not hold, of course. With this ordering, then, we can define the partial sum

$$F_p = \sum_{i=1}^{i=p} f_i$$

of the first p instructions, ordered according to the given workload. As a percent, F_p is then the percent of the total instructions for this workload executed by the top p instructions of the given workload. This metric, a cumulative frequency distribution, is of interest as it is indicative of the "working set" of instructions for this workload. The differences between these values for different workloads, keeping the same instruction ordering, shows the amount of variation which can occur between environments, with implications as to the necessity of robust design. One notes that the F_p for the given workload itself must be at least as great as any F_p for this workload generated by the order of some other workload.

If we then look at the total execution time for all instructions, i.e., the total processor busy time, we can try to allocate it to individual instructions, as follows. Let t_i be the fraction of the total busy time attributable to the execution of the i^{th} instruction, in such a fashion that the *whole of the busy time can then be accounted for.* Using this definition, it is then true that

$$1 = \sum t_i$$

It should be noted that this is a definitional statement, where we are apportioning the total amount of processor busy time between all instructions, including the time spent on all the other machine dependent factors noted above.

A simple way to achieve this is to attribute all the time spent between the start of execution of one instruction and the start of execution of a second instruction to the first instruction. In a strictly sequential machine, the applicability of this simple approach is clear, while in a pipelined machine, this amounts to placing emphasis on the execution element, and ignoring some instruction fetch and other overlapped activity. An alternative simple approach, employed in Clark and Levy [2], is to attribute the time between successive *decodes* to the first instruction: in a sequential machine this is largely equivalent to the first approach (i.e., between starts of execution) but in a more pipelined machine, this places more emphasis on instruction element processing (missing some overlapped execution). While some care must be taken in interpretation in either case*, we use the first approach here (between successive starts of execution) as we prefer an execution element emphasis as providing more insight into processor performance behavior.

Other ways of attributing time may be more meaningful depending on machine implementation, and, in fact, one may gain additional insight into machine behavior by not apportioning all the busy time to actual instruction execution, but splitting some of the time off for other factors (e.g., for cache effects as suggested by LaMaire and White [8], or for more detailed performance factors as delineated in MacDougall [9]). A very good example of this is in Emer and Clark [5], where this is done on groups of opcodes. In practice, much of this depends on the signals available from the processor under study. One could also go further and develop expressions relating to the average execution time per instruction, but we will not do so here, as it is less important to the development of this paper.

As with instruction frequencies, one can also assume an ordering for instruction times. The one which we shall generally employ here will be the same as for instruction frequencies, i.e., we shall assume an ordering of the t_i according to the frequency, *not* time. Thus T_p as defined by the relation

$$T_p = \sum_{i=1}^{i=p} t_i$$

for the first p instructions ordered according to the frequency of occurrence in the given workload, is the contribution to the total busy time of these instructions. The degree to which T_p is less than F_p is indicative of the performance impact of infrequently used but "long" instructions. In words, one can talk about p instructions accounting for F_p of the instruction use, but only for T_p of the time (with some implicit ordering assumed).

We shall focus on these two metrics F_p and T_p as the items of interest, in that they summarize, in the first case, the usage of the instruction set, and in the second case, the impact of this usage on

* We note that either of these approaches can be used for other processor organizations, including vector processors which execute instructions synchronously, although they both become less and less applicable the more overlapped the operations become, e.g., for multiple execution units fed from a single instruction processing element. Overlapping in multiprocessor systems can be handled by examination of each processor in the configuration separately.

processor performance, i.e., on where the processor spends its time. A more detailed analysis could delve into individual instructions and their characteristics (as noted in Section 6), but our main purpose is to develop some overall characterizations of instruction set usage. Such overall system-level characterizations will serve to illustrate our principal points regarding instruction set skew, environmental differences and similarities, and the importance of considering supervisor content in such analyses.

3. The Measurement Approach

There are many different ways to get instruction usage data, often depending on, or limited by, the nature of the workload environment being examined. In laboratory environments one can instrument processors, both by hardware and software monitors, to gather a wealth of information. In such cases, one can often repeat measurements (in fact, repeatability is a major feature of laboratory environments), so as to extract more data in multiple passes. This might be necessary, for instance, when the amount of information gathered per pass must be limited, in order to minimize processor interference induced by the monitor, or because of a limited collection capability in the monitor.

There is a difficulty in focusing on workloads in laboratory environments, though, in that it means one is dealing with closed, largely known entities, which may or may not be representative of how real production workloads execute on these processors. Both this representativity, and the question of how many other environments may exist, indicate the need to address oneself to real world behavior. In the very least, one can then develop a feel for how representative are the laboratory benchmark workloads. In other cases, one can get input from workloads not easily created in the laboratory, such as large data base systems, and see if such workloads lie in the design space of the processors themselves.

Gathering data from real production workloads implies many operational restrictions on the collection process. First, there must be minimal impact on the real system. Second, one has to get all the data 'on the fly', as there is no controlled environment -- repeating an experiment by re-running is not possible. This points to the use of hardware monitors, as software monitors tend to cause processor degradation (although for some kernel analyses, as in Bonnes [1], they can be of use). An additional problem with software monitors in general environments is that, to be efficient, they must be sampling monitors, and it is difficult to handle the bias introduced when the operating system inhibits getting a sample (e.g., when interrupts are inhibited). The fact that one is interested in all instructions, including those executed while in supervisor state (meaning that the software monitor cannot simply be an application code) compounds the problem.

For our measurement activity we have employed a specially designed hardware monitor to collect such data as may be available from the large IBM processors in which we have an interest. This monitor operates transparently to the processor being measured, that is, there is no processor degradation, and is readily transported to different real production locations. These sites are chosen as leading edge systems, both in terms of the compute power required for the applications, and for the importance of the applications themselves. Effort is made to look at a variety of different production workloads. Typically, a measurement takes place over a week, 24 hours a day, to gather data on the overall measured system, with data being written to a recording device at a frequency sufficient to profile the system at, for example, 15 minute intervals. During periods of greater interest, however, such as during peak hour operation, snapshots of 5 to 15 minutes are taken at a high resolution, i.e., a high recording rate, to allow for more detailed study. There is sufficient commonality in the data being collected so that, from the overall profile, one can identify if anomalous behavior existed during one of the snapshot periods (e.g., extensive error processing) and therefore ignore the data gathered during that unrepresentative interval.

The hardware monitor employed has some special features which allow the collection of instruction information. In addition to a set of accumulators generally available in these monitors, it contains an 8 bit decoder. Since the primary instruction code, the operation or *op code*, for System/370 instructions (see the architecture documents [6], [7]), is eight bits long*, decoding these eight bits and then incrementing one of 256 registers addressed by this decoding effectively counts the occurrence of that instruction, at the time when the decoding takes place. In order to make use of this facility, one must guarantee a valid strobe for telling when the particular 8 bits are to be decoded (and, of course, one must know that the 8 bits do in fact represent a valid op code at that time). Typically, one can generate a strobe signal corresponding to the first machine cycle of the execution of an instruction. Assuming the 8 bits present at that time do in fact represent the instruction being executed, this facility will then collect in its 256 registers the instruction mix being executed. Alternatively, if one 'latches up' the 8 bits so that they are valid until the next instruction is executed, then by strobing on every machine cycle one can get a time distribution of the instructions, i.e., each register then contains the number of machine cycles spent executing the corresponding instruction**. By performing logical combinations on the strobe signal, for example, 'ANDing' it with the supervisor state signal, one can get instruction information about what's happening in supervisor state. During a week's measurement, several snapshots are in fact taken with different such 'conditionings' being done.

Another practical aspect is that to gather both instruction mix and instruction time distributions requires two such facilities, and if one is measuring a two-processor multiprocessor system such as the IBM 3081K, getting all the information desired would require four such facilities. This then becomes a substantial hardware and software issue, as well as an operational one. To ease these difficulties, we multiplex the use of a single facility, as follows: during one recording interval (say of one second's duration) we gather the data one way, and, after writing it out, we gather the information a second way during the next interval, thus alternating among the possibilities. For a single processor machine such as the IBM 3083J this amounts to alternatively collecting the data so that half the time we are collecting instruction mix data, and half the time instruction time data, interleaving the collection periods. By interleaving many small (relative to the run length) periods, and performing some calculations as to the stability of the mean of the

* Technically, for those instructions with an extended op code, the secondary op code, also 8 bits, is also of interest. To some extent, since not all 256 possibilities of the primary or secondary op codes are present, one might 'fold' these together into one set of 256 registers, thus collecting a full set of information. In this paper, however, we will restrict our attention to the primary op code only, without differentiating on the basis of different secondary op codes.

** In practice, looking at every machine cycle requires a very fast monitoring capability, particularly on modern high speed processors with cycle times of under 25 nanoseconds. Consequently, a sampling procedure is usually employed, looking every *k* machine cycles and decoding at that time. By taking *k* to be a small, prime number, say, less than 32, the sampling error for runs the length considered here is minimal.

collected data, one can collect both kinds of instruction data during one measurement, thus providing most of the information needed with an economy of operation and expense.

4. Measurement Experience

Table 1 gives a high level description of several different measured real life production systems. While these are all IBM 308x processor family environments, one should note that the 9083 is a uniprocessor, the 3081's are dyadic (2-way multiprocessors), and the 3084 is a 4-way multiprocessor (although when run in partitioned mode, it runs as two separate 2-way processors). The 3081D and 3081G processors each have a 32K cache per processing unit (i.e., 2 32K caches total), while the other processors have 64K caches per processing unit (plus other enhancements), so that one would expect different ranges for the performance parameters of interest, particularly those dependent on cache activity (see LaMaire and White [8] for more detail on this). Also, the 3081D and 3081G processors differ somewhat in their internal organizations from each other and from the 3081K and Q machines which will further change the average cycles per instruction. Additionally, the cycle times on the machines are not all the same.

Three different operating systems are present, and the MVS operating system itself has two distinct versions, SP1 for System/370 mode operation, and SP2 for System/370 Extended Architecture (370-XA) mode. The workload environments range from scientific batch, to VM/370 and TSO time-sharing for interactive program development and execution, to three different data base data communication environments, IMS and CICS operating under MVS, and the TPF high transaction rate environment for airline reservations. The VM/370 environments also contain a fair amount of 'personal computing': mail, text processing, and the like.

ID	Processor	Operating System	Description
A	3081D	VM/370 HPO2	Program Development, Text, Scientific Processing
B	9083	TPF2	Airlines reservations
C	3081G	MVS/SP2.1	CICS production data base, background batch
D	3081G	MVS/SP2.1	CICS production data base (dedicated)
E	3081K	MVS/SP1.3	Scientific batch
F	3081K	MVS/SP1.3	Scientific interactive
G	3081K	MVS/SP1.3	Scientific interactive with background batch
H	3081K	VM/370 HPO2	Program Development, Text, Scientific Processing
I	3081K	MVS/SP1.3	Scientific batch
J	3081K	MVS/SP1.3	Scientific TSO, interactive graphics, background batch
K	3081K	MVS/SP1.3	Scientific TSO, interactive graphics, background batch
L	3081K	MVS/SP1.3	Scientific TSO, batch
M	3084Q	MVS/SP2.1	IMS production data base (2 of 4 CPUs measured)
N	3084Q	MVS/SP2.1	IMS production data base (Partitioned mode, performance enhanced)
O	3084QX	MVS/SP2.1	TSO, background batch (2 of 4 CPUs measured)

Table 1: Workload Summary

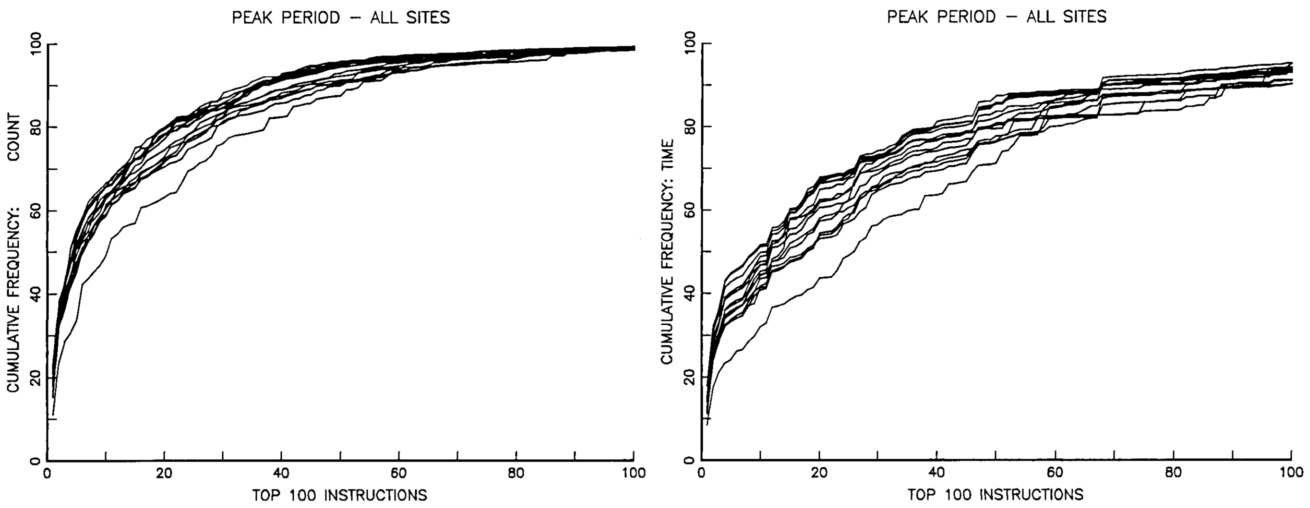
There is a mix of languages present across workloads, and most of the workload environments themselves include many different languages. The operating systems tend to use assembler or related low level languages, as does the code in the major subsystems such as IMS and CICS. The scientific applications tend to use FORTRAN in various flavors, and PL/I in some instances, while the more commercial applications can be COBOL or PL/I; some special constructs are also used for graphics processing. In general, it is not possible to pick out individual language characteristics from such a melange: more controlled studies would be necessary, which is not possible in these production environments (it is usually difficult enough just to identify which applications are being run, e.g., to what extent sorts or other utilities in general are part of the workload mix). From other experience, we share with Clark and Levy [2] the conclusion that it is how the application uses the language, not so much the language itself, that is important. As such, we have characterized the environments in broad terms indicative of their principal activity.

The measurement data represents peak period operation of these workloads. Peak period is taken to be a two-hour period, which can vary between sites, during the day time when the processing load is the heaviest, e.g., in terms of processor utilization*. Often this is in the afternoon, such as between 2 and 4 PM. The data comes from the 5 to 15 minute snapshots taken during this period, for as many days of the week as possible, usually comprising on the order of 2 hours total.

For each of the measured environments, Figure 1 presents instruction frequency data in terms of the cumulative frequency, F_p for $p \leq 100$. The instruction ordering used here is that of the average instruction frequencies for all the environments, so that the figures represent the top 100 instructions of this 'average', respectively. As there are about 170+ primary op codes in the S/370 and S/370-XA instruction sets, slightly under 60 percent of them are represented in Figure 1. The 'outlier' is a scientific batch workload, Workload I, probably the most heavily scientific of the set (it is, however, a real workload -- there is no basis for discarding its data as anomalous). The other workloads separate, of sorts, into two pieces, as can be noted by looking at the gap between the sets of curves at the top 20 or top 40 instructions: the lower group is predominantly more scientific in nature than the upper group.

If we consider the top 17 instructions (10 percent of all instructions), we see that these account for from slightly more than 60 to somewhat under 80 percent of the instructions executed, depending on workload; the average is slightly more than 70 percent. For the top 35 instructions (20 percent of all instructions), we see that these account for from somewhat under 80 to slightly more than 90 percent of the instructions executed, again depending on workload; the average here is in the high 80's.

* This 'peak period' view is oriented toward workloads for which response time is a criteria, since much of the work done at that time has an interactive content. As such, the data is indicative of those sites' stress environments which, for example, one might use as a basis for characterizing high daytime load. Not included here is overnight processing, which more often has a 'turn-around' criteria, e.g., the work must finish by the next morning. This kind of work often consists of longer running jobs, utilities, and the like, and may have more problem program activity. Scientific work, in particular, may have a higher computational content. This means that one may well expect more variability in instruction use data were one to include nighttime activity in the set of measured data.



Figures 1 and 2: Cumulative Instruction Distribution for All Sites
by Count and Time for the Top 100 Instructions Ordered by Average Frequency

From another perspective, to achieve 70 percent of the instructions executed requires anywhere from 13 to 25 of the top 100 instructions, varying according to workload (13 to 20 disregarding the 'outlier'). This 50+ percent variation of the maximum over the minimum is not atypical for other percentiles, and gives some indication of the range one must design for, in terms of 'instruction working sets', when addressing these environments.

We note that instruction mix data should not be as sensitive to machine implementation as instruction timing data should be, since the instruction mix is principally driven by the kind of work done on the machine. Instruction timing data, however, is influenced both by the work done, and how (in terms of processor implementation) it is done, thus leading us to guess a larger variation in the cumulative instruction times across workloads.

Figure 2 in fact shows what the instruction time distribution is for the measured sites. Again, the instructions are the top 100 instructions executed, ordered by frequency, *not* time, for the overall average frequencies. In other words, we have plotted the cumulative instruction times T_p for $p \leq 100$ for the same instructions p as we did above. The variation is indeed larger. Again, Workload I still stands out, but the other workloads do not separate as obviously. However, the more scientific workloads tend to be the lower curves, as before. The differing machine implementations (cache size, cycle time) do not stand out significantly; the workload effects are substantially more dominant. The plotted curves are much more 'wavy' than those in Figure 1, indicating the effect of 'long' (in terms of machine cycles per instruction) ops, and the extent of their commonality across the environments.

When considering where processors spend their time, then, we observe that now the top 17 (10 percent) of the instructions executed account for from about 40 to somewhat over 60 percent of the time of execution, and the top 35 (20 percent) account for from about 60 to somewhat under 80 percent of the time of execution. In the extreme, in some of the environments, 10 percent of the time has not been accounted for by the top 100 instructions, indicating that some very infrequently used ops may account for significant portions of the execution time.

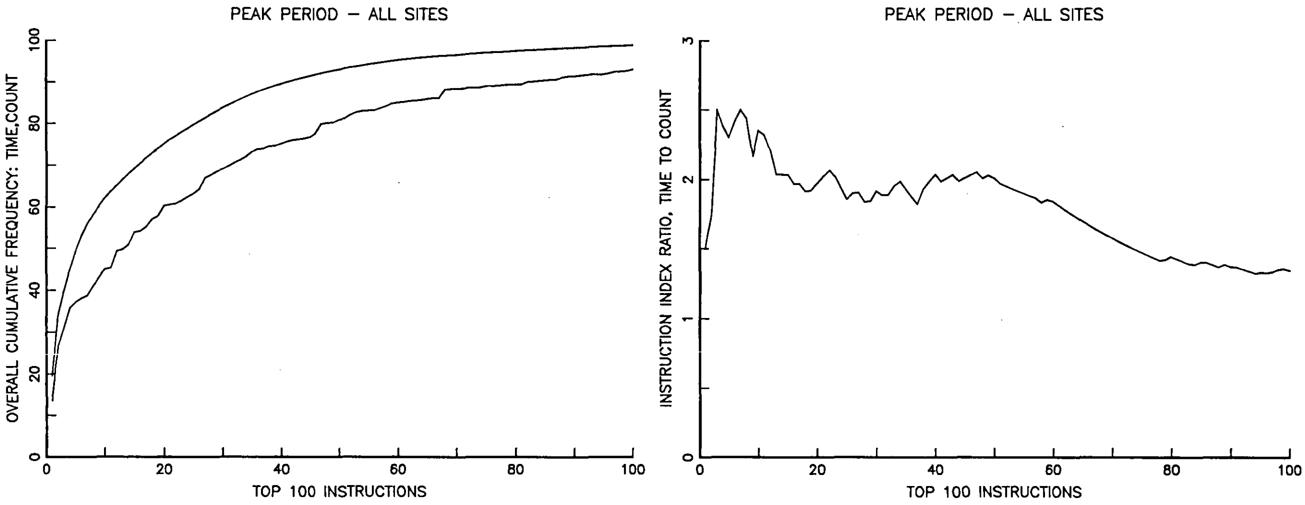
From our other perspective, to achieve 70 percent of the instruction time being accounted for requires anywhere from 26 to 47 of the most frequently used (on the average) instructions, according to workload (26 to 42 disregarding the 'outlier'). The 50+ percent variation of the maximum over the minimum is still generally true for other percentiles, and again shows the range one must design for, from an instruction execution point of view.

One can put this data, both count and time frequencies, together to see how much coverage of execution time is given by instruction usage. To simplify things, we just do this for the overall averages in Figure 3. The two curves then represent the cumulative average instruction use F_p and time T_p frequencies, with the former being the upper curve. The instruction order is, as before, that of decreasing average instruction use frequency, so that, as one would expect, the upper curve is the smoothest presented so far.

From this figure we can note the on-the-average 'coverage' behavior. The top 17 (10 percent) of the instructions account for slightly more than 70 percent of the instruction usage, but only around 55 percent of the time, assuming the given instruction ordering. In order to account for, say, eighty percent of the execution time, one has to consider those instructions accounting for over 90 percent of usage. And while it is true that a small number (12-14) of instructions account for two thirds of the use, they account for under half of the time.

Figure 4 presents another way of looking at the data of Figure 3. Here is plotted the ratio of the number of instructions needed to get roughly equal percents, timing to counting. That is, if one draws a horizontal line on Figure 3 and notes the two instruction indices of the places where the line intersects (one for the cumulative instruction count distribution, and one for the cumulative time), the ratio is that index for the time curve over the index for the count curve*. The ratio then gives the factor increase for the number of instructions needed to obtain the same 'coverage' of

* Actually, since the distributions are discrete, the index for the time distribution is the average of two indices, one being the maximum index i for which $T_i \leq F_p$ and the other being the minimum index j for which $T_j \geq F_p$, for the same given ordering.

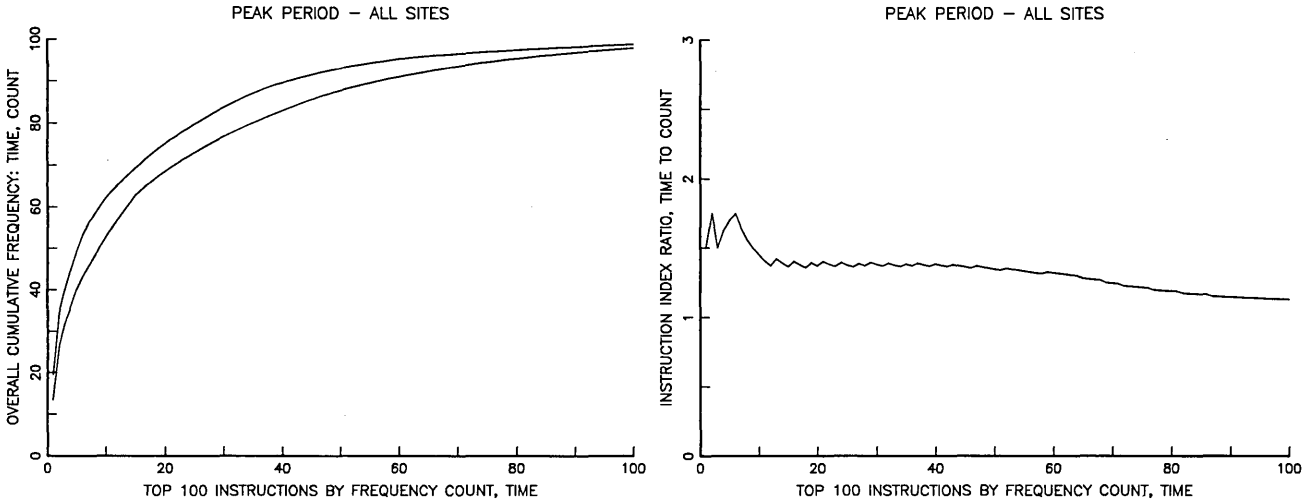


Figures 3 and 4: Cumulative Instruction Count and Time Distribution and Ratio of Equivalent Instruction Indices for the Average of All Sites for the Top 100 Instructions Ordered by Average Frequency

execution time as the given number of instructions 'cover' instruction use. One can note that, over a wide range, one needs 1.5 to 2 times as many of the top most frequently used instructions to get the same percentile coverage of execution time as of instruction use.

It is clear that in order to gain maximum performance, one should concentrate on a somewhat different set of instructions than would be dictated by strictly frequency-of-use considerations. For a general architecture, however, this can lead to difficulties, as one would expect that over time implementations will differ as new processor models are introduced, and what was stressed at one time may not be as important later. The general frequency of use should be a more important consideration long term, as this is more closely associated with the work which the processors must execute (although seeing how this evolves over time is interesting, and is important both for architectural considerations, and to see where design emphasis should be placed). This would give one a more solid base, and the time distribution of instructions would then be indicative of how 'all-encompassing' and robust the most frequently used instructions should be implemented.

One can compare the distributions, instructions ordered by frequency to those ordered by time, to get a rough estimate of what the 'best case' might be in terms of 'coverage'. Figure 5 shows these two cumulative distributions for the top 100 instructions of each ordering. The top curve is still the frequency curve, as in Figure 3, while the bottom curve is the time curve. It is evident that even if the most frequently used instructions were the same as the ones to which the most execution time were attributed, it



Figures 5 and 6: Cumulative Instruction Count and Time Distribution and Ratio of Equivalent Instruction Indices for the Average of All Sites for the Top 100 Instructions Ordered by Average Frequency for Count and Execution Time for Time would still take more instructions to 'cover' the same percent for time than for frequency. In fact, the plot of the instruction index ratios for equal coverage, Figure 6, shows that, for a wide range of interest, one still needs about 1.4 times as many instructions to achieve the same percent coverage by time as by count, even in this 'best case'. This same property holds on a workload by workload basis as well, although the 'equal coverage factor' does vary.

5. Workload Content Considerations

In the Introduction it was mentioned that the supervisor component of workloads, because it is present to some extent in all workloads, might provide a thread of commonality across environments. And to the extent that it may dominate some workloads, it could be quite important in and of itself. We can see how important this might be by borrowing some ideas presented in LaMaire and White [8]. If we let N be the average instruction time (in, say, nanoseconds per instruction), then we can write

$$N = \lambda N_s + (1 - \lambda) N_p$$

where N_s is the average instruction time when in supervisor state, and N_p is the average instruction time when in problem state. Thus λ is the fraction of the time in supervisor state. Clearly, as λ approaches 1, the supervisor state workload component dominates the overall execution time.

To see how important this may be, we can examine the measured workloads. But here again, we run into practicalities. Some workloads treat supervisor time differently than others. For example, the IMS data base control program executes largely in supervisor state, but is not present unless one is running an IMS data base; other major application subsystems have similar characteristics. But let's consider that what we are really looking for in terms of commonality is the functions which are accomplished in the operating system itself, in what is called the system control program. For the MVS operating system, this is code which executes predominantly in Storage Protect Key 0. As a further simplification, we will just look at the measurements from sites using the MVS operating system. Thus, as a surrogate for a general supervisor state time, we shall consider MVS Key 0 time. The fraction of the total busy time spent in Key 0 for nine of the MVS environments appears in Table 2*. This Key 0 ('supervisor') fraction ranges from .2 to .7, so that for some of these environments the Key 0 component is indeed a major contributor to performance.

Id	Description	Key 0 Fract.
E	Sci. Batch	.2
F	Int. Sci.	.6
G	Int. Sci with Batch	.3
I	Sci. Batch	.2

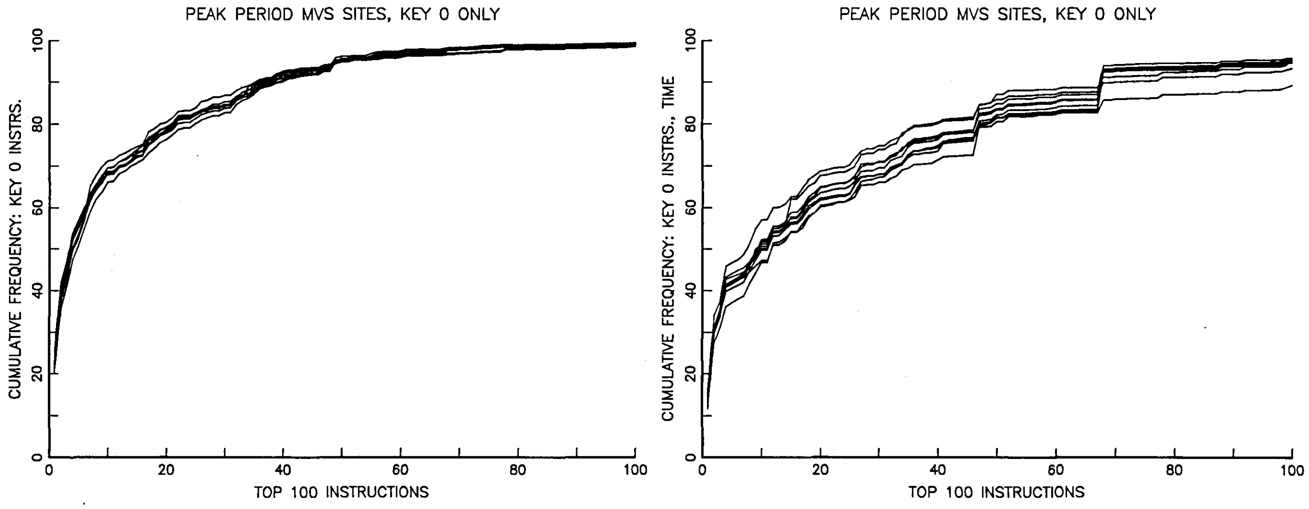
K	Sci. Graph with Batch	.5
M	IMS data base	.5
N	IMS data base	.6
O	Prog. Devt with Batch	.7

Table 2: Fraction of Busy Time in Key 0 for the MVS Sites

Let us now consider the instruction usage of our pseudo-supervisor code, i.e., the code executing in MVS Key 0. This Key 0 instruction data for the sites in Table 2 was gathered similarly to the way the overall data for all the sites was gathered. In this case there were also 5-15 minute snapshots taken during the 'peak periods', although there were fewer snapshots, and, of course, not at the same time. Thus while the data for these Key 0 periods is still representative of peak period behavior, one would expect some small differences between this data and the overall data in some of the principal performance metrics, the source of which comes from the natural variability of the workload. These differences are not significant in any major way.

* Data is not included for the 3081G (Workloads C and D), as related instruction data was not readily available, nor for Workload L, one of the 3081K sites (for which the related instruction data was not available).



Figures 7 and 8: Cumulative Instruction Frequency and Time For Selected Sites for Key 0 Instructions Ordered by Frequency of Top Instructions Averaged over All Sites

Figure 7 presents the Key 0 instruction mix cumulative frequency for the measured sites. The ordering of instructions is the same as before: the decreasing average frequency of all instructions over all sites. Note now the high degree of similarity between the Key 0 instruction usage between these sites. The 'waves' indicate differences between instruction usage between the Key 0 ('supervisor') component and the overall general instruction usage., i.e., show where some instructions occur more frequently in Key 0 than in the general case. By comparing Figure 7 with Figure 1, one notes that the curves in Figure 7 lie more along the upper curves of Figure 1, which as we had noted, were the workloads which have a higher interactive content (and as Table 2 shows, have a higher fraction of Key 0 time). One sees that indeed a fair commonality exists across the workloads coming from the Key 0 component, and that it is dominant in workloads with a high fraction of Key 0 time.

Figure 8 shows the corresponding Key 0 cumulative instruction time distribution. Again there is less variation across the sites than in the general case, though more so than when considering just instruction frequencies -- while Key 0 uses similar instructions, some of them may be taking more time in some of these workloads than in others.

This commonality of Key 0 usage across the sites seems indeed to reflect the commmonality of supervisor function. All environments require I/O and interrupt handling, task scheduling and switching, and various other supervisor services, albeit in possibly somewhat different proportions. If one accepts the paradigm of an operating system providing its service at the request of a user program or to handle an interrupt, the similarity across environments seems intuitively likely, even though these services are invoked less frequently in some environments than in others. For the sites given here, for example, there is no readily apparent differentiation between the curves for more compute bound as opposed to more I/O bound environments.

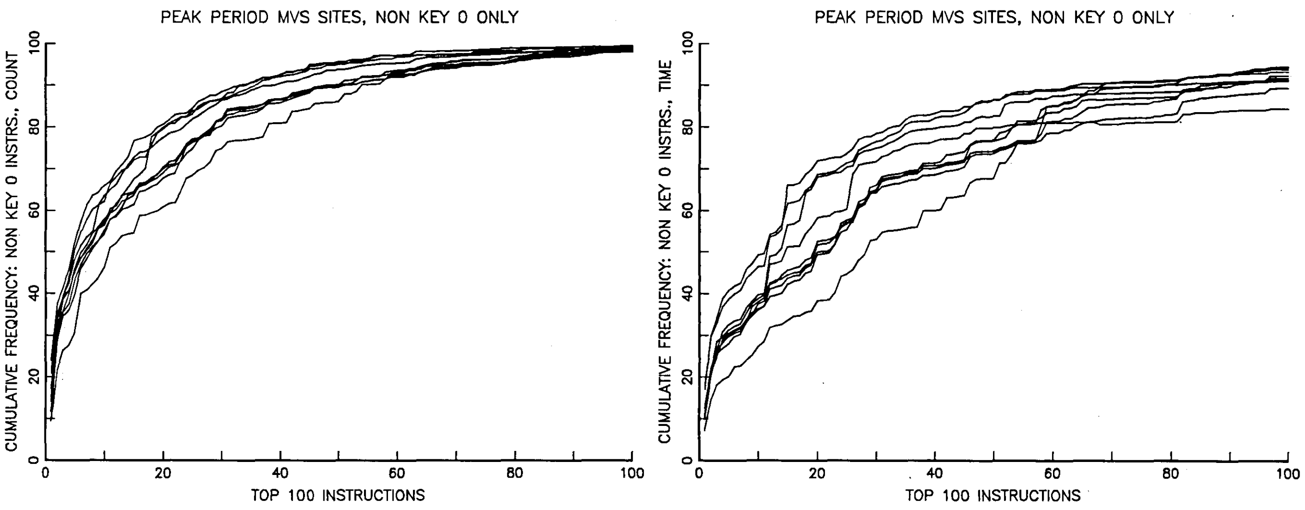
We can also examine the pseudo non-system code instruction usage, or, as we use it here, the 'non-Key 0' instruction usage. This non-Key 0 component corresponds to application code and major subsystem (e.g., IMS) code. The data is derived by subtracting the Key 0 data from the overall data, with appropriate weightings. As such, it is somewhat artificial, since the overall data and the Key 0 data came from two different sets of snapshots, but it is a reasonable representation of 'non-Key 0' activity.

Figures 9 and 10 present cumulative instruction mix and instruction time distributions for the non-Key 0 instruction usage; the instruction ordering is our standard decreasing overall average frequency for all sites. There is substantially more variation between sites than seen earlier, indicating that the variation in the overall instruction use (and time) comes from non-Key 0 usage differences. In addition to the 'outlier', Workload I, showing up, one can also see a similarity within the four 'scientific' workloads, and, above them, the four 'interactive' workloads, particularly for instruction use frequency (Figure 9).

6. Discussion

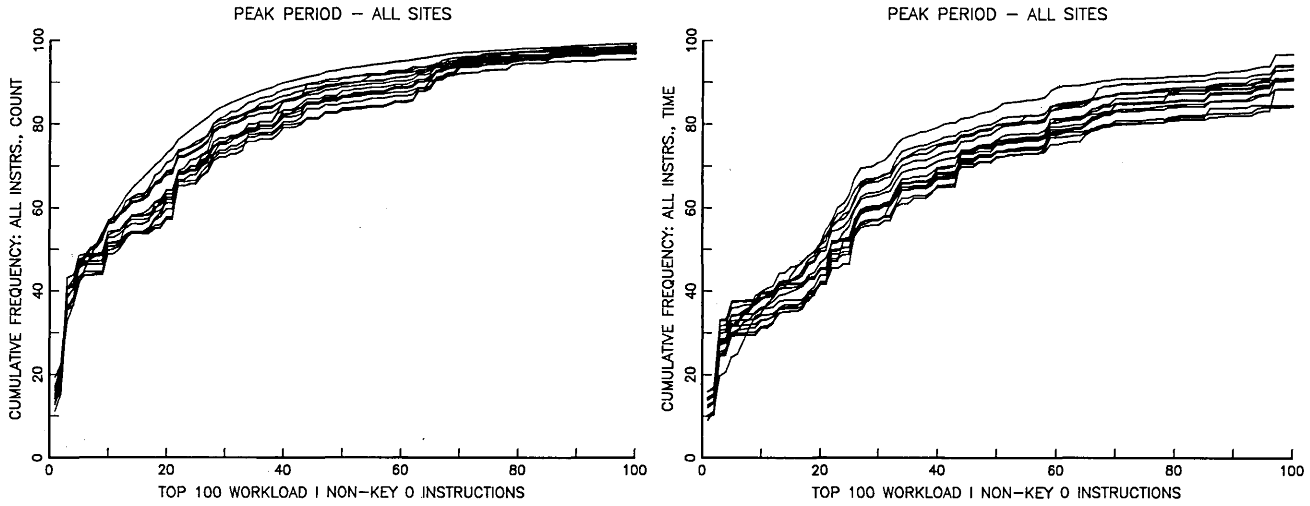
The foregoing shows that there is a certain amount of variability in instruction usage across different environments, with some commonality based on the presence of supervisor code in each environment. The way processors are implemented affects instruction execution time, and accentuates the variability. Because of this variability, it is important for robust design to consider different possible instruction mix contexts when evaluating potential system performance.

As an example of this, suppose that instead of the decreasing overall average instruction frequency as an ordering, we select an ordering based on the decreasing average instruction frequency for one particular workload. Even more, let us use the decreasing average non-Key 0 frequency. This would be somewhat akin to basing design decisions on a particular sort of application code. To illustrate this, we shall use Workload I.



Figures 9 and 10: Cumulative Instruction Frequency and Time For Selected Sites for non-Key 0 Instructions Ordered by Frequency of Top Instructions Averaged over All Sites

* The curve in Figure 11 is not as smooth as, for example, the top curve in Figure 3, since the curve represents the cumulative use of *all* instructions, but the ordering is based on *non-Key 0* instruction frequency.



Figures 11 and 12: Cumulative Instruction Frequency and Time For All Sites for All Instructions Ordered by Frequency of Top non-Key 0 Instructions of Workload I

Figures 11 and 12 present cumulative instruction mix and instruction time distributions for instruction usage for all sites; the instruction ordering is now the decreasing average frequency for the non-Key 0 instructions of Workload I.*. In both figures, the curve for Workload I starts out below the curves for the rest of the workloads, but becomes the top-most curve after 12 to 20 or so instructions, for counting and timing respectively. This shows the extent of mismatch with general instruction usage, on the average, were one to use Workload I application code as a design point: while for the first few instructions, one would be safe (since their use in other workloads is higher than in Workload I), one would be exposed after that. And comparing Figures 1 and 11 and Figures 2 and 12 shows that the extent of coverage is less when using Workload I application code as the base, since the general curves in Figures 1 and 2 are generally higher than their counterparts, particularly in Figure 2 in the range of 10 to 30 top instructions.

Akin to the problem of just using application code as a base for instruction use analysis (unless, of course, one only wants to characterize that particular code) is just using a subset of the instructions as a base for analysis. It was noted in the discussion following Figure 3 in Section 4 that while a given set of the top instructions may 'cover' a fair portion of the total instruction use, they usually 'cover' less of a portion of the total execution time. From a design point of view, this means that analyses based on the top so many instructions may not generalize well, i.e., there could be performance exposures in not evaluating substantially more of the instructions. In Figure 3, 90 percent of the instruction use accounted for about 75 percent of the execution time. If, for example, one did not look closely at the instructions accounting for the last 10 percent of the usage, resulting in an implementation which was slower by, say, a factor of 2 for these instructions, then 40 percent of the total execution time would not have been accounted for, a 25 percent increase in overall execution time.

There are several extensions that would be of interest, both from an instruction use and from a performance analysis orientation. For instruction use, one could do more in terms of instruction categories, such as statistics on instruction type usage (e.g., register-to-register, register-to-storage, etc.), or instruction function usage (e.g., loads vs. stores vs. branching, etc.). A number of these would have implications as to addressing hardware, storage bus, computational (e.g., floating point) element design, and so forth. Clements and Kolence [3] provide three general categorizations for software-sampled data, and Peuto and Shustek [10] give several in-depth examples of such categorizations, albeit for problem programs, along with a good discussion of why one looks at them. Emer and Clark [5] present results for groups of instructions where the data is obtained directly, not by summarization from individual instructions; the groups are meaningful for their analyses. What would be harder here would be to look at sequences of instructions and operand length distributions, for which data is not directly gathered (although some of this can be backed out, e.g., BC instructions generally follow TM instructions, and one might estimate operand length by looking at the cycles per instruction for particular instructions, such as LM or MVCL).

A more interesting extension is the integration of the approach presented here with more general processor performance models. Conceptually, one would like to incorporate implementation considerations, such as pipeline breakage, cache effects, and so forth, as noted in Section 2 above, and as presented in MacDougall [9]. The extent of the model presented in that paper is generally beyond the ability of a single performance tool to produce the data for, particularly in real environments. But there may be ways to extend the measurement capability, combining the approach presented here with that in LaMaire and White [8]. In that paper a fairly simple model of internal processor performance is given, which separates performance into a component having to do with execution time when all instructions and data are found in the cache, and a component relating the effect of delay when information is not found in the cache. The attempt here would be to try to apportion the in-cache effect on an instruction basis, similar to that presented in this paper.

7. Conclusion

One can conjecture about how wide the application of the foregoing is to different architectures and implementations. It does provide some insight into current instruction usage and its performance impact for large IBM mainframe processors. However, the actual numbers should be less important than some of the general observations that have been noted.

The first of these is another confirmation of the skew (with long tails) in instruction usage, as has been noted by others (Clark and Levy [2], Peuto and Shustek [10], etc.), and that this holds at the system-wide level as well as for problem code. Related to this is the general tendency in these cases of instruction mix 'coverage' to be higher than instruction execution time 'coverage', for the same most frequently used instructions. Presumably, the frequency of use data for the top instructions should always dominate the time data for these instructions for most of the environments for which a processor is designed, because the biggest performance gains come from speeding them up, and hence the most attention should be paid to their implementation. Considering these two points, the implication here is that analyses based on a certain number of frequently used instructions may be overly optimistic when considering the performance impact.

Another observation relates to the commonality of supervisor code across environments. This does, in effect, provide a "core" set of instructions which should occur with some degree of regularity, even though this core may appear in different proportions in different environments.

Concomitantly, the particularity of problem program code is what will give an environment its own flavor. These more workload specific instructions provide the variability which must be addressed in order to design an effective, general purpose machine. Consequently, there is a need to address a variety of mixes (especially for general purpose machines) to get a feel for the need for robust processor design.

Finally, one should analyze production systems; after all, the final assay of value lies in the crucible of the real world.

Abstract

In this paper, we investigate dynamic load sharing strategies for locally distributed database systems in which the database is partitioned and distributed among multiple transaction processing systems and a common front-end processor is employed for transaction routing. In this environment, if a transaction issues a database request referencing a non-local database partition, the request has to be shipped to the system owning the referenced partition for processing. A total of four different dynamic strategies have been studied. Their performances are compared with that of the optimal static strategy. A dynamic load sharing strategy which takes into account previous transaction routing decisions is found to provide a substantial improvement over the optimal static strategy. The robustness of this strategy is further studied through sensitivity analysis over a wide range of conditions, including transaction load, communication overhead and database reference distribution.

1.0 Introduction

When processing power is distributed over multiple computer systems, load sharing is critical in achieving higher aggregate throughput and better response time. To attain appropriate sharing, arriving tasks are allocated according to some strategy. Strategies are static in nature if allocation decisions are based solely on the static characteristics of arriving tasks and the processing systems. The other category, in which allocation decisions depend upon not only the static characteristics but also the current system state, is referred to as dynamic strategies.

Numerous load sharing strategies, both static and dynamic, have been studied for models of distributed systems. Queueing network analysis, mathematical programming, and other techniques can be used to obtain performance estimates and then to derive optimal static strategies; for example, the optimal deterministic allocation of tasks in [Ston77, Ston78], and optimal probabilistic assignments in [Ni85,Tant85]. On the other hand, certain optimalities in the dynamic approach have also been discovered. For instance, the send-to-shortest queue strategy is found to be the best for the case of Poisson arrivals and identical exponential servers [Wins77] and the round-robin strategy becomes optimal when the queue length at each server can not be observed, provided that all servers have the same initial state [Ephr80]. A survey on load sharing strategies in distributed systems can be found in [Wang85]. For other more complex cases, like heterogeneous servers, multiple classes of tasks and different arrival and service time distributions, simulations have been adopted to study the performance of various strategies [Agra82, Care84, Chow79].

The dynamic load sharing approach takes into account the changing condition of the system state and would appear to be more advantageous than the static approach. However, if a significant amount of overhead is needed to collect the required system state information to make routing decisions, the dynamic strategy can become impractical. The collection, the usages and the impacts of different levels of information are critical issues in the study of dynamic strategies. In [Eagr84, Eagr85], a probe limit scheme based on queue length threshold is proposed to make a compromise between the overhead of collecting information and the amount of information collected. Their results show that using a small amount of state information can improve performance considerably.

In these previous studies, it is assumed that incoming tasks can be serviced completely at any processing system. This implies that either all tasks are purely computational or requested resources, e.g. database or files, are shared or replicated among all processing systems. This assumption can be quite restrictive. Consider a locally distributed database environment as shown in Figure 1.1. By locally we mean so close together that communication delay are negligible, e.g., the entire system is located in the same machine room. The database is partitioned among the various processing systems and a common front-end system is employed for routing transactions to one of the processing systems. If a transaction issues a database request referencing a remote database partition, the request has to be shipped to the system owning the referenced partition for processing. This is referred to as a remote database request. Thus, a new dimension, the reference pattern or the reference locality, has to be considered in load sharing strategies.

In a locally distributed database complex, the processing associated with each transaction can be divided into two categories. The first category denoted as routing dependent processing, is to be executed at the processing system where a transaction is routed to. The application process belongs to this category. The other is partition dependent processing which is a service request against a particular database partition, e.g. the

CH2345-7/86/0000/0675$01.00 © 1986 IEEE

database requests, and can only be executed at the processing system owning the partition. To balance the loads among processing systems, only the routing dependent processing can be used as leverage. In addition, different transaction routing strategies may affect the number of remote database requests and, thus, incur different communication load. Load sharing has become more complicated compared to the case without request shipping between processing systems.

In this paper, we consider four different dynamic strategies for load sharing in a locally distributed database environment and evaluate their impacts on system performance. These strategies require different levels of information on the system state. The usefulness of different levels of state information is quantified through performance comparisons. From simulation results, we notice that good dynamic load sharing strategies should strike a compromise between balancing the processing load and reducing remote database requests. Neglecting either the load condition or database reference information during routing decision making can lead to less than satisfactory results. Also, detailed information on instantaneous system state, e.g. queue length at a particular moment, is found not to be beneficial to improve performance.

In the next section, the locally distributed database environment and transaction characteristics are described. The model of the system complex is also described. In section 3, various load sharing strategies are discussed. Section 4 presents simulation results on response time under different load sharing strategies. Detailed sensitivity analyses are also provided. We summarize the results in Section 5. Note that the model studied is not limited to the database system. It can be applied to any system with distributed resources and requests.

2.0 Model Description and Formulation

We consider a locally distributed transaction processing system as shown in Figure 1.1. The system consists of N transaction processing systems and a front-end system, connected by an interconnection network. The transaction processing systems execute transaction application processes and handle database requests. The whole database is partitioned into N databases which are denoted as $DB_1, ..., DB_N$, where DB_i is attached to the transaction processing system, P_i . All database requests to DB_i are assumed to be handled by the processing system P_i. The processor speeds and the I/O service times at the different processing system are assumed to be identical.

Transactions submitted by users enter the system through the front-end system where transactions get formatted and are routed to one of the processing systems. After a transaction processing is completed, output messages will be mapped into the user's screen format and delivered back to the user via the front-end system. A load sharing strategy is employed at the front-end system to determine the assignment of an incoming transaction to a processing system.

At the assigned processing system, a transaction invokes an application process which may issue a number of database requests. The application process of a transaction will be executed completely at the assigned processing system, whereas database requests will be executed at the processing system owning the database partition. During the execution of database request, I/O devices will be accessed if the required data is not in the processing systems. The flow of transaction processing is shown in Figure 2.1, where a transaction will be completed after several iterations of application processing segments and database requests. Transactions, then, can be characterized into different classes by (1) the processing service demand of each application processing segment, (2) the number and reference distribution of database requests, and (3) the processing and I/O service demands of each database request. For simplicity, we assume that these service demands are exponentially distributed. Also, at the end of each application processing segment, fixed probabilities of issuing a database request to a particular database or terminating the transaction processing are assumed where the probability can depend on the transaction class.

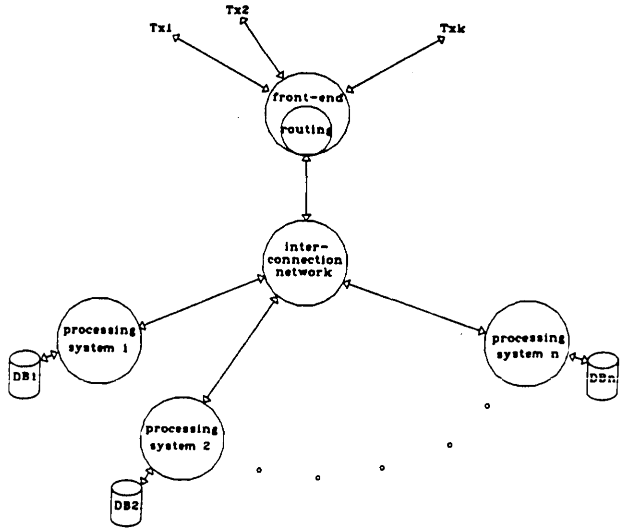

Figure 1.1 The Configuration of a Locally Distributed Database System

Based on the sequence of transaction processing, we construct the model of transaction processing as shown in Figure 2.2. Let there be K transaction classes in the system and let tx_k denote a class k transaction, $k = 1,...,K$. For each k tx_k 's arrive according to a time-invariant Poisson process with rate λ_k, where $k = 1,2,,...,K$. The mean processing service demands of an application processing segment and a database request of tx_k are a_k and b_k, respectively. Both a_k and b_k can be estimated by measuring pathlength of application processing and database request. For each database requests issued by tx_k, we assume that, with a fixed probability p_k^{IO} , an I/O device will be accessed and the service time of each I/O access is exponentially distributed with mean d_k . When the execution of an application processing segment is completed, transaction tx_k may issue a database request to database DB_i with probability p_{ki} , or may terminate with probability p_{k0}. The p_{ki} is referred to as the database request probability of transaction k to DB_i. Thus, the total processing load of incoming transactions per unit of time to the whole system becomes

$$S = \sum_{k=1}^{K} \frac{\lambda_k}{p_{k0}} (a_k + (1 - p_{k0}) b_k)$$

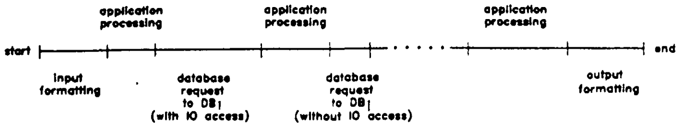

Figure 2.1. The Sequence of Transaction Processing

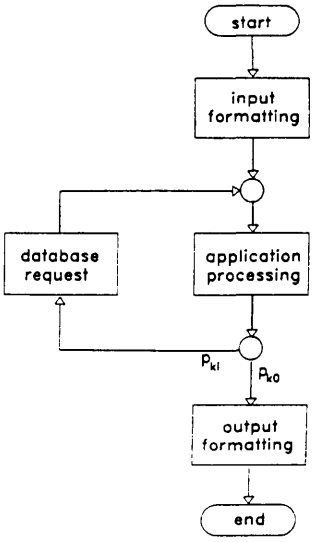

Figure 2.2. Model of Transaction Processing

Among this total processing load, there is a portion associated with the processing of database requests. We denote the processing load of database requests per unit time at P_i as follows

$$S_i^b = \sum_{k=1}^{K} \frac{\lambda_k p_{ki} b_k}{p_{k0}}$$

Notice that S and S_i^b only depend upon the characteristics of transactions and are independent of the transaction routing decisions. When a database request is issued, it must be shipped from processing system P_i to P_j if a transaction being executed at P_i issues a database request to DB_j, where $i \neq j$. After the request gets processed, the result will be sent back. Both P_i and P_j have to perform sending and receiving services in this case. The service demands of sending and receiving a database request or the results of a request are referred to as communication overhead and are assumed to be exponentially distributed with mean c.

The system model is illustrated in Figure 2.3. Each processing system is modeled by a single server processor sharing queue to represent the processor and an an infinite server queue to represent the I/O. After a transaction is routed to a processing system, its various tasks may be executed sequentially at different processing systems. The transmission delay of shipping database requests in the network and the delay due to the decision process at the front-end system are assumed negligible. The former assumption while reasonable in a locally distributed system would not be in a geographically distributed system.

3.0 Load Sharing Strategies

We now consider four different dynamic routing strategies which can be employed at the front-end system. Different system static and state information are considered in making the routing decision under each strategy. We call the number of tasks being executed at processing system P_i the queue length at i, where a task is either application processing, database request processing or communication overhead. The number of tasks receiving IO service at system i is not included in the queue length at i.

3.1 Minimum Instantaneous Queue Length

The minimum instantaneous queue length strategy (denoted as MQL) routes each arriving transaction to the processing system that has the least number of tasks being executed. Let $\underline{n} = (n_1,...,n_N)$ where n_i is the instantaneous queue length of the processing system P_i, for $i = 1,2,..,N$. The minimum queue length strategy selects the processor element P_i such that $n_i = \min_{1 \leq j \leq N}\{n_j\}$. If the minimum is not unique, a processing system, among the ones that achieve the minimum, is randomly chosen. This strategy is only based on the state information $\underline{n}$ and does not require any static information.

The minimum instantaneous queue length strategy, also known as the send-to-shortest queue policy, is optimal for a system with identical exponential queues, a single Poisson arriving transaction stream and where each transaction executes on only one processor and can executed on any processor. For more complex systems with multiple classes and/or transactions which cannot execute on certain processor and/or transactions which must execute on more than one processor, the minimum queue length strategy is not in general optimal.

3.2 Minimum Expected Response Time Strategies

p. Consider a set of dynamic strategies where the routing decision process consists of two steps. First, the expected response time of the incoming transaction given the transaction is routed to the processing system P_i, is estimated. Then, the incoming transaction is routed to the processing system P_i which provides the minimum expected response time.

Assuming the system state on arrival is known, the expected response time of the incoming transaction should be estimated using a transient analysis. For simplicity, a steady-state analysis is applied. Consider the system model shown in Fig. 2.3. Let us assume that the class k transactions are routed, according to a certain probability distribution, to the processing system P_i. Then the system can be represented by a product form open queueing network [Bask75] with K chains corresponding to the transaction classes and N processor sharing queues representing the processors, each connected with an infinite server queue representing the I/O servers. If the steady state queue length $\bar{L} = (L_1,...,L_N)$, where L_i denotes the mean queue length of P_i, for $i = 1,...,N$, is known, then the mean response time of an arriving type k transaction, denoted as $R_{ki}(\bar{L})$, provided that it will be routed to P_i, can be approximated as follows.

Let $R^a_{ki}(L_i)$ denote the expected response time for completing the application process for a class k transaction, tx_k, which is routed to a processing system P_i. Consider the processing time of a database request at a processing system given there is no I/O access. The expected response time of serving a local database request to DB_i at P_i, for a transaction tx_k routed to P_i, is denoted by $R^l_{ki}(L_i)$. For a database request to DB_j issued from P_i, where $i \neq j$, a database request must be shipped from processing system P_i to P_j. Then, in this case, there are two components in the expected response time: the first, $R^{ov}_{ki}(L_i)$, is due to the communication overhead in P_i of shipping the request and receiving the result, and the second, $R^r_{kj}(L_j)$, is due to the servicing a remote database request in P_j, which includes receiving the request, processing the request and sending the result back. Hence, the total expected response time $R_{ki}(\bar{L})$, for an arriving type k transaction assigned to processing system P_i can be written as

$$R_{ki}(\bar{L}) = \frac{1}{p_{k0}}[R^a_{ki}(L_i) + p_{ki}\, R^l_{ki}(L_i) + \sum_{\substack{j=1 \\ j\neq i}}^{N} p_{kj}\, R^{ov}_{ki}(L_i) + \sum_{\substack{j=1 \\ j\neq i}}^{N} p_{kj} R^r_{kj}(L_j) + p^{IO}_k d_k] \tag{1}$$

where $p^{IO}_k d_k$ is the expected I/O service time for each database request and p_{kj} is the database request probability of a class k transaction to DB_j.

On the other hand, each component in the expected response time in (1) can be approximated by

$$R^x_{ki}(L_i) = S^x_{ki}\ (L_i + 1) \tag{2}$$

for $k = 1,...,K$, $i = 1,....,N$, where $x = a,l,ov,r$, S^x_{ki} is the service time of tx_k on P_i for service x. Given the mean service demand for tx_k of application processing segments, database requests and sending or receiving requests, i.e. a_k, b_k and c, respectively, one can write

$$S^a_{ki} = \frac{a_k}{\mu}\ ,\quad S^l_{ki} = \frac{b_k}{\mu}\ ,\quad S^{ov}_{ki} = \frac{c}{\mu}\ ,\quad S^r_{ki} = \frac{b_k + c}{\mu} \tag{3}$$

where μ is the processing speed of each processor. Hence, by (2) and (3), the total expected response time given by (1) for transaction tx_k routed to P_i can be rewritten as

$$R_{ki}(\bar{L}) = \frac{1}{p_{k0}}\{(L_i + 1)[S^a_{ki} + S^l_{ki}\, p_{ki} + S^{ov}_{ki} \sum_{\substack{j=1 \\ j\neq i}}^{N} p_{kj}] + \sum_{\substack{j=1 \\ j\neq i}}^{N} (L_j + 1) S^r_{kj}\, p_{kj} + p^{IO}_k d_k\} \tag{4}$$

Note that the above equation is a steady-state expression of the expected response time of the arriving transaction as a function of mean queue length $\bar{L}$. We now consider three different ways to estimate $\bar{L}$ which result in three different routing strategies.

3.2.1 Instantaneous Queue Length Based Strategy

We assume that the instantaneous queue length $\bar{n} = (n_1, ..., n_N)$ is known on arrival and we estimate $\bar{L}$ by $\bar{n}$. i.e., the expected response time is estimated by $R_{ki}(\bar{n})$. Thus, this strategy requires state information $\bar{n}$ and static information $\{a_k, b_k, c, p_{k0}, p_{ki}, \mu\}$. We refer to this strategy as MRT.IQL for minimum response time based on instantaneous queue length. Note that the instantaneous queue length information required can be costly to collect. In addition, the instantaneous queue length may not be representative of the mean queue length.

3.2.2 Service Time Based Strategy

Consider the moment that a new transaction arrives. Let m_{ki} be the number of class k transactions assigned to the processing system P_i, and not yet completed, i.e., m_{ki} is determined by the previous routing decisions for all transactions still in the complex. Let $prob_k(i,j)$ denote the probability that a class k transaction assigned to processing system P_i is waiting for or receiving processing service at P_j. Hence, we can express the expected queue length L_j of P_j as

$$L_j = \sum_{i=1}^{N} \sum_{k=1}^{K} m_{ki}\, prob_k(i,j) \tag{5}$$

for $j = 1,...,N$. Assuming that the fraction of time that a type k transaction is either (a) waiting or receiving processing service at P_j, or (b) receiving I/O service is proportional to the corresponding overall service time, one can approximate the unknown probabilities in (5) as follows

$$\begin{aligned} prob_k(i,j) &= S^r_{kj}\, p_{kj} \frac{1}{C_{ki}} \qquad i \neq j \\ prob_k(i,i) &= [S^a_{ki} + S^l_{ki}\, p_{ki} + S^{ov}_{ki} \sum_{\substack{j=1 \\ j\neq i}}^{N} p_{kj}] \frac{1}{C_{ki}} \end{aligned} \tag{6}$$

where the normalizing constant C_{ki} is given by

$$C_{ki} = S^a_{ki} + S^l_{ki}\, p_{ki} + S^{ov}_{ki} \sum_{\substack{j=1 \\ j\neq i}}^{N} p_{kj} + \sum_{\substack{j=1 \\ j\neq i}}^{N} S^r_{kj}\, p_{kj} + p^{IO}_k d_k \sum_{j=1}^{N} p_{kj}$$

Notice that the probabilities $prob_k(i,j)$ are normalized by considering the transactions assigned to P_i and receiving either processing or I/O service. the I/O devices.

Hence, given $\vec{m} = (m_{ki}: k = 1,...,K;\ i = 1,...,N)$ and the approximate probabilities $prob_k(i,j)$ based on the service time proportions, one can derive estimates from Eq. (5) of the mean queue length $\vec{L}$. Each incoming transaction is then routed to the processing system P_i such that $R_{ki}(\vec{L}) = \min_{1 \le j \le N}\{R_{kj}(\vec{L})\}$. This strategy is called MRT.ST which requires state-dependent information $\vec{m}$ and static information $\{a_k, b_k, c, p_{k0}, p_{ki}, \mu\}$.

3.2.3 Residence Time Based Strategy

The residence time based strategy, which will be called MRT.RT, is different from MRT.ST only in the computation of probabilities $prob_k(i,j)$. With MRT.RT strategy, the probability $prob_k(i,j)$ is proportional to the residence time at the processing system P_j, instead of the service time. An iterative approach based on the MVA equations [Reis80] is applied in order to derive the probability $prob_k(i,j)$ and the expected queue length, $\vec{L}$.

The residence time $T_k(i,j)$ in P_j of a transaction of class k initially assigned to P_i can be written as

$$T_k(i,j) = S_k(i,j)\ (N_k(i,j) + 1)$$

where $N_k(i,j)$ is the mean number of tasks that a type k transaction assigned to P_i finds in P_j and $S_k(i,j)$ is its total service time at P_j. Values of $S_k(i,j)$ can be simply derived from the service times expressed in (3). $N_k(i,j)$ can be approximated by $N_k(i,j) = L_j - prob_k(i,j)$ which is similar to the well known Bard-Shweitzer's algorithm [Schw79, Bard80]. Thus, the probability $prob_k(i,j)$ which is proportional to the residence time $T_k(i,j)$ is given as

$$prob_k(i,j) = S^r_{kj} p_{kj} (L_j - prob_k(i,j) + 1)\frac{1}{C_{ki}} \qquad (7)$$

$$prob_k(i,i) = [S^a_{ki} + S^l_{ki} p_{ki} + S^{ov}_{ki} \sum_{\substack{j=1 \\ j \ne i}}^{N} p_{kj}]\ (L_i - prob_k(i,i) + 1)\frac{1}{C_{ki}}$$

where the normalizing constant C_{ki} is given by

$$C_{ki} = [S^a_{ki} + S^l_{ki} p_{ki} + S^{ov}_{ki} \sum_{\substack{j=1 \\ j \ne i}}^{N} p_{kj}](L_i - prob_k(i,i) + 1) + \sum_{\substack{j=1 \\ j \ne i}}^{N} S^r_{kj} p_{kj} (L_j - prob_k(i,j) + 1) + p_k^{IO} d_k \sum_{j=1}^{N} p_{kj}$$

Hence, given a system state $\vec{m}$, the mean queue lengths are computed by iterating (7) and (5), starting with zero values for both queue lengths L_j and probabilities $prob_k(i,j)$, for $k = 1,...,K$, $i,j = 1,...,N$. The MRT.RT strategy uses the same static and state-dependent information as the MRT.ST strategy. The iteration between (7) and (5) should not impose any substantial overhead during decision making.

4.0 Simulation Study and Performance Comparisons

In the following, we use simulation to investigate the effectiveness of the proposed load sharing strategies. Mean transaction response time is the main concern and is used to indicate system performance under the different load sharing strategies. To compare the performance of tne above strategies, we also consider the optimal static load sharing strategy. Under a static load sharing strategy, an incoming transaction is routed to a processing system according to a predefined routing probability. The optimal static load sharing strategy takes account of all static information, i.e. $\{\lambda_k, a_k, b_k, c, p_{k0} p_{ki}, \mu\}$, to determine the routing probabilities such that the mean transaction response time is minimized. The details of solving this optimization problem have been given in [Yu85a], where a simplex reflection method is used to find the optimal routing probabilities.

4.1 Description of the Simulations

In order to evaluate dynamic load sharing strategies, we simulated the model for a locally distributed database system illustrated in Figure 2.3. The simulation was implemented using RESQ [Saue82]. The routing decision is implemented as a separate function and is invoked upon transaction arrival at the front-end system. In addition, for all simulation runs, 95% confidence level was obtained. The simulations were run until the relative width of the confidence interval (width divided by midpoint) was less than 0.1.

In the experiments reported in the following, we assume that there are three transaction processing systems ($N = 3$) and three transaction classes ($K = 3$). Based on data from some IBM IMS systems [Corn85, Yu85b], the average number of database requests per transaction is set to 15 for all transaction classes, i.e., $p_{k0} = 0.0625$ for $k = 1,2,3$. The matrices $\frac{1}{1-p_{k0}}[p_{ki}]$, which indicate the distribution of database requests, are given in Table 4.1 to reflect low, middle, and high localities of database requests.

To study the impact of processing load on database requests and request shippings, various service demands and processing powers are assigned with relative values. We regard $a_k + b_k$ as a unit of service demand for all k. The mean service time of this unit is assumed to be 0.04, i.e., $\mu = 25$. The service demand of shipping a request, c, is defined in terms of this unit. The IO access time, d_k, and the probability of having IO access, p_k^{IO}, are assumed to be 0.4 and 0.7 for all transaction classes, respectively. Also, we denote the ratio of b_k to $a_k + b_k$ as r_k. The complexity of database requests can be represented through this ratio.

The load of a processing system could be due to the services of transaction application processing, database request processing, and communication overhead processing. Let $\rho_p = \frac{S}{N\mu}$, where S is given in Section 2, which indicates the average processing load per system due to application processing and database requests and is independent of the routing decisions. By changing the arrival rates λ_k, we can study the transaction response time under different ρ_p. The load of a processing system P_i due to processing database requests, de-

	low locality			middle locality			high locality		
Database	1	2	3	1	2	3	1	2	3
Tx type 1	0.65	0.20	0.15	0.75	0.11	0.14	0.90	0.10	0.0
Tx type 2	0.17	0.52	0.31	0.07	0.82	0.11	0.07	0.87	0.06
Tx type 3	0.21	0.21	0.58	0.11	0.06	0.83	0.11	0.03	0.86

Table 4.1 The Distribution of Database Requests Used in Experiments

noted by $\rho_b(i)$, is routing independent and is equal to $\frac{S_i^b}{\mu}$, where S_i^b is given in Section 2. By changing the arrival rates subject to a fixed ρ_p, we can vary the relative value of the $\rho_b(i)$ which represent the partition depending processing loads.

4.2 Performance Comparisons

First, we study the effectiveness of load sharing strategies under different processing loads, ρ_p. The incoming transactions are assumed to have middle locality in regard to the distribution of database requests and $r_k = 0.3$ for all transaction classes. The partition dependent load on each processing system is assumed to be equal, i.e., $\rho_b(1):\rho_b(2):\rho_b(3) = 1:1:1$. Figures 4.1 and 4.2 show the transaction response times versus ρ_p for $c = 0.05$ and $c = 0.25$, respectively.

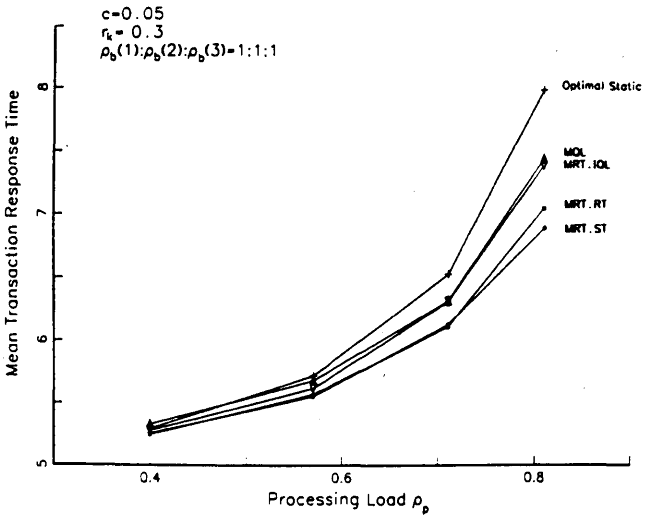

Figure 4.1 Mean transaction response time vs. processing load ($c = 0.05$)

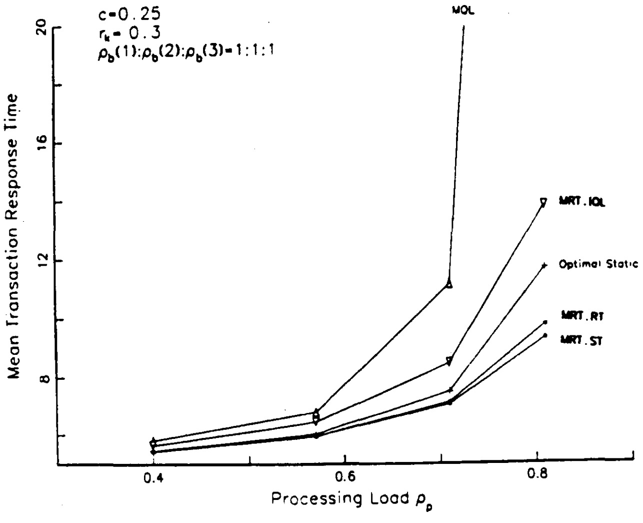

Figure 4.2 Mean transaction response time vs. processing load ($c = 0.25$)

Notice that when the communication overhead of shipping remote requests is low, all dynamic load sharing strategies have better performance than the optimal static strategy. When the communication overhead is high, optimal static strategy becomes better than MQL and MRT.IQL, strategies. Over all strategies considered, MRT.ST and MRT.RT strategies yield the best performance. Neither of these two strategies needs instantaneous state information. If we keep a count at the front-end system of the previous transaction routings and completions, both strategies can be implemented without the extra communication between the front-end system and the transaction processing systems that would be needed to collect instantaneous state information.

Both MQL and MRT.IQL strategies use instantaneous queue lengths to make transaction routing decisions. The queue length at each processing system contains the tasks of application processing, database request processing and communication overhead. The instantaneous queue length may fluctuate frequently due to the issuing of database requests. As a consequence, the decision processes using MQL and MRT.IQL are based on more instance where the system has unbalanced load than under the other strategies. Thus, more transactions are routed to a non-preferred system where only small percentage of database requests are designated to and more remote database requests are introduced. When the communication overhead is high, these additional remote database requests lead to an increase of system utilization and transaction response time. Both the MQL and MRT.IQL strategies end up with inferior performance to the optimal static strategy, which does not consider the system state in making the routing decision.

4.3 Sensitivity Analyses

In Figures 4.1 and 4.2, it has been shown that both MRT.ST and MRT.RT are superior to the other load sharing strategies considered in this paper. We shall proceed further to investigate the robustness of these two strategies through sensitivity analyses on various system and workload parameters. Specifically, we vary communication overhead, distribution of database requests and degree of balance of the partition dependent loads.

1. Sensitivity to communication overhead

The relationship between transaction response time and communication overhead is illustrated in Figure 4.3 where simulation results for various communication overheads are presented for MRT.ST, MRT.RT, and the optimal static strategies. Two groups of curves are shown; one is for $\rho_p = 0.57$, the other is for $\rho_p = 0.71$. The response times increase more than linearly in the second group which is under higher processing load. Figure 4.4 shows the increase in mean communication load at each processing system when the communication overhead of shipping database requests and results becomes large.

Although both MRT.ST and MRT.RT are superior to the optimal static strategy, the mean communication load under the optimal static strategy is less than that under MRT.ST or MRT.RT. This is shown in Figure 4.4. Compared with the optimal static strategy, the larger shipping loads under MRT.ST and MRT.RT indicate that more transactions are routed to a non-preferred processing system to eliminate temporary load unbalancing. Despite the increase in communication load, the dynamic routing balances the loads among processing systems, eliminates possible bottlenecks, and thus reduces the response time. The other interesting observation in Figure 4.4 is that the number of non-preferred routings under MRT.RT is greater than that under MRT.ST. In contrast to MRT.ST, the MRT.RT's approximation captures queueing effects. Thus, the difference of estimated queue lengths between processing systems under MRT.RT tends to be larger than that under MRT.ST. As a consequence, more transactions are routed to a non-preferred processing system under MRT.RT.

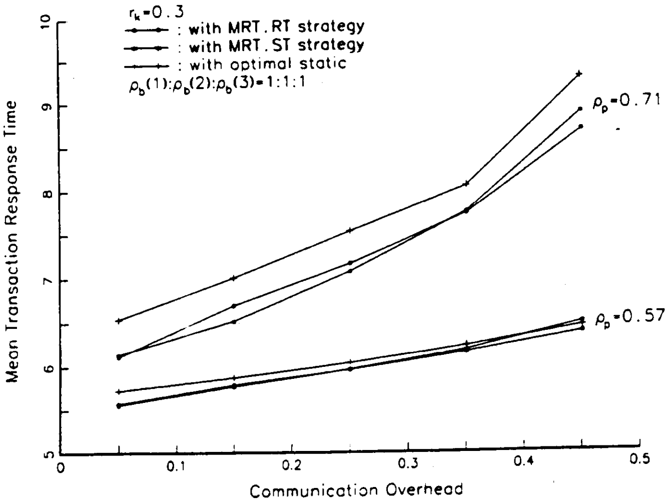

Figure 4.3. Mean transaction response time vs. communication overhead

2. Sensitivity to the degree of balance of database request processing

In Figure 4.5, the performance of MRT.ST, MRT.RT and the optimal static strategy is studied for different proportions of $\rho_b(1):\rho_b(2):\rho_b(3)$ which is changed from 0.5:1:1 to 2.5:1:1 . This is achieved by changing the arrival rates of different transaction classes. Since the application processing load can be allocated to any processing system, the changes of arrival rates only vary the load of serving database requests. The load of serving application processing and communication at each processing system is determined by the load sharing strategy. However, this underlying unbalancing certainly increases the difficulty in trading off sharing transaction processing load and reducing communication overhead load. As shown in Figure 4.5, when the $\rho_b(i)$'s are unbalanced, the response time increases apparently because (1) more contention for one or two processing systems when database requests are issued, and (2) more communication load is introduced during balancing the load at each processing system. In addition, the MRT.ST strategy is much more sensitive to the degree of balancing of $\rho_b(i)$.

The unbalanced loads in the processing systems can also be used to differentiate the performances under MRT.ST and MRT.RT. Since the routing decision is based on the difference of estimated loads between processing systems, the accuracy in estimation only becomes clear when the loads are quite different. As shown in Figure 4.5, the performance under MRT.RT can be a lot better than that under MRT.ST for highly unbalanced cases. When $\rho_b(1):\rho_b(2):\rho_b(3)$ = 2.5:1:1, the response time under the MRT.ST gets even worse than that under the optimal static strategy.

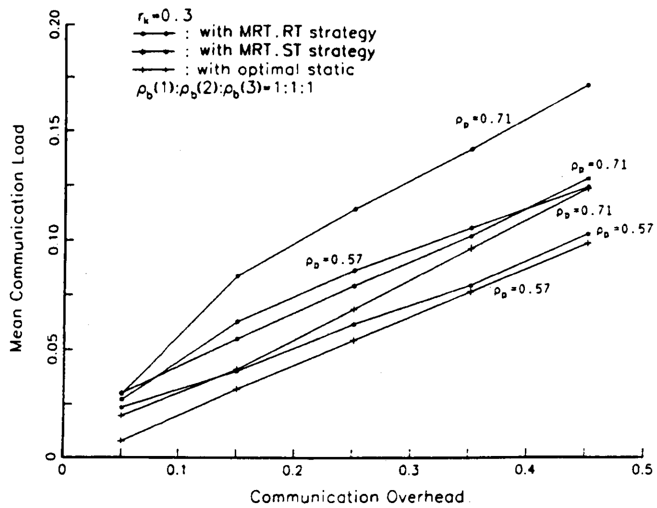

Figure 4.4. Average communication load vs. communication overhead

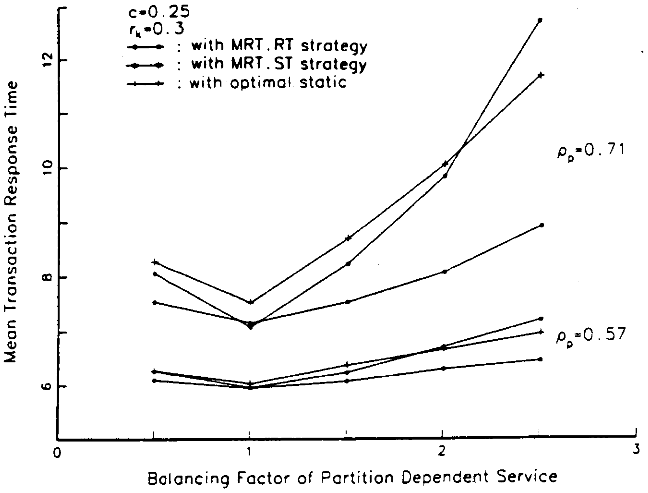

Figure 4.5 Mean transaction response time vs. degree of balancing on partition dependent load

3. Sensitivity to the database reference pattern

Under the MRT.RT strategy, Figure 4.6 shows the mean response time versus processing load for the different reference distributions of database requests defined in Table 4.1. As expected, the cases with less locality have longer response times. When ρ_p = 0.81 and c = 0.25, the processor utilization of the low locality case can reach 0.99. The decrease in the locality leads to higher communication load. When the locality of database request decreases, the benefit of routing transactions to the preferred processing system decreases. Thus, more transactions get routed to a non-preferred processing system to balance the load. Figure 4.7 shows the percentage of transactions routed to non-preferred processing systems versus processing load. Clearly, the percentage of non-preferred routing in the case with low locality is larger than that of the cases with middle or high locality. The changes in transaction routing under different processing load can be studied in Figure 4.7. When the utilization increases, the communication load incurred from assigning transactions to a non-preferred processing system may deteriorate transaction response time more than the gain from balancing the load. Thus, this percentage will be reduced to avoid system saturation.

5.0 Conclusion

In this paper, we have evaluated different strategies for dynamic load sharing in a locally distributed database environment. The issue is how to make effective load sharing decisions at the front-end system with the least amount of communication between the front-end and processing systems to collect system state information. A total of four different dynamic strategies have been considered. The minimum queue length (MQL) strategy which does not consider the transaction's database reference pattern has the worst performance among all the dynamic strategies considered. It often performs worse than the optimal static strategy. The dynamic strategy which uses the instantaneous queue length to estimate the mean response time of each possible routing is also not very successful. This is due to the fact that instantaneous queue length does not accurately reflect the current loads of processing systems.

The other two dynamic strategies, MRT.ST and MRT.RT, estimate the mean response time at each processing system based on the number of executing transactions at each processing system. Both strategies lead to very satisfactory results when the partition dependent load is well balanced. The difference between the two strategies is in the estimation of the mean queue length at each processing system: the MRT.ST is simply based on the remaining processing load, whereas the MRT.RT further considers the queueing effect. The sensitivity analyses show that the MRT.RT is much more robust for unbalanced database load and can provide substantial performance improvement over the optimal static load sharing strategy.

In summary, dynamic strategies can be superior to the optimal static strategy if good routing decisions are made using appropriate information about the system state. Good dynamic strategies need to consider both balancing the load and reducing remote processing requests. The state information used in making decisions must be able to characterize the average system behavior instead of the instantaneous load fluctuation. An immediate extension of the study, which is currently being investigated, is to consider the collection of the above information and the load sharing strategies for a transaction processing complex with distributed front-end systems.

A LOAD INDEX FOR DYNAMIC LOAD BALANCING (*)

Domenico Ferrari and Songnian Zhou

ABSTRACT

The problem of selecting the load index or indices to be used in dynamic load balancing policies is discussed. One such index, based on a mean-value equation, is proposed, and its main characteristics investigated. The index is obtained assuming that the goal of the load balancing scheme is the minimization of the response time of the user command being considered for possible remote execution. The main advantages of the proposed index are its being based on a mathematical foundation and on a clearly specified criterion, the simplicity of its calculation, and its suitability for use in a heterogeneous network. The main problems with it are its dependence on the command's arguments and the steady-state assumption on which it is based. However, it can be argued that, in most practical cases, the index does not have to be used in its full generality, but reduces to simpler expressions for which the former problem does not arise. The results of some experiments to study the latter problem are presented and discussed.

1. INTRODUCTION

One of the most important potential benefits of loosely-coupled distributed systems is in the area of resource sharing. By interconnecting a number of machines via a data communications network with an adequate bandwidth, a larger variety and a larger number of hardware and software resources can be made available to the users of the resulting distributed system than is usually possible in a centralized system. The processing powers of the hosts in a distributed system are among the sharable resources, and are indeed made available to remote users in most such systems, sometimes via a *remote login* mechanism, some other times by allowing users to subdivide the work to be accomplished between a foreground machine and a background "number cruncher," and some other times by having on the network a pool of "public" machines (compute servers) accessible on demand to the users.

In spite of these mechanisms and provisions, we cannot state that the processing resources of a distributed system are always shared as much as they could and should be. This unsatisfactory state of affairs is particularly noticeable, and particularly unfortunate, in many local-area network (LAN) based distributed systems, where the small intercomputer distances, the relatively broad bandwidths, and the greater homogeneity of host ownership (which is frequently restricted to a single organization) would make it easier and more rewarding to share the processing resources of the hosts among all or most of the system's users. The dramatic imbalances among the loads of the various hosts we often observe in these systems cause poor performance and a waste of system resources. In certain LAN-based installations, both the workload imposed on the system by each user and the set of active users have largely predictable and not too rapidly changing characteristics; under these conditions, the *manual* (or *static*) approach to load balancing, which consists of distributing the users over the available hosts (one of them being defined as the "usual host" of each user), may be quite successful. Since no workload is absolutely constant in its volume and characteristics, it will be necessary to rebalance the loads periodically; that is, we will have to retune the system when its operating point has gone far enough from the point of balance. However, a large fraction of the LAN-based installations are characterized by a workload so dynamic that the maximum frequency at which the load can be rebalanced manually is too low for manual rebalancing to be effective. As in the case of the bottlenecks that are found in centralized systems, the initial balancing and periodic retuning with the manual approach may be useful; however, shorter-lived bottlenecks, whose impact on performance grows with the width of the workload's frequency spectrum, can only be eliminated by *automatic* (or *dynamic*) approaches[1]. In principle, providing the users with such mechanisms as a *remote login* and a network-wide load reporting command allows them to give their individual contributions to the balancing of the loads. This may, however, be ineffective and even counterproductive, due to the frequency of the possible interventions, which is likely to be too low, and to the necessarily limited and incomplete information that each individual user has about the system's state. Thus, for a large number of installations, dynamic load balancing is required to improve resource usage and performance.

This paper discusses the problem of selecting the load index or indices to be used in dynamic load balancing policies, and proposes one such index. Section 2 defines the load balancing schemes the rest of the paper refers to. Our criteria for load index selection and our assumptions are presented in Section 3. The specific index we propose in this paper is introduced in Section 4, together with the arguments for its

choice. Section 5 presents the results of experiments performed to verify the validity of some of the assumptions on which the new index is based. The main characteristics of the index and the major problems that arise with its use in a load balancing scheme are discussed in Section 6.

2. DYNAMIC LOAD BALANCING POLICIES

Since the terminology used in the load balancing literature is still fluid, we must provide our definitions of the terms we will use, and clarify, by introducing a classification of schemes as well as the various assumptions we are making, the scope of our investigation. This will be done both in this and in the next section.

First, we notice that the two terms *load balancing* and *load sharing* very often appear in the literature with the same meaning. One could easily introduce a distinction between them based on the different meanings the terms "balancing" and "sharing" suggest: for instance, use of the term "balancing" could be restricted to those schemes whose objective is to keep the loads on the machines within a relatively narrow band around the instantaneous average, whereas "sharing" could refer to those schemes in which a machine sends some of its load away (or accepts some of the load of other machines) only when its load goes beyond an upper threshold (or falls below a lower threshold). In both types of schemes the decision-maker must know the load existing on the machine being considered; in the load balancing ones, also the current average system load[2] must be known. However, even though drawing a distinction between "balancing" and "sharing" may be useful in certain contexts, both types of schemes are dealt with in the same way in this paper. We therefore use "load balancing" as a generic term encompassing both, even though our primary objective in selecting a load index is not that of equalizing the loads (we shall indeed see that, with our approach, this objective would be meaningless).

It is also useful to distinguish *preemptive* from *non-preemptive* load balancing schemes. In the former, a running process may be suspended and migrated to a remote machine, where its execution will resume from the point of suspension. A non-preemptive scheme is one in which a process is assigned to a machine before beginning its execution, and cannot be moved to another after its execution has begun. We shall usually refer to non-preemptive schemes in the sequel, though most of our considerations apply to the preemptive ones as well. In either type of scheme, the *local machine* is the machine at which a given process entered the system.

Another classification of load balancing schemes that is sometimes useful is the one based on the identity of the machine which takes the initiative. When the scheme involves a centralized controller that makes the placement decisions, this controller can be thought of as the initiative-taker as well as the decision-maker, even though it may be a prospective *source* or *destination* machine which takes the initiative and asks the controller to decide. In other schemes (the so-called *sender-initiated* ones[3]), the local machine takes the initiative when a new process is to be executed or when its load has gone beyond the upper threshold. In the *receiver-initiated* schemes[3], instead, underloaded prospective receivers take the initiative of broadcasting information about their enviable state so as to attract currently running or soon-to-arrive new processes.

Thus, the initiator will have to select senders and receivers in the centralized controller case, one of the eligible receivers in sender-initiated schemes, and one of the eligible senders in receiver-initiated schemes. This selection can be either load-independent or load-dependent.

Among the *load-independent* policies are Random[4] or Random Splitting[5], which chooses at random the destination of a process to be executed remotely; Fixed Destination or Fixed Source[5], which, in the sender-initiated version, statically binds a given receiver to a given sender or group of senders, or, in the receiver-initiated version, a given sender to a given receiver or group of receivers; Cyclic Splitting or Cyclic Service[5], in which the destination (respectively, the source) is selected according to a cyclic ordering of the available machines; and Proportional Branching[6], a probabilistic policy which selects destinations or sources according to probabilities proportional to their processing speeds.

Examples of *load-dependent* policies include Lowest Load[6,7,8], which selects the machine with the smallest load at the time the decision is to be made; Shortest[4], which does the same but restricts its search to a randomly chosen subset of the eligible machines; Threshold[4], which probes randomly selected machines to determine whether adding a process would raise their loads above a given threshold; Broadcast When Idle or Poll When Idle[7], a receiver-initiated policy in which a lightly loaded machine invites or polls the others, so that only those prospective senders whose loads are heavier than a threshold will ship processes to the initiating machine (note that, if priority is given to the most heavily loaded machine, we obtain the Highest Load policy, i.e., the receiver-initiated analog of Lowest Load); Neighbor Pairing[9], which shifts load from the more heavily to the less heavily loaded machine in dynamically defined pairs of machines; and the policy used in the MOS operating system[10], which cyclically selects machines among the lightly loaded ones in a subset of the eligible machines.

While in load-dependent policies the load of each machine in the system is to be measured, and its value must be known by at least some of the possible decision-makers, load-independent policies do not have such a requirement. However, as was observed at the beginning of this section, at the very least a policy must rely on the knowledge of the load on the local machine, as moving processes is not a zero-cost operation and should be done only when necessary. Thus, the load of each machine must be measured, i.e., quantitatively expressed, in all cases. What index (or indices) should be used to measure a machine's load?

3. A CRITERION FOR LOAD INDEX SELECTION

Many indices have been explicitly or implicitly used in the load balancing literature to express the load existing on a machine at a given time. Examples of such load indices include the utilization of the CPU, the length of the ready queue (in UNIX* terminology, the "load average"), the stretch factor (defined as the ratio between the execution time of a process on a loaded machine and its execution time on the same machine when it is empty), and more complicated functions of these simple variables. However, to the authors' knowledge, a scientific justification for the choice of a load index has never been given. In fact, some papers

* UNIX is a trademark of AT & T Bell Laboratories

even ignore the question altogether, and simply refer to "the load" as if there existed a well-known and universally accepted definition of this term. Is any of the indices used in the literature a valid one? Which? And what does it mean for a load index to be "valid"?

To simplify our discussion, we shall assume that the object to which load balancing applies is the *interactive user command*, as represented by the typing in of a command line or equivalent action on the part of an interactive user. In other words, the execution of a command will be considered atomic from the load balancing viewpoint, even when a command causes the creation and execution of several processes that, in principle, could be executed on different machines. This assumption is made to facilitate the description, but is not essential for the application of our approach.

An assumption that is essential is the choice of *the command's response time* as the performance index to be minimized by the load balancing scheme. This is another area in which some of the papers on load balancing leave something to be desired: the objectives of the schemes proposed therein are sometimes not clearly specified. Our choice of the response time objective is certainly questionable, since the exact relationships between it and such system-wide objectives as throughput maximization are unknown, but (we believe) not unreasonable.

Under these assumptions, a valid load index *li* must be such that the relationship between the response time *rt* of a command and the index is represented by a *single-valued curve*. In other words, *rt* must be a *function* of *li*. The reason for this condition is obvious: if the function *rt*(*li*) for a given machine, a given configuration, and a given command is known, the value of *li* at the time a decision is to be made can be used to predict the response time that the command will have if it will be sent to that machine. The predicted response times for all the eligible machines (including the local one), adjusted for the expected communications delays due to the shipment of the command, of the output, and possibly of the files it needs to execute, can be compared by the decision-maker in order to determine the machine which is likely to process the command in the shortest possible time. Note that this condition, even though it seems not to be very restrictive, is not generally satisfied by any of the indices proposed in the literature. Simple experiments performed by the authors have shown that the curves relating *rt* to CPU utilization, ready queue length, stretch factor, and other indices are multi-valued ones for at least some types of commands.

If more restrictive conditions are imposed, the selection of the least loaded machine can be made more efficient. For instance, in a system consisting of identical machines, a monotonically non-decreasing *rt*(*li*) function would allow the decision-maker to restrict the choice to the local machine and the remote machine with the smallest value of *li*, and to compute the function only for these two machines. Furthermore, if the monotonic function has a known minimum slope or, even better, is linear, then all comparisons will involve only the values of *li*, and no computation of *rt* will have to be performed. These observations can be extended to heterogenous systems, but will apply only to each group of identical machines within them.

Note that our choice of command response time minimization as the objective of load balancing makes it impossible to define the load of a machine as a command-independent quantity. This means that our answer to the question: "How much load is there on this machine?" will be another question, that is: "For what command?". Thus, our approach does not help when the policy is load-independent, unless a standard "basket" of commands is defined to be used in the computation of a command-independent load index for each machine.

4. A LOAD INDEX BASED ON A MEAN-VALUE EQUATION

In this section, we shall propose a load index which, under certain assumptions, satisfies the criterion introduced in the previous section.

Consider a machine M, a command A, and a mix of commands B. Among all the possible loads that M may be processing, consider the following three:

(A) command A *alone*;

(B) mix B (the *background* load);

(C) the *combination* of A and B.

Our problem can now be expressed in these terms: predict the response time of A when load C is running on M from the knowledge of A and of the background load B (the load that was there just before the arrival of A).

We make the assumption that machine M can be accurately modeled by a closed queueing network model having:

(i) R chains;

(ii) L service centers 1, 2, . . . L of the FCFS, PS (processor sharing), LCFSPR (last-come-first-served-preemptive-resume), and IS (infinite servers) types [11]; center 1 is an IS-type service center representing user terminals;

(iii) a fixed number of customers (i.e., commands) in each chain (note that customers never change chain);

(iv) service rates independent of the number of customers at the respective centers;

(v) FCFS centers that are all single-server centers, and have a chain-independent service rate.

The three loads A, B, and C can be modeled as follows:

(a) command A is the only customer in chain 1;

(b) the commands in load B are clustered, and each cluster is represented by one of the chains 2 through R (R is set equal to the number of clusters of B plus 1);

(c) load C is represented by chains 1 through R.

Under these assumptions, the mean-value equation of Corollary 1 of [12] holds for each non-IS center l in such a model:

$$w_{r,l}(\mathbf{K}) = \tau_{r,l}[1 + n_l(\mathbf{K} - \mathbf{e}_r)], \tag{1}$$

where

$\mathbf{K} = (k_1, k_2, \cdots k_r)$: population vector ($k_r$ = population size of chain r);

$\mathbf{e}_r$ = R-dimensional unit vector in direction r;

$w_{r,l}(\mathbf{K})$ = mean time spent by a chain r customer at center l at each visit in the network with population vector $\mathbf{K}$;

$\tau_{r,l}$ = mean service time per visit of a chain r customer at center l;

$n_l(\mathbf{K} - \mathbf{e}_r)$ = mean number of customers (mean "queue length") at center l in the same queueing network with one less customer in chain r.

Note that, for a FCFS center l, we have $\tau_{r,l} = \tau_l$, and that, for an IS center,

$$w_{r,l} = \tau_{r,l}. \tag{2}$$

If the model includes IS centers other than center 1, the corresponding n_l will be defined to be 0.

Denoting by $rt_r(X)$ the mean response time (i.e., the mean time spent outside service center 1) of a chain r command under load X, and by $v_{r,l}$ the mean number of visits a chain r customer makes to service center l, we can write for command A

$$rt_1(A) = \sum_{l=2}^{L} v_{1,l}\tau_{1,l}, \tag{3}$$

and for load C

$$rt_1(C) = \sum_{l=2}^{L} v_{1,l}\, w_{1,l}(\mathbf{K}). \tag{4}$$

Substituting (1) into (4), and using (3), we obtain

$$rt_1(C) = \sum_{l=2}^{L} v_{1,l}\tau_{1,l} + \sum_{l=2}^{L} v_{1,l}\tau_{1,l}\, n_l(\mathbf{K} - \mathbf{e}_1) =$$

$$= rt_1(A) + \sum_{l=2}^{L} v_{1,l}\tau_{1,l}\, n_l(B), \tag{5}$$

since $\mathbf{K} - \mathbf{e}_1$ represents load C with one less customer in chain 1, i.e., with no customers in that chain; in other words, it represents load B.

By (2), the increase in command response time can be written as:

$$\Delta rt = rt_1(C) - rt_1(A) = \sum_{l=2}^{L} v_{1,l}\, w_{1,l}(A)\, n_l(B). \tag{6}$$

Thus, under the assumptions made, the response time of a command A is a ***linear combination*** of the mean queue lengths at the non-IS centers under load B, the coefficients being the total times spent by A in the respective centers when running alone on the same machine. Note that, in the terminology adopted here, the queue length at a center also includes the customer in service at that center. Furthermore, note that IS centers do not contribute to the sum on the right-hand side of (6).

Equation (6) can be used to predict $rt_1(C)$. Its right-hand side is a load index satisfying the condition discussed in Section 3. Furthermore, rt is a linear function of the index, which, in turn, is a linear function of the mean queue lengths.

The load index we have just introduced does not have to be always used in its full generality. Indeed, it could be argued that this will in practice be the exception rather than the rule. We expect that very often one of the terms in the linear combination on the right hand side of (6) will dominate its value. If the machine has a bottleneck, the term corresponding to the saturated resource will tend to be the dominant one, and only for commands making much heavier use of other resources this will not be the case. For instance, all of the machines we have observed on our local internetwork are very substantially CPU-bound; thus, only for the (few) heavily I/O-bound commands will it not be possible to define the load as expressed by the normalized CPU queue length (note that the coefficient of this queue length in (6) for a given command is inversely proportional to the CPU's instruction execution speed, hence, in a heterogeneous network, the CPU queue length of each machine will have to be normalized by dividing it by this speed). I/O-bound commands are rare in an environment similar to ours. Thus, the mistakes possibly made by a load balancing scheme that ignores them (e.g., one based on the normalized CPU queue length as the load index), are likely to have a small impact on the scheme's performance.

In summary, the index proposed in this section may be approximated in practical cases by indices that have been adopted in a number of previous studies, such as the CPU queue length, and even implemented in existing systems, such as the load average in UNIX. The main contribution of this proposal does not consist so much of a new index, but of a theoretical foundation for all the load indices based on resource queue lengths. This foundation provides a justification for these indices, specifies the assumptions under which they are valid, and gives an indication of the limits of their applicability. As for those indices that are mentioned in the literature and cannot be obtained from (6), we have not proved their lack of validity (though some experiments based on a simple queueing model have convinced us that they do not satisfy the criterion in Section 3). We would only like to see any proponent of a load index specify the reasons for choosing it in a way that will subject such a choice to scientific scrutiny instead of requiring much guesswork or an act of faith.

5. EXPERIMENTAL VERIFICATIONS

In the preceding section, we pointed out that, according to a mean value equation valid for closed queueing networks, a linear combination of the queue lengths of a machine's resources should be a good predictor of command response time, provided that the system is in steady state and that the queueing disciplines of the resources are FCFS, PS, LCFSPR, or IS. However, these assumptions are not generally satisfied in real-world computer systems. For example, in Berkeley UNIX, a multi-class priority scheduling algorithm with round-robin preemption is used for the CPU. The scheduling discipline for the disks in Berkeley UNIX is one-way scan; thus, an incoming I/O request may find itself right ahead of the disk arm, and hence be serviced first. With the usually complicated queueing disciplines adopted for various resources, it is not clear whether a linear relation exists between resource queue lengths and command response times. The closed system and steady state assumptions in the model are also not generally satisfied in computer systems; users log on and off, and the number of jobs submitted can fluctuate widely. On the other hand, modeling experiences have repeatedly demonstrated that fairly simple models can provide results that closely reflect reality, even though some of the assumptions of the model do not strictly hold.

In order to evaluate the suitability of the resource queue lengths as load indices, and to study the sensitivity of responsiveness to variations in the queue lengths for different types of commands, we conducted a series of measurement experiments on production VAX-11/780 systems running Berkeley UNIX 4.3BSD and under both natural workloads and artificial workloads. The resource queues measured were:

(1) the *CPU ready queue*: the number of processes that are loaded and running or waiting to be scheduled to run; the process in execution is included;

(2) the *disk request queue*: the number of disk I/O requests that are waiting to be processed; this is the aggregate queue for *all* the disks in the machine's configuration.

There are other types of resources, such as memory space and network bandwidth, but our measurements show that the contention for them is very low.

While the resource queue lengths and other indices were being traced, we ran benchmark commands periodically and measured their response times. Three types of commands were used at different times:

(1) A text processing command (TROFF) that is mostly CPU-bound, with some I/O.

(2) A purely CPU-bound benchmark (CPU) that performs a large number of arithmetic computations.

(3) A predominantly I/O-bound benchmark (IO) that copies a large file block by block in reverse order to defeat the read ahead mechanism in UNIX.

For each of the measurement sessions, we computed the correlation coefficient between the average queue lengths *during* the entire command execution and the command response times. Linear regression tests were also performed to determine the amount of improvement in correlation we can obtain by using both CPU and disk queue lengths. We found that the correlation between the average CPU queue length and the response time of a CPU-bound job (TROFF or CPU) is very close to 1 under a wide spectrum of system load conditions, both live and artificial. On the other hand, the correlation between the aggregate disk queue length and the response time is much lower (the correlation coefficient was between 0.45 and 0.85), and the amount of improvement obtained by taking it into consideration is negligible. This is not only true for live workloads that usually do not cause much contention on the disks, but also with artificial workloads having high disk demands. Similarly, for the I/O-bound benchmark, when the disk is highly contended, the correlation between the disk queue length and the response time is very high (always greater than 0.85), whereas the CPU queue length has a much lower correlation (0.65 - 0.75). Considering both CPU and disk queues provides little improvement even in this case.

These results suggest that, at least for strongly CPU-bound or I/O-bound commands, resource queue lengths are excellent load indices. We have thus experimentally verified the boundary-case validity of the load index proposed in the previous section. To evaluate the ability of the resource queue lengths in predicting the response times of commands still to be started, we computed the correlation coefficient between the command response time and the average queue lengths measured during a period (5, 10, 15, 30 or 60 seconds) *before* the start of the command's execution, instead of those measured *during* the execution of the command. The coefficients were found to be much lower than in the "during" case, almost never exceeding 0.7. Attempts to improve the accuracy of the predictions by using an exponentially smoothed average of the queue lengths yielded little improvement. Furthermore, the higher the load, the greater the fluctuations observed, and the poorer the prediction. The consistently poor correlation in all the sessions suggests that the resource queue lengths are changing so rapidly that their values just before the execution of a command poorly predict those during the execution, and hence the command's response time cannot be accurately predicted. In other words, the steady state assumption in the model on which the load index proposed in Section 4 is based does not hold. This is confirmed by our measurements of the rate of change of the CPU queue length. Figure 1 shows the distribution of net CPU queue length changes during 30-second intervals over an entire session (about eight hours). As can be observed, 33% of the time the net change is 3 or beyond. For an average queue length of 6, which is fairly high, this represents a 50% change in CPU load. For the machine we measured, the average net change in CPU queue length in a 30-second interval is 2.31.

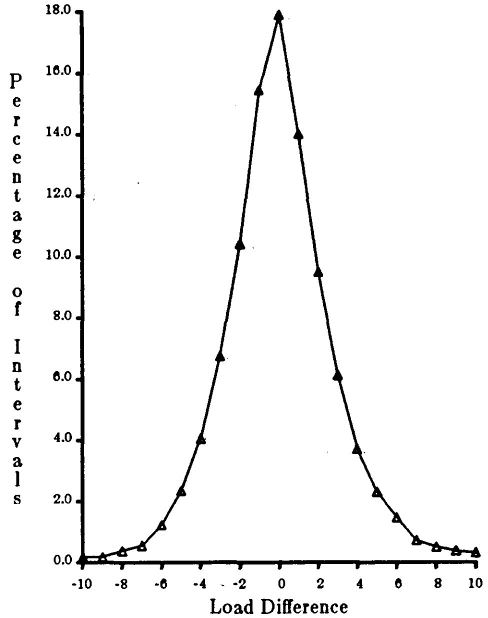

Figure 1. Load Change Frequency (in 30 Seconds) from Measurement

The prediction of command response times gets worse as the command's execution gets longer, which is a negative characteristic of our index since load balancing is most advantageous when it deals with heavy commands. However, it should be pointed out that, for load balancing, we are interested in *comparing* the loads of a number of machines in order to choose a machine that is lightly loaded, rather than determining the absolute response times the command would have if it were executed on each of the eligible machines. Another factor that is likely to ease the difficulty of prediction is that load balancing, if effective, should tend to reduce the fluctuations of the load on each machine, thereby improving the accuracy of response time prediction. In other words, load balancing should provide a *negative feedback* that will tend to stabilize machine loads. This conjecture was confirmed by the results obtained from a trace-driven simulator that we constructed for studying load balancing[14]. Records containing the CPU and disk I/O resource demands for all the jobs submitted to a production system during a number of tracing sessions were used to drive the model that simulated the executions of the jobs on a number of hosts, with and without load balancing. It was found that load balancing tends to smooth out the temporal fluctuations in the load of each machine. For a typical machine, the distributions of load changes during 30-second intervals as described above were computed for cases with and without load balancing, and are shown in Figure 2. The average net change in load decreased from 2.42 for the no-load-balancing case to 0.93 for that with load balancing. Our simulation study also demonstrates that load balancing based on resource queue lengths can reduce the average job response time by half or more when the system is loaded (average CPU utilization above 60%), even when the costs of message exchanges and job transfers are taken into consideration.

6. CONCLUSION

A load index for dynamic load balancing schemes has been presented. The index is based on a mean-value equation that applies to closed multichain queueing network models with population-independent service rates and PS, LCFSPR, IS, or single-server FCFS service centers. The objective that has guided the choice of the index is the minimization of a command's execution time. The proposed index is a linear combination of the mean queue lengths in the machine being considered, the coefficients being the total times the command would spend in each service center if it ran alone on the machine.

Our measurement experiments have shown that mean queue lengths can be good load indices indeed, if used properly. For CPU-bound commands, the CPU queue length accurately predicts the response time, whereas the disk queue lengths have negligible effect. For I/O-bound commands, the particular disk queue length reflects the response time very well when processes are queued up there. However, for live workloads characterized by short queues at the disks, the response time seems to be relatively insensitive to both CPU and disk queue lengths in this case.

The load of the live systems we measured in our environment changes very rapidly, making response time predictions difficult. On the other hand, load balancing is expected to smooth out the wide fluctuations, thereby improving the accuracy of the predictions. Also, predicting absolute response times accurately is not necessary, as long as the relative rankings of the machine loads are reflected in the respective values of the index.

Instantaneous queue length measurements are not difficult to perform. They could be gathered periodically (or on demand) and broadcast (or sent to the requesting machine). Whether instantaneous or smoothed queue lengths should be used is not clear, and can only be decided after careful experimentation; however, we note that smoothing can be easily performed when instantaneous values are available. In the fully general case, the contribution of each machine to the value of the load index would thus be a vector[13]. That of each command would be another vector, with components equal to the times spent by the command in each server when running alone. Clearly, each command must be represented by different vectors of coefficients for different machines or even different configurations. This characteristic should not, however, be regarded only as a drawback: in fact, the ability elegantly to adapt to configurationally and architecturally heterogeneous networks is a major advantage of the load index proposed in this paper.

The dependence of the value of the index on the particular command being considered is a very simple one, and the coefficients that characterize each command are easy to measure. However, command dependence causes two problems:

(i) the *absolute* load of a machine cannot be defined; this problem can be alleviated, as noted in Section 3, by referring to a standard workload (a "basket" of commands); in any case, the index only measures the load *relative* to a given command or mix of commands;

(ii) the coefficients characterizing a command generally depend on the command's arguments (input files, input data, options, and so on); thus, an accurate characterization of a command type may turn out to be very complex and very expensive to build; also, any modifications to the command's code may cause appreciable changes in the values of the coefficients.

As stated at the end of Section 4, the index will very seldom, if ever, have to be applied in its full generality. Problem (ii), which does not arise when only the CPU term of the linear combination is taken into account, is a very hard one to solve. Our hope is that, for most important commands, the dependence of the coefficients on the arguments can be approximated by functions with simple mathematical forms, and that their sensitivity to changes is low. For instance, we conjecture that the coefficients (or at least some of them) of text processing and compilation commands are roughly linear functions of the size of the input file. These and other similar conjectures will, however, have to be validated by an extensive study which is being planned now.

ACKNOWLEDGEMENTS

The authors are grateful to Harry Rubin for making his benchmark program available to them, and for his comments on the manuscript. They are also indebted to Hamid Bahadori, who provided useful comments, and to Jean Richter for her impeccable preparation of the various human-readable versions of this paper.

AN APPROXIMATION OF THE PROCESSING TIME FOR A RANDOM GRAPH MODEL OF PARALLEL COMPUTATION

E. Gelenbe (*), R. Nelson, T. Philips, and A. Tantawi

IBM Thomas J. Watson Research Center
Yorktown Heights, New York 10598

Abstract

The task graph of a parallel computation is modeled by a random, acyclic, directed graph (K, p) where K is the number of nodes and p is the probability that an arc exists between two nodes (from a smaller numbered node to a larger one). In this model, each node corresponds to a task that is to be processed and each arc implies a precedence relationship that must be satisfied during processing. An approximation for the expected processing time of a task graph of this type on an infinite number of processors is derived under the assumption that each task requires an exponentially distributed amount of processing. This approximation shows that the expected processing time grows linearly with K at rate $2p/(1+p)$. Furthermore, maximum likelihood estimators for the value of p given specified characteristics of a particular task graph are obtained.

1. Introduction and Model Description

In multiprocessing computer systems, a job is divided into a number of tasks, each executing on a processing unit concurrently with other tasks. The division of a job into a set of tasks is governed by the logical structure of the job and the interdependencies among tasks. This is usually described by a computation graph where nodes in the graph represent tasks and directed edges represent precedence relations. Such a graph may be used to represent the detailed processing stages in a single program; it may also be used to represent the dependencies between separate programs in a large software system. Another interpretation of this graph model is in terms of a PERT diagram (or activity network), commonly used to organize or schedule tasks in industrial engineering and operations research.

In general, one associates processing or execution times with the nodes of a computation graph in order to represent the time it would take to carry it out assuming a given processing system. Furthermore, it is assumed that each task represented by a node cannot itself be subdivided any further into smaller tasks. An important performance measure of parallel processing systems is the processing time of a job described by a computation graph.

The computation graph, also referred to as a task graph, is characterized by the number of tasks, their processing times, and the structure of precedence relations. Special cases of structures of precedence relations represented by series parallel graph models have been considered[5,6]. Fayolle et al.[1] consider a tree structure of precedence relations where the number of sons of a node in the tree is described by a random variable. They analyze such a structure and obtain the distribution of the job processing time of a job on an infinite number of processors, in the special case that the number of sons is geometrically distributed and the task processing times are constant. Otherwise, numerical solutions are calculated.

Again, Mussi and Nain[4] assume a tree structure with exponentially distributed task processing times and consider two execution policies: (1) level-by-level and (2) take-a-leaf. They obtain the Laplace-Stieltjes transform of the processing time of the tree under the two policies. For policy (1), they assume an arbitrary number

CH2345-7/86/0000/0691$01.00 © 1986 IEEE

of processors, whereas for policy (2) they assume equal expected task processing times and consider two cases: two processors and an infinite number of processors.

In many cases the structure of precedence relations is either unknown or the number of tasks is so large that a characterization of the structure of precedence relations is hard to obtain. In such cases, since a detailed analysis of the task graph is intractable, one attempts to characterize the interdependencies between nodes using a higher level model. Solutions of such models can provide insights into performance characteristics inherent in the underlying system. One such model is to assume that precedence relationships between nodes are determined in a probabilistic manner. Specifically, in such models one assumes that for every ordered pair of nodes there is a specified probability that the first node is a predecessor of the second. By varying the value of these probabilities one can model both very sparse and very dense task graphs. Random graph models of this type can be found in the literature for various applications. Indurkhya et al.[3], for example, consider a random graph model of a distributed program and derive properties of the optimal task assignment policies for heterogeneous processors. Random graphs are also used to model concurrency in transaction processing systems. A node in such a graph represents a transaction and an edge represents a conflict. An edge between pairs of transactions exists with some fixed probability. Franaszek and Robinson[2] consider such a random graph model and obtain bounds on the expected number of transactions that can run concurrently.

In this paper, we consider parallel computations which are modeled by random, acyclic, directed graphs consisting of K nodes in which an arc from node i, $i = 1, 2, ..., K - 1$ to node j, $j = i + 1, i + 2, ..., K$ exists independently with a fixed probability p. In this model, each node corresponds to a task that is to be processed and each arc implies a precedence relationship that must be satisfied during processing. We assume that each task requires an exponentially distributed amount of processing with mean 1. The processing time of a task graph of this type on an infinite number of processors is denoted by $T_K(p)$, and its expectation by $E[T_K(p)]$.

An approximate expression for the expected processing time of a job described by such a graph is derived in Section 2. In Section 3, this approximate expression is compared to simulation results. In Section 4, maximum likelihood estimators for the value of the probability p are derived.

2. Approximate Analysis of the Expected Processing Time

We next show that the expected processing time varies almost linearly with K, the slope being given by $2p/(1 + p)$. To do this, we will consider a particular realization of a $(K + 1, p)$ graph. We can imagine that this graph is generated by taking an already generated (K, p) graph, adding a $(K + 1)$st node and then adding directed edges from nodes $1, 2, ..., K$ to node $K + 1$ independently with probability p. We note that because no directed edge exists from node $K + 1$ to any lower numbered node, the completion times of the nodes in the original (K, p) graph are not influenced by the addition of node $K + 1$. Furthermore, we note that the distribution of the processing time of the $(K + 1)$st node is not influenced by the existence of edges leading into it.

Consider the execution of the original (K, p) graph, with $K > 1$ (the case of $K = 1$ is trivial). We relabel the nodes in the graph in the following manner: Let 0 be the last node to finish execution and let 1 be the direct predecessor of 0 that, among all the predecessors of 0 finished executing last. By this definition, the completion time of node 1 is the starting time of node 0. In a similar manner, let node i, $i = 1, 2, ..., L - 1$, be the direct predecessor of node $i - 1$ that was the last to finish executing. It is clear that all the nodes of the original (K, p) graph are not necessarily relabeled by this procedure but those that are labeled lie on a path. Furthermore, by definition, this path contains the node that completes last. Accordingly we will call, for this particular execution, the path defined by nodes $L - 1, L - 2, ..., 0$ the *longest path* of the original (K, p) graph. Nodes not labeled in this procedure will play no role in our approximation. We will now use these relabeled nodes to derive an approximation to the expected processing time for the $(K + 1, p)$ graph defined above. Basically our method of approximating the expected processing time of the $(K + 1, p)$ graph is to consider the relationship between the longest path of the original (K, p) graph and the longest path of the new $(K + 1, p)$ graph.

The processing time of the $(K + 1, p)$ graph depends on the processing time of the longest path for the underlying (K, p) graph and upon the arcs directed into the

$(K + 1)$st node. Define e_i, $i = 0, 1, \ldots, L - 1$ to be the event that in the reordered graph, an arc exists from node i to the $(K + 1)$st node, but that no arc exists between node j and it for $j < i$. Furthermore, let e_L be the event that no arcs exist from node i, $i = 0, 1, \ldots, L - 1$, to the $(K + 1)$st node. Denote the probability of event e_i by $P[e_i]$. It is clear that

$$P[e_i] = \begin{cases} pq^i, & i = 0, 1, ..., L - 1, \\ q^L, & i = L. \end{cases} \qquad (1)$$

By conditioning on these events, we write the expected increase in processing time as

$$\mathrm{E}[T_{K+1}(p) - T_K(p)] = \sum_{i=0}^{L} \mathrm{E}[T_{K+1}(p) - T_K(p) \,|\, e_i] \times P[e_i]. \qquad (2)$$

We will develop an approximation to this expression by assuming that nodes not lying on the longest path do not influence the increase in processing time that arises when the $(K + 1)$st node is added to the graph. One can easily create examples where this assumption is false. Our justification for this assumption and for the assumption that we will next make concerning the processing time of nodes along the longest path, essentially lies in the mathematical difficulty of obtaining an exact solution to equation (2) and the intuitively plausible argument that the processing time of a random graph of this nature should depend on the processing time of the longest path. Using simulation we will show that these assumptions lead to a good approximate formulae for the expected processing time of these graphs.

To continue with the derivation of our approximation we next must determine an approximation to the conditional expected increase in processing time given in equation (2). If $i = 0$, then the expected processing time is clearly incremented by 1. For $i > 0$, we will assume that the intercompletion intervals are exponentially distributed with parameter 1. Since node i, $i = 1, 2, ..., L - 1$, is defined to be the direct predecessor of node $i - 1$ that finished execution *last*, its expected processing time is lower bounded by the expectation of an exponential random variable with parameter 1. This assumption will thus lead to an approximate expected processing time of the $(K + 1, p)$ graph that is a lower bound to the actual expected processing time. If we condition on the event e_i it is apparent that there are two possible cases for the execution of the resultant $(K + 1, p)$ graph. The first is that node $K + 1$ finishes executing before nodes lying on the path i, $i - 1, ..., 0$ and the second is that it finishes after these nodes along the longest path. Since the processing times of nodes i, $i - 1, ..., 0$ are assumed to be independent and exponentially distributed with parameter 1, the sum of their processing times is Erlangian with parameter i. Then the expected increase in the processing time that results from the addition of node $K + 1$ can be calculated by determining the expectation of the positive difference between an exponentially distributed random variable and one whose distribution is Erlangian with parameter i. In Appendix A it is shown that this quantity equals $(1/2)^i$.

By substituting $\mathrm{E}[T_{K+1}(p) - T_K(p) \,|\, e_i] \cong (1/2)^i$ into equation (2) we get

$$\mathrm{E}[T_{K+1}(p) - T_K(p)] \cong \sum_{i=0}^{L} (1/2)^i P[e_i]. \qquad (3)$$

As K grows the number of nodes on the longest path also increases. For large K we will approximate the finite sum in equation (3) with an infinte sum and thus write:

$$\mathrm{E}[T_{K+1}(p) - T_K(p)] \cong \sum_{i=0}^{\infty} p(\frac{q}{2})^i = \frac{2p}{1 + p}.$$

The expected processing time can now be approximated by

$$E[T_K(p)] \cong E[T_N(p)] + (K - N) \times 2p/(1 + p), \quad (4)$$

$K \geq N \geq 1$, where $E[T_N(p)]$ is an initial value that is determined by some other method. One possible method to determine this initial value is to use the boundary condition $E[T_1(p)] = 1$. Another method is to run a simulation for some suitably large N.

3. Comparison of Approximation and Simulation

In this section we compare our approximation to results obtained from simulation. We ran simulations for values of p ranging from .01 to .9 and values of K in the range of 25 to 500. Accurate simulation for greater K values was found to be computationally intractable. For each (K, p) graph our simulation worked as follows: We first generated a random (K, p) graph. This is performed by creating a $K \times K$ adjacency matrix where each element is initially set to 0. We added random arcs to this graph by independently replacing each zero in the lower triangular portion of of the matrix with a 1 with probability p. The resultant (K, p) graph was then simulated to determine its expected processing time. To do this we generated confidence intervals using independent replications. More precisely, after 30 replications we sampled the processing times obtained and continued the replication process until the width of the 95% confidence interval was less than 5% of the sampled average or until a maximum of 200 replications had been performed. We then continued by generating another instantiation of a (K, p) graph and determined its expected processing time in the same manner. After generating processing times for 30 different (K, p) graphs we checked the confidence intervals obtained over this set of graphs and continued to generate graphs until the 95% confidence interval was less than 5% of the average or until a maximum of 200 graphs had been generated.

The results of this simulation are shown in Figure 1 where we also plot our approximation using equation (4). The accuracy of our simulation is shown by the fact that the 95% confidence interval widths are approximately the size of the points used to indicate the values obtained from simulation. The value of the offset values in equation (4), denoted by $E[T_N(p)]$, is given by the simulated values obtained for $N = 25$ and the corresponding value of p. As shown in the Figure, our approximation compares favorably with the simulation results and, as noted before, is an underestimation for the expected processing time. It is important to note that for a fixed value of p, our approximation holds for sufficiently large K. If $p \geq .1$, the approximation is accurate for graphs with as few as twenty or thirty nodes. On the other hand, if p is close to 0, K may have to be very large indeed (on the order of a thousand nodes) for the approximation to be useful. The reason for this behavior is as follows. If both p and K are small, then the graph consists primarily of roots. As all the roots can be processed simultaneously, one would expect the completion time to grow logarithmically with K. As K grows, however, a rich interdependency among the various nodes appears, and it is this interdependency that finally gives rise to the observed linear growth in the processing time with K. These considerations explain the observation, a shown in the figure, that for a given value of K the approximation is more accurate for large values of p.

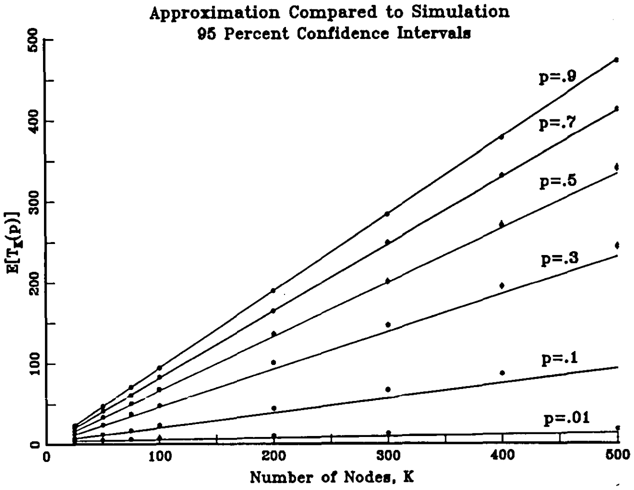

Figure 1

4. Maximum Likelihood Estimation of the Probability of Conflict

Often, when modeling an actual computation by a random graph, no apriori knowledge of the probability of conflict is available, and consequently it is necessary to have an estimation procedure so that the value of p can be determined experimentally. In this section, three estimators for p are presented. The first estimates p from the indegree of a randomly chosen node, the second estimates p from the number of 'roots' or nodes of indegree 0 in the graph, and the third estimates p from the total number of arcs in the graph.

4.1. Estimating p from the Indegree of a Randomly Chosen Node

Given a (K, p) graph, we denote the probability that the indegree of a randomly chosen node equals D by $L_K(D, p)$. This likelihood function is given by

$$L_K(D,\ p) = \frac{1}{(K-D)} \sum_{i=0}^{K-D-1} \binom{D+i}{D} p^D (1-p)^i,$$

where the ith term in the summation is the probability that vertex $D + i$ has indegree D. Expanding the binomial coefficient out we get

$$L_K(D, p)$$
$$= \frac{(-p)^D}{(K-D)\, D!} \times \frac{d^D}{dp^D}\Big[\sum_{i=0}^{K-D-1} (1-p)^{D+i} \Big]$$

$$= \frac{(-p)^D}{(K-D)\,D!} \times \frac{d^D}{dp^D}\left[\frac{(1-p)^D - (1-p)^K}{p}\right]$$

$$= \frac{(-p)^D}{(K-D)\,D!}$$

$$\times \frac{d^D}{dp^D} \sum_{i=1}^{K}\left[\binom{K}{i} - \binom{D}{i}\right](-1)^{i-1} p^{i-1}.$$

Only powers of p greater than D survive the differentiation, and some rearrangement gives us

$L_K(D,p)$

$$= \frac{-1}{K-D}\binom{K}{D} p^{D-1} \sum_{i=0}^{K-D} \binom{K-D}{i} \frac{i}{i+D}(-p)^j$$

$$= \frac{-1}{K-D}\binom{K}{D} p^{D-1}$$

$$\times \int_0^1 \frac{d}{dx}\sum_{i=0}^{K-D}\binom{K-D}{i}(-x)^i y^{D+i-1}\Big|_{x=p}\, dy$$

$$= \binom{K}{D} p^D \int_0^1 y^D (1-py)^{K-D-1}\, dy$$

$$\cong \binom{K}{D} p^D \int_0^1 y^D e^{-pyK}\, dy$$

$$= \binom{K}{D} p^D \frac{D!}{(pK)^{D+1}}\left[1 - e^{-pK}\sum_{i=0}^{D}\frac{(Kp)^i}{i!}\right].$$

Let $\hat{p}(D)$ be a maximum likelihood estimate of p, i.e.

$$L_K(D,\hat{p}) \geq L_K(D,p'), \qquad \forall p' \in [0,1].$$

To find $\hat{p}$, the expression for $L_K(D,P)$ must be maximized, and this is most easily done by differentiating it with respect to p, equating it to 0, and then solving it for $\hat{p}$. On doing so, we get after some simplification

$$\frac{(K\hat{p})^{D+1}}{D!} = \sum_{i=D+1}^{\infty}\frac{(K\hat{p})^i}{i!}$$

or

$$\sum_{i=D+2}^{\infty}\frac{(K\hat{p})^{i-D-1}\times(D+1)!}{i!} = D. \qquad (5)$$

If we replace the product $K\hat{p}$ by the single variable x the left hand side can be seen to be a polynomial of infinite degree. As it is strictly convex, and takes on a value of when $x = 0$, we may conclude that a unique solution exists. This in turn implies that $\hat{p} = \alpha(D)/K$ where $\alpha(D)$ is the solution to the above equation. To insure numerical stability of the solution to equation (5), it is convenient to define the following set of functions. We let $F_0(x) = x/(D+2)$, and let $F_{j+1}(x) = F_j(x)(1 + x/(D + j + 3))$. It is clear that $F_j(x)$ is the value of the summation of equation (5) truncated at $j + D + 2$. Using these relationships, the equation $F_j(x) - D = 0$ can be approximated numerically to any degree of desired precision by choosing j suitably large. Clearly, p can be estimated from the outdegree of a randomly chosen node in exactly the same manner.

4.2. Estimating p from the Number of Roots

Let R be the number of roots, or nodes of indegree 0 in a particular realization of a (K,p) graph. As all of these nodes can be processed simultaneously the number of roots in a (K,p) graph is the maximum level of concurrency that can be achieved when the program or task begins execution. Define $P_K(R,p)$ to be the probability that a (K,p) graph possesses exactly R roots. As before, define $\hat{p}(R)$ to be a maximum likelihood estimate of p, i.e.

$$P_K(R,\hat{p}) \geq P_K(R,p'), \qquad \forall p' \in [0,1].$$

The following recurrence can be written for the distribution of the number of roots:

$P_K(j,p) =$

$$\sum_{i=\max(1,j-1)}^{K-1} \binom{i}{i-j+1} p^{i-j+1}(1-p)^{j-1} P_{K-1}(i,p).(6)$$

The ith term in the sum is the probability that the addition of a single node to a $(K-1,p)$ graph with i roots results in a (K,p) graph with j roots. Unfortunately, this recurrence cannot be solved to give $P_K(j,p)$ in closed form, though it can be computed from (6) starting with $P_1(1,p) = 1$ and $P_1(0,p) = 0$. On the other hand, the mean of the distribution is easily found as follows. Define a set of K indicator random variables $\{x_i\}$ as

$$x_i = \begin{cases} 1 & \text{if node i is a root,} \\ 0 & \text{if node i is not a root.} \end{cases}$$

Clearly, $Pr\{x_i = 1\} = q^{i-1}$. Let X be a random variable that counts the number of roots. Then $X = \sum_{i=1}^{K} x_i$, and

$$\overline{X} = \sum_{i=1}^{K} q^{i-1} = \frac{1 - q^{K+1}}{p}. \tag{7}$$

This leads us to consider the following estimator for p, which is *not* a maximum likelihood estimator. Our estimate of p, $\tilde{p}$, is the solution to the equation

$$\tilde{p} = \frac{1 - \tilde{q}^{K+1}}{R}, \tag{8}$$

where R, as stated before is the observed number of roots. As the distribution of $\tilde{p}$ is not known, the mean and the variance of the estimator cannot be found. Computational experience with (8) however shows $\tilde{p}$ to lie within 5% of the maximum likelihood estimate of p.

4.3. *Estimating p from the Number of Edges in the Graph*

Let E be the number of arcs in a particular sample realization of a (K,p) graph, and $L_K(E,p)$ the likelihood function for p. Then, we have

$$L_K(E,p) = \begin{pmatrix} \binom{K}{2} \\ E \end{pmatrix} \times p^{E} \times q^{\binom{K}{2} - E}.$$

By differentiating this expression and equating it to 0, we find that the maximum likelihood estimate of p, $\hat{p}$ is the solution to

$$E(1 - \hat{p}) = \hat{p}(\binom{k}{2} - E)$$

or that

$$\hat{p} = \frac{E}{\binom{K}{2}}$$

exactly as one would suspect.

5. Conclusions and Future Research

In this paper we have considered the execution of a job modeled by a task graph with precedence relationships on an infinite number of processors. Our model of the task graph was a random, acyclic, directed graph consisting of K nodes in which an arc existed from node i, $i = 1, 2, ..., K - 1$ to node $j, j = i + 1, i + 2, ..., K$ independently with probability p. In this model, each vertex corresponds to a task that is to be processed and each arc implies a precedence relationship that must be satisfied during processing. The processing time of the tasks in our model was assumed to consist of independent and identically distributed exponential random variables. The approximation we derived for the expected processing time of the task graph, which we call a (K,p) graph, exhibits linear growth with the number of tasks for a given value of p and compares favorably to simulation values.

In our model we assume an infinite number of processors, or more precisely that whenever a task is available for execution there exists an idle processor upon which it can be executed. For other than very small values of p this is not a restrictive assumption. The reason for this follows from equation (7) which shows that, for large K, the expected number of tasks that can be simultaneously executed in a (K,p) graph is approximately equal to $1/p$. This approximation becomes more accurate with increasing K. Thus the expected number of processors necessary to *begin* execution of a (K,p) graph is not large for all but small values of p. The same reasoning cannot be used to determine the expected number of processors needed *during* the execution of a (K,p) graph. This follows from the fact that as tasks are removed from the graph (i.e. they finish executing) the remaining graph is no longer an example of a (K,p) graph. In other words, conditioned on the fact that a root is removed from the graph, the underlying statistics are not the same as those for the initially generated graph. Simulation results (not shown here) however, show that as the graph is executed the expected number of processors required is non-increasing. Thus we can conclude that $1/p$ is an approximation to the expected number of processors required at any point in the execution.

Appendix A

Lemma 1.

Let X be an exponentially distributed random variable with parameter 1, and let Y be the sum of $i \geq 1$ independent exponentials with parameter 1. Assume that X and Y are independent and let $Z = \max(0, X - Y)$. Then $E[Z] = (1/2)^i$.

Proof.

The density functions for X and Y are defined on the non-negative real line and are given by

$$f_X(x) = e^{-x}, \qquad x \geq 0,$$
$$f_Y(y) = \frac{y^{i-1} e^{-y}}{(i-1)!}, \quad y \geq 0,$$

respectively. The density function for Z consists of an impulse at $z = 0$ and for $z > 0$ can be written as

$$\begin{aligned} f_Z(z) &= \int_{0^+}^{\infty} f_X(x+z) f_Y(x) dx \\ &= \frac{e^{-z}}{(i-1)!} \int_{0^+}^{\infty} x^{i-1} e^{-2x} dx \\ &= \frac{e^{-z}}{2^i}, \quad z > 0. \end{aligned}$$

Using this expression we thus have that the expectation of Z is given by

$$E[Z] = \int_{0^+}^{\infty} \frac{ze^{-z} dz}{2^i} = (1/2)^i. \qquad \blacksquare$$

Abstract

The paper is concerned with performance analysis of a transaction processing system due to both hardware and data resource contention. Hardware resource contention is taken into account by analyzing the queueing network model of the computer system on which the transactions are executed. Transactions lock the data items they access from the database dynamically, according to strict two-phase locking. Data contention manifests itself as lock conflicts and deadlocks. Lock conflicts (resp. deadlocks) are resolved by blocking (resp. restarting) the transaction that caused the lock conflict. Probabilistic analysis is used to determine the frequency of lock conflicts/deadlocks. A multilevel solution method based on decomposition is then used to obtain system and user-level performance measures. An iterative solution scheme with reduced computation cost is also derived from the decomposition solution method. Graphs/Tables are provided to show validation results against simulation and to study the behavior of the system. The analysis presented in this paper can be generalized in several directions.

1. Introduction

In this paper we develop a detailed Queueing Network Model (QNM) of transaction processing in a centralized database. Concurrency control of dynamic lock requests is attained by a strict two-phase locking (2PL) scheme [4], i.e., locks are released upon transaction completion. Transactions encountering lock conflicts are blocked and the transaction causing a deadlock is restarted.

An analytic solution based on multilevel decomposition is adopted. A top-down method is used to identify the parameters required to compute the performance measures of interest at each level with the ultimate goal of user-level performance measures. Such parameters are then computed at the lower level, perhaps requiring the computation/measurement/estimation of additional lower level parameters. Probabilistic analysis is used to estimate the probability of lock conflict based on an estimate of locks held by in-progress transactions. We also present an iterative solution based on the analysis developed for the decomposition method.

The performance of dynamic locking schemes has been studied by numerous researchers. Extensive simulation studies of dynamic locking were presented in [9, 1]. A system with two-phase locking was simulated in [8]. Regression analysis was then applied to simulation results to obtain equations relating lock conflict probabilities to key system parameters such as number of transactions, transaction size, and database size.

The probability of lock conflict and deadlock was computed in [5, 14]. In [5], each transaction was assumed to hold half of the locks it will request in its lifetime. Simple expressions for probability of conflict and deadlock were obtained based on this simple assumption. In [14], the state of the system was represented by a forest of trees, where the roots of the trees denote active transactions and the non-root nodes of each tree denote transactions blocked by their parent node.

A two-phase locking scheme with dynamic lock request policy was presented in [6, 18], using a lock-wait station to represent the delay due to blocking. In [6], the lock-wait station was modeled by an infinite-server station with a fixed service time corresponding to the no-queueing transaction response time. A more accurate solution was presented in [18], by using a service time at the lock-wait stations related to residual transaction residence times. Since transaction residence times are unknown a priori, iteration was used to solve the model. The results of this analysis could be further improved by adopting a state-dependent server for the lock-wait queue.

A mean value analysis method to study locking in database appeared in [15, 16, 17]. The analysis was based on estimating the mean number of transactions holding a given number of locks in the active and blocked states.

Individual transactions were treated in isolation and analyzed in steady state in [2]. The influence of other transactions in the system was represented by the probabilities that a data item required by a transaction is unavailable on the first and second attempts. An iterative method was used for the solution and a proof of convergence was given.

The work reported in this study was undertaken to alleviate the shortcomings of previous work from the viewpoint of obtaining a very accurate model for dynamic locking. A solution method is based on decomposition for a comprehensive model of centralized databases. We were able to determine detailed performance measures,

CH2345-7/86/0000/0698$01.00 © 1986 IEEE

previously only reported in simulation studies. A comparison of some of our conclusions with those of others appears in Section 4.

In what follows, we first describe the model of the computer system. A solution method based on multilevel decomposition is discussed in Section 3. In Section 4 we validate the proposed analytic methods and carry out a limited parametric study of the system behavior. A detailed analysis of Data Contention Model appears in the Appendix.

2. Description of the Model

We are concerned with concurrent transaction processing on a multiprogrammed computer system. The behavior of transactions from the viewpoint of accessing the database is described in Section 2.1. We then describe the processing of transactions by the computer system in Section 2.2.

2.1. Database Model

The database consists of **D** data items. There are **N** locks in total, each lock is associated with **G** data items (G=D/N). A single level of locking is considered in our studies. Lock requests are exclusive. Each transaction accesses a fixed number of data items (**n**), which are uniformly distributed over the D data items in the database. The case of variable number of lock requests is considered in [10]. The probability $P_m(k|n)$ that k locks are requested by a transaction accessing n data items can be computed according to the following recursion for k>0 and $n \geq 1$:

$$P_m(k|n)=\frac{kG-n+1}{D-n+1}P_m(k|n-1)+\frac{D-(k-1)G}{D-n+1}P_m(k-1|n-1) \qquad (1)$$

with the initialization $P_m(k|0)=1$ for k=0 and $P_m(k|0)=0$ for k>0. Thus the mean number of locks requested by a transaction ($\bar{L}$) is given by:

$$\bar{L} = \sum_{k=1}^{L} P_m(k|n)\ k \qquad (2)$$

when n is fixed and L is the maximum number of lock requests per transaction: L=min(n,N).

We ignore the variability of the number of lock requests and assume that each transaction requests $\bar{L}$ locks and that the $\bar{L}$ lock requests are distributed uniformly over the lifetime of a transaction (it attains the same amounts of service demands at the devices of the computer system in each interval preceding a lock request and leading to transaction completion). The fact that data item requests are uniformly distributed over the D data items in the database implies that the $\bar{L}$ lock requests are also uniformly distributed over the N locks (all lock requests are unique). A transaction requesting $\bar{L}$ locks has $\bar{L}$+1 phases, where the last phase results in the release of all locks rather than a new lock request. Such a model has been used in [5, 6, 16, 18]. Note that this assumption is compatible with an assumption that n database accesses are uniformly distributed over the lifetime of a transaction in the case of the finest granularity of locking (one lock per data item), since each access to the database results in a lock request. This is not so for coarse granularity of locking, where it is possible that the transaction already holds the lock on a data item when it makes a lock request. Thus the lock request rate by a transaction decreases as it acquires more locks, i.e., lock requests are concentrated in the beginning of transaction execution. Thus the uniform lock request distribution assumption will result in underestimating lock utilization, since locks are in fact held for more than half of transaction's residence time in the system. The results of our analysis tend to be less accurate for coarse granularity of locking (see Figure 4.1 in Section 4.3). This is of little concern, since a coarse granularity of locking is inappropriate for dynamic locking.

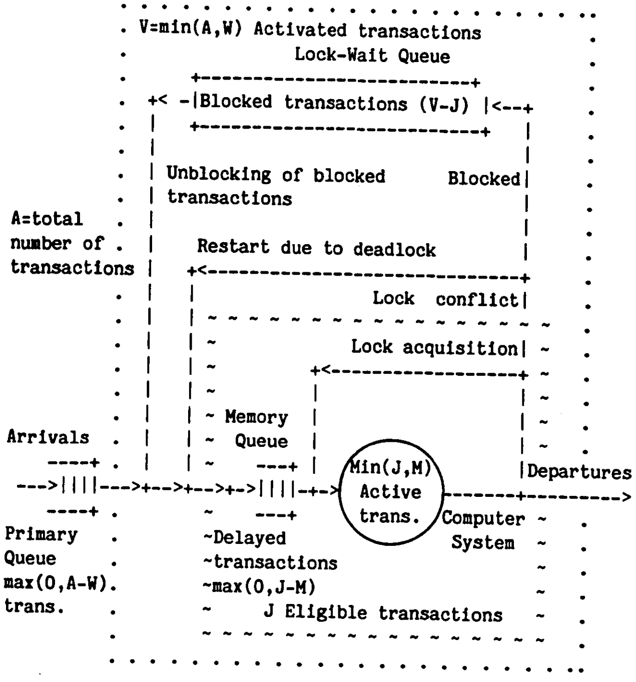
2.2. The Computer System Model

Transaction arrivals at the computer system are assumed to be Markovian, according to a random (Poisson) process with fixed rate λ, or terminal-driven arrivals, in which case the arrival rate is a function of the number of transactions in the system.

The maximum number of transactions that can be activated is limited to W, which acts as a congestion control parameter.[1] Activation means that the transaction is admitted from the Pending Queue into the Memory Queue, as shown in Figure 2-1. The number of Activated transactions is V=min(A,W), where **A** is the total number of transactions available for processing. Activated transactions can be processed by the Computer System, which has a maximum Multi-Programming Level (MPL) equal to **M**. The value of W should be chosen appropriately in order not to degrade system throughput by reducing the effective MPL. On the other hand activating a large number of transactions can result in excessive lock conflicts and deadlocks. In fact, thrashing, similarly to multiprogrammed virtual memory computer systems, may occur if congestion control is not exercised (see Section 4.5).

The flow of transactions is shown in Figure 2-1. Transactions that are admitted into the Memory Queue and proceed to execute at the Computer System are referred to as Eligible transactions. The number of Eligible transactions is denoted by J and there are min(J,M) Active transactions and max(0,J-M) transactions delayed in the Memory Queue. A transaction making a lock request either succeeds, in which case it continues with its processing, or it fails: lock conflict. A transaction causing a deadlock releases all of its locks (unblocking at least one transaction from the Lock-Wait Queue) and is immediately restarted by becoming an Eligible transaction again. Otherwise, the transaction is blocked in the Lock-Wait Queue until the requested lock becomes available.

[1] We use capital letters to refer to terms with a special meaning in our model.



V=min(A,W) Activated transactions
Lock-Wait Queue
Blocked transactions (V-J)
Unblocking of blocked transactions
Blocked
A=total number of transactions
Restart due to deadlock
Lock conflict
Lock acquisition
Memory Queue
Arrivals
Min(J,M) Active trans.
Departures
Computer System
Primary Queue max(0,A-W) trans.
Delayed transactions max(0,J-M)
J Eligible transactions

Figure 2-1: The computer system model.

Each transaction is considered to consist of elementary transactions, each corresponding to a data item access or a lock request. Only the latter model is considered in this paper, while the former model is considered in [11, 10]. Based on an earlier assumption that lock requests are uniformly distributed over the lifetime of a transaction, it follows that all elementary transactions are homogeneous, i.e., belong to a single job-type. A transaction consists of $\bar{L}+1$ elementary transactions on the average, with the first $\bar{L}$ phases leading to a lock request and the last phase resulting in the release of all locks. Upon the completion of a transaction a check is made to unblock transactions in the Lock-Wait Queue, which were waiting on the locks held by the completed transaction. Newly unblocked transactions and delayed transactions in the Memory Queue are allocated at the Computer System in FCFS order (observing the MPL constraint).

The Computer System consists of **K** state-independent devices: a CPU and K-1 disks. It has a maximum MPL equal to **M**. Transactions are characterized by the service demands at the K devices of the Computer System per data item access/lock request: s_k, $0\le k\le K-1$. Note that a more comprehensive queueing network model for the multiprogrammed computer system incorporating other workloads can be handled under this modeling framework and would only affect Level 3 of the analysis (see Section 3.3).

3. Analysis of the Model

An analysis of the model described in Section 2 using hierarchical decomposition similarly to [19] is presented at this point. The analysis is carried out from top to bottom in the following four sections. The analysis at each level uses quantities derived at lower levels. Also the details of the probabilistic analysis of the Data Contention Model appears in the Appendix. The iterative solution approach is discussed in Section 3.5.

3.1. User Response Model (Level 1)

The final stage of analysis deals with computing user response times. The Computer System is specified by its mean throughput as a function of Activated transactions ($\mu(V)$). Since only V=min(A,W) transactions can be activated, we compute $\mu(V)$, $1\le V\le W$. Note that $\mu(V)=\mu(W)$, $V>W$. The behavior of the system can be represented by a one-dimensional birth-death process, where the arrival (birth) process is random or terminal-driven. The birth-death model can be solved easily yielding the state probabilities. The mean transaction response time (R) can be computed, using the state probabilities and applying Little's law. The computation cost at this level is determined by the cost of solving the birth-death model.

3.2. Transaction Throughput Model (Level 2)

This stage of analysis entails the computation of the effective system throughputs $\mu(V)$, $1\le V\le W$. There are J Eligible and V-J Blocked transactions in a closed system with V Activated transactions such that the completion of each transaction results in the immediate activation of a new transaction. The behavior of the system can be represented by a Markov chain with V states, where the number of Eligible transactions (J) determines the state.

The transition rate from state J (S_J) is determined by the completion rate (throughput) of *elementary transactions*: t(J), which is computed at the Hardware Contention Model (Level 3). The following transitions are possible from S_J as implied by Figure 2-1:

1. Successful lock request with probability $P_a(J|V)$: $S_J \rightarrow S_J$,
2. Conflicting lock request without causing a deadlock with probability $P_c(J|V)$: $S_J \rightarrow S_{J-1}$.
3. Transaction restart due to a deadlock with probability $P_r(J|V)$: $S_J \rightarrow S_I$, $I>J$.
4. Transaction completion with probability $P_t(J|V)$: $S_J \rightarrow S_I$, $I\ge J$.

The routing probabilities for elementary transactions: $P_a(J|V)$, $P_c(J|V)$, $P_r(J|V)$, and $P_t(J|V)$ are derived in the Appendix based on the analysis carried out for the Data Contention Model (Level 4).

The transition rate from S_J to S_I is given by:

$$r_{tran}(J,I|V)=P_{tran}(J,I|V)t(J) \qquad 1\le I\le V \qquad (3)$$

where $P_{tran}(J,I|V)$ is the transition probability from S_J to S_I at the completion instants of elementary transactions and is obtained by solving the Data Contention Model (Level 4). The balance equations for the state probabilities of the system are given as follows:

$$P_S(J|V)t(J) = \sum_{I=1}^{V} P_S(I|V)r_{tran}(I,J|V) \quad 1\le J\le V \tag{4}$$

and solved to obtain the steady-state probabilities $P_S(J|V)$, $1\le J\le V$.

The throughput of elementary transactions is:

$$\mu_e(V) = \sum_{J=1}^{V} t(J)\ P_S(J|V) \tag{5}$$

The effective transaction throughput under the same condition is given by:

$$\mu(V) = \sum_{J=1}^{V} P_t(J|V)\ t(J)\ P_S(J|V) \tag{6}$$

where $P_t(J|V)$ is the probability that the completed elementary transaction was the last phase of a transaction. When the fraction of restarted transactions is negligible, $\mu(V) \approx \mu_e(V)/(\bar{L}+1)$.

The residence time components of transactions are computed using Little's result:

$$R_a(V) = \frac{1}{\mu(V)} \sum_{J=1}^{V} \min(J,M)\ P_S(J|V) \tag{7}$$

$$R_m(V) = \frac{1}{\mu(V)} \sum_{J=1}^{V} \max(J-M,0)\ P_S(J|V) \tag{8}$$

$$R_b(V) = \frac{1}{\mu(V)} \sum_{J=1}^{V} (V-J)\ P_S(J|V) \tag{9}$$

$$R(V) = \frac{V}{\mu(V)} \tag{10}$$

where $R_a(V)$, $R_m(V)$, $R_b(V)$, and $R(V)$ are the mean residence time at the Computer System, the mean waiting time at the Memory Queue, the mean waiting time at the Lock-Wait Queue, and the total residence time in the system, respectively, when V transactions are activated. The wasted time due to restarts can be obtained as follows:

$$R_d(V) = R(V) - (\bar{L}+1)\ \frac{V}{\mu_e(V)} \tag{11}$$

The computational cost at this level for a given value of V is determined mainly by the cost of solving the balance equations (4).

3.3. Hardware Contention Model (Level 3)

At this level we compute the throughput of the Computer System in processing elementary transactions: t(J). The Computer System model was described in Section 2.2, where we noted that it has a maximum MPL equal to M. The service demands for a transaction that accesses n data items is $S_k = n\cdot s_k$, $0\le k\le K-1$. The service demand for elementary transactions is given then by $b_k(J) = S_k(J)/(\bar{L}+1)$, $0\le k\le K-1$.

The throughputs t(J), $1\le J\le \min(V,M)$ for elementary transactions are computed using one of the available algorithms in [7]. When we have a product-form queueing network model for the Computer System the computational cost to obtain these throughputs is O(KM).

3.4. Data Contention Model (Level 4)

At this level we proceed to compute $P_{tran}(J,I|V)$ the transition probabilities of the Markov chain for the Transaction Throughput Model (Level 2). The routing probabilities $P_a(J|V)$, $P_c(J|V)$, $P_r(J|V)$, and $P_t(J|V)$ defined in Section 3.2 are also computed. The derivation of the probabilities, due to its lengthy nature, is given in the Appendix.

3.5. An Iterative Solution Method

In the decomposition method described in previous sections, we must solve the linear equations at Level 2 and solve Level 3 and 4 for $1\le J\le V$. The computational complexity of the decomposition method increases rapidly with V. To reduce the computational cost, an iterative solution method based on the decomposition method is proposed for a given V as follows. Define A(J|V) as mean of the variation in the number of eligible transactions at the completion of an elementary transaction. A(J|V) can be computed as follows:

$$A(J|V) = \sum_{I=J-1}^{V} (I-J)\ P_{tran}(J,I|V) \tag{12}$$

It can be shown numerically (using the decomposition method) that A(J|V) is a monotonically decreasing function in J and that:

$$A(J|V) = 0 \qquad \text{for } J = \bar{J} \tag{13}$$

where $\bar{J}$ denotes the mean state at the completion instants of elementary transactions. The interpretation of equation (13) is that the system's mean state is its balance point, such that the system tends to stay there [3]. For fractional values of J, A(J|V) is defined as a linear interpolation of the neighboring two states $\lceil J\rceil, \lfloor J\rfloor$:

$$A(J|V) = A(\lceil J\rceil)P_H(J) + A(\lfloor J\rfloor)P_L(J) \tag{14}$$

where $P_H(J) = J-\lfloor J\rfloor$ and $P_L(J) = 1-P_H(J)$.

Equation (13) can be solved using the bisection method, since A(J|V) is a monotonically decreasing function in J. This implies that the computation at the Data Contention Model (Level 4) needs to be carried out only for values of J encountered during the iteration. The number of iterations required is bounded by log_2V, and the reduction in computational cost is therefore proportional to V/log_2V. The QNM at Level 3 need only be solved for the two states $\lceil J\rceil$ and $\lfloor J\rfloor$. The need to solve the set of linear equations at Level 2 is also obviated and substituted by the computation of throughput when the system is in its mean state.

In order to compute the throughput of elementary transactions, we first compute the mean interdeparture time of elementary transactions when the system is at its mean state $\bar{J}$. This can be accomplished by noting that $P_L(\bar{J})$ and $P_H(\bar{J})$ are the fractions of elementary transactions that leave behind $\bar{J}$ transactions, i.e., the probabilities pertain to *departure instants*. It follows:

$$\frac{1}{\mu_e(V)} = \frac{P_H(\bar{J})}{t(\lceil \bar{J} \rceil | V)} + \frac{P_L(\bar{J})}{t(\lfloor \bar{J} \rfloor | V)} \qquad (15)$$

The probability of termination at an elementary transaction completion is obtained by interpolation:

$$P_T(V) = P_t(\lceil \bar{J} \rceil) P_H(\bar{J}) + P_t(\lfloor \bar{J} \rfloor) P_L(\bar{J}) \qquad (16)$$

The effective system throughput at the Transaction Throughput Model is computed by:

$$\mu(V) = P_T(V)\ \mu_e(V) \qquad (17)$$

instead of equation (6) in Section 3.1.

4. Validation and Results

We first define the parameters for the test case. A summary of validation results and comments about the accuracy of the solution methods are then given. After ascertaining that the iterative method has an accuracy comparable to the decomposition method (see explanation in Section 4.1) we proceed to use this technique in reporting further results. We proceed to discuss the effect of varying the granularity of locking, database size, number of transactions, and the no-waiting policy, i.e., transactions making conflicting lock requests are restarted.

4.1. Parameters of the Test Case

A database with D=1024 data items was considered. The granularity of locking was varied such that the number of locks was N=32, 64, 128, 256, 512, and 1024. The number of data items accessed by a transaction (n) was set to 2, 4, 8, 16, and 32 to investigate the effect of transaction size. The Computer System consists of 10 devices disks and the service demands at all devices are the same (balanced): s_k=0.002, $0 \le k \le K-1$. The maximum MPL of the Computer System was set to M=15 and the number of Activated transactions (V) was varied.

4.2. Validation

The hierarchical nature of our model lends itself to hierarchical validation (from bottom to top), such that inaccuracies at each level can be rectified by adopting a more accurate model at the appropriate level. In this manner inaccuracies are not allowed to propagate to higher levels, where the tracing of the sources of inaccuracy is more difficult. Due to space limitation, we consider a system with a fixed number of Activated transactions (V) since the open model at Level 1 has been shown to be accurate elsewhere [20].

A simulation program was written taking advantage of hierarchical decomposition to reduce the simulation cost. The Computer System was represented by a flow-equivalent service center characterized by its throughput characteristic for elementary transactions: t(J), $1 \le J \le \min(M,V)$. The residence times of active elementary transactions were sampled from the exponential distribution with the mean J/t(J). The hierarchical simulation was validated using a discrete-event simulation and shown to be adequately accurate. In the simulation elementary transactions were specified at the data item request level. The service demands for elementary transactions were $n \cdot s_k/(n+1)$. When a transaction requested a conflicting lock, the deadlock detection routine was invoked. When a cycle was found in the waiting-for-graph, the transaction causing the deadlock was restarted after releasing its locks. The data items (locks) requested by restarted transactions were *resampled*. This has a negligible effect on the performance measures obtained by simulation since the probability of deadlock is expected to be low in the region under consideration.

The analysis of the Data Contention Model (Level 4) is based on the initial estimates that the number of locks held by Eligible and Blocked transactions are $L_e \approx \bar{L}/2$ and $L_b \approx (\bar{L}-1)/2$, respectively. This estimate is quite accurate when lock contention is low [11]. Iteration[2] can be used to improve on the initial estimates for L_e and L_b (see Appendix). The estimates obtained by this iteration used in conjunction with the decomposition (DEC) and iterative (ITR) solution methods are very accurate except for cases of severe data contention [11]. No iteration is required to estimate L_e and L_b when lock contention is not severe. A comparison of blocking and restart probabilities derived here with other results [5, 16] appears in [11].

		Lock Grant		Blocking		Completion		Deadlock

Table 4-1: Transaction routing probabilities.

[2] This iteration is different from the one described in Section 3.5.

Table 4-1 shows the routing probabilities at the completion of an elementary transaction for a given value of V. The results show that the probabilistic analysis in the Data Contention Model provides accurate estimates for the routing probabilities. It can be observed that the probability of lock conflict increases linearly with the number of activated transactions minus one (V-1) and the number of lock requests per transaction. The probability of deadlock increases even more rapidly. Since the average number of transaction completions in simulation runs was 50000, the estimate for probability of deadlock is not accurate enough for some cases. When lock contention is very severe, e.g., L=32 and V=10, the probability of deadlock per transaction exceeds 60%. This is atypical of operational databases, but this parameter settings were used to estimate the accuracy of our analysis under heavy data contention.

Table 4-2: Transaction throughput, mean MPL, and mean residence time of transactions.

Transaction throughput (μ(V)), the mean number of eligible transactions (mean MPL), and mean transaction residence time (R(V)) are given in Table 4-2. Throughputs given for the simulation are the mean values with relative half-widths about the mean of less than 5% at 90% confidence level. The proposed analytic methods provide reasonably accurate estimates for all three parameters except in the case of heavy data contention. It is observed that the transaction throughput decreases when the number of Activated transactions becomes too large. This is due to the increase in the probability of lock conflict and deadlock. The loss of accuracy for L=32 is due to the inadequacy of the Data Contention Model to estimate lock conflict probabilities for the case of high data contention.

Table 4-3 shows the components of the mean transaction residence times and the mean time wasted due to restarts. The decomposition method provides quite accurate estimates for all components. In heavy data contention, the delay at the Lock-Wait Queue is overestimated due to the inaccuracy in modeling the unblocking probability of blocked transactions. Note that the delay at the Lock-Wait Queue due to blocking is much larger than the time wasted due to restarts, except for the case of heavy data contention. The degradation in performance can be ascribed mainly to blocking due to lock conflicts rather than restarts due to deadlocks. The analysis can be simplified without a significant effect on accuracy (except in the case of high data contention) by setting the probability of deadlock equal to zero and ignoring transaction restarts.

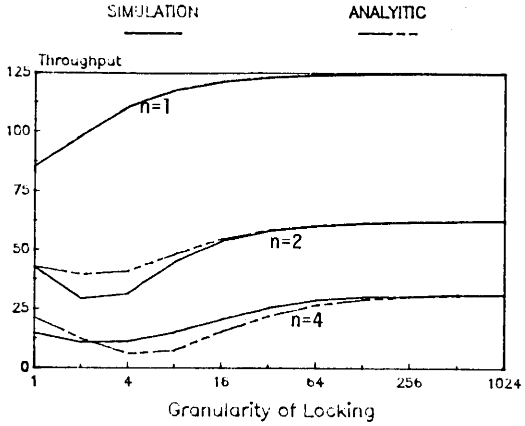
Table 4-3: Residence time components.



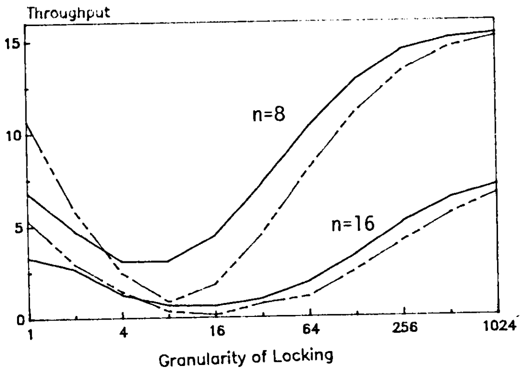


Figure 4-1: Throughput versus granularity of locking with V=10 and s_k=0.001, 0≤k≤9.

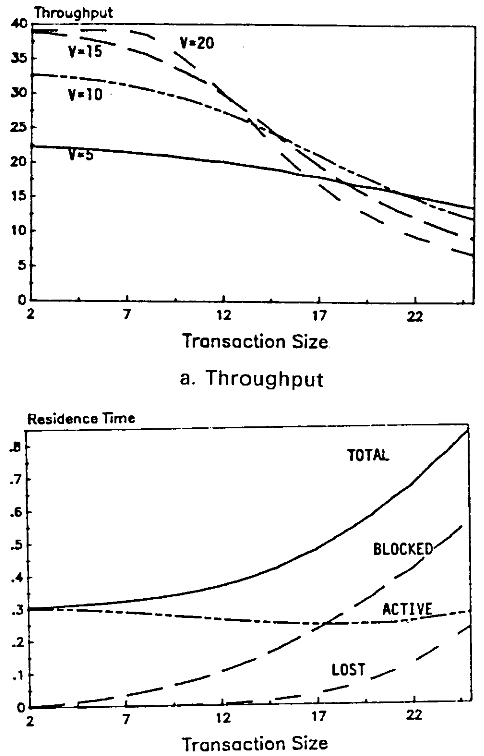
In Figure 4-1 we plot transaction throughput versus granularity of locking for different transaction sizes. Simulation results were obtained using the data item access model, while the analysis was carried out using the iterative solution method in Section 3.5 with the lock access model. It is observed that the analysis is accurate for fine and medium granularities of locking as long as transaction sizes are not excessively large, in which case analytic results tend to be pessimistic for fine granularity of locking. This is partially due to inaccuracies in estimating the lock conflict probabilities. For coarse granularity of locking lock requests are usually made in the first stages of processing while the analytic model presumes that they are uniformly distributed over the lifetime of a transaction. The analytic method overestimates the throughput for coarse granularity as was predicted in specifying the database model in Section 2.1.

Analytic results are used in Section 4.2-4.6 with the understanding that they are somewhat inaccurate for high data contention regions, which are of little practical interest.

4.3. Granularity of Locking

Fine granularity of locking is beneficial as can be observed in Figure 4-1. For small transactions the throughput reaches its peak (saturates) very quickly as a finer granularity of locking is adopted. The degree of data contention becomes insignificant for fine granularity and the throughput is determined mainly by hardware resource contention. For large transactions the throughput initially drops in coarse granularity due to increased restarts as the number of locks increases, i.e., the system progresses from serial processing to concurrent processing with high degree of conflicts. The throughput eventually improves for our test case since the largest transactions with n=16 access a small fraction of the database granules.



a. Throughput

b. Residence time components

Figure 4-2: Performance measures vs transaction sizes.

4.4. Transaction Size

Figure 4-2 shows the transaction throughput and residence time components as a function of transaction size. For small transaction size, few transactions are blocked due to lock conflicts and the throughput is determined mainly by hardware contention. The residence time at the Lock-Wait Queue and the time wasted due to restarts are insignificant. When transaction size increases, the effect of lock conflicts becomes significant. The mean MPL and throughput decrease with transaction size. Up to medium size transactions, the performance degradation is mainly due to lock conflicts since the increase of residence time is mainly due to the increase of blocking time. For very large transactions, the mean MPL is independent of the number of Activated transactions (V). The residence time at the Lock-Wait Queue increases rapidly with transaction size as shown in Figure 4-2.b to the extent that there is a drop in mean MPL, which also results in a drop in active residence time at the Computer System. The wasted time in this figure corresponds to the sum of active and blocked time spent in the system by transactions which were restarted.

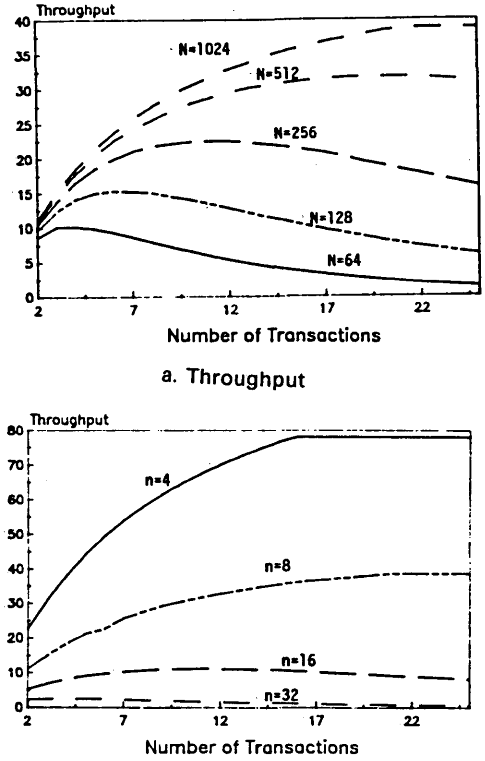
4.5. Number of Transactions

The effect that the number of transactions (V) has on the system performance was discussed qualitatively in Section 2.2, and it was noted that increasing V potentially results in an increase in the effective MPL. On the other hand, lock conflicts are more probable due to the fact that more locks are held by transactions. To investigate the effect of varying number of transactions quantitatively, we plot throughput versus V for different granularities of locking in Figure 4-3.a. In Figure 4-3.b we plot the throughput as a function of V for different transaction sizes.

From Figure 4-3.a, it is observed that system throughput increases with V for fine granularity of locking ($V \leq 10$ and N=256, 512, 1024) for small transactions. On the other hand a degradation in performance is observed for coarse granularity of locking, which is attributable to excessive lock conflicts.

It follows from Figure 4-3.b that increasing V initially results in an increase in throughput. On the other hand, for large transactions (n>8) a point of diminishing returns is soon reached and performance actually degrades. This is because of the increase of lock conflicts, such that the mean MPL decreases with increasing V. This thrashing behavior phenomenon due to lock conflicts was also observed in [15, 18].

Degradation in performance is possible in transaction processing systems with very high MPL's even for fine granularities of locking, as can be observed in Figure 4-3 for large V. It should be noted, however, that the



a. Throughput

b. Throughput

Figure 4-3: Performance measures vs number of transactions.

probability of lock conflict per transaction is proportional to V-1 and the second power of transaction size (n) [5]. Therefore the combination of high V and n has the potential of inducing thrashing and W can be used for congestion control in this case.

4.6. The No-Waiting Policy

At this point we consider the no-waiting policy, according to which a transaction is restarted whenever there is a lock conflict. The no-waiting policy obviates the need to check for deadlock, since there are no blocked transactions. On the other hand, the processing attained by a transaction is lost when it is restarted.

In Table 4-4 we show the transaction throughput versus the number of transactions (V) for different transaction sizes for the waiting (our original model) and the no-waiting policy considered in [15], where a transaction encountering a lock conflict is replaced by a new transaction (resampling of locks). It can be observed that the performance of the no-waiting policy is inferior to the waiting policy with the exception of small transactions. This can be ascribed to the fact that the analysis in [15] considers transaction processing in a system with no hardware contention. A more detailed analysis of the no-waiting case appears in [12].

5. Conclusion

Two methods based on decomposition and iteration were proposed in this paper for analyzing the performance of a centralized database with dynamic locking scheme. The iterative solution method was introduced to reduce the computational cost of the decomposition method by estimating the mean number of eligible transactions, rather than their distribution (as obtained by the decomposition method). Simulation was used to validate both methods, which were shown to be of adequate accuracy except for systems with excessive data contention.

n	Case	V=5	V=10	V=15	V=20
2	Waiting	89.06	131.0	155.3	156.2
	No Wait	89.05	130.8	154.8	154.3

	No Wait	2.328	1.531	0.975	0.690

Table 4-4: Throughputs for Waiting and No-Waiting cases.

We also investigated the effect of varying system parameters on system performance. Our conclusions generally concur with those of other researchers. The same framework can also be used to study the effect of exclusive/shared locks, update/readonly transactions [11] and to compare the performance of concurrency control schemes based on locking, optimistic concurrency control, and timestamp ordering [13].

The main contribution of this paper is the methodology developed for the probabilistic analysis of lock conflict/deadlock probabilities. These are then used to compute transaction routing and transition probabilities for the embedded Markov chain. An advantage of the hierarchical solution method is that the probabilities for the Data Contention Model can be obtained by means of simulation (trace or random number driven).

I. Analysis of the Data Contention Model

This appendix is concerned with computing the transition probabilities among the states of the Markov chain model for the Transaction Throughput Model (Level 2) as explained in Section 3.2. and the lock conflict probability for the Hardware Contention Model. The reader is forewarned that the derivations are carried out in a top-down manner, such that parameters used in earlier derivations are themselves derived later. Also note that the parameter V is elided, since it remains fixed in the following derivations.

The transition probability $P_{tran}(J,I|V)$ depends on whether the completed elementary transaction belongs to a transaction holding k-1 locks and its routing probabilities: $P_a(k)$ {successful lock request}, $P_c(k)$ {blocking}, $P_t(k)$

{completion}, and $P_r(k)$ {deadlock}. These probabilities are computed in (21), (24), (20), and (22), respectively.

Defining $P_{tr}(J,I|k)$ as the probability that transition occurs from S_J to S_I when an elementary transaction holding k-1 locks is completed, we have:

$$P_{tr}(J,I|k)=\begin{cases} P_c(k) & \text{for } I=J-1 \\ P_a(k)+P_t(k)P_{ta}(J,I|k) & \text{for } I=J \\ P_t(k)P_{ta}(J,I|k)+P_r(k)P_{ra}(J,I|k) & \\ & \text{for } I>J \end{cases} \qquad (18)$$

where $P_{ta}(J,I|k)$ (resp. $P_{ra}(J,I|k)$ is the probability that I-J blocked transactions are unblocked when a transaction holding k-1 locks teminates (resp. is restarted after releasing its locks). These probabilities are derived in (33) and (34), respectively. The unconditional transition probability from S_J to S_I is:

$$P_{tran}(J,I|V) = \sum_{k=1}^{L+1} P_{tr}(J,I|k)\ P_i(k) \qquad (19)$$

where $P_i(k)$ is the probability that the completing elementary transaction holds has k-1 locks and is obtained in (25) and (26).

The routing probabilities ($P_a(J|V)$, $P_c(J|V)$, $P_r(J|V)$, and $P_t(J|V)$) are then computed by unconditioning on k using $P_i(k)$ from $P_a(k)$, $P_c(k)$, $P_r(k)$, and $P_t(k)$.

When all transactions access a fixed number of data items: n, $P_t(k)$ is given by:

$$P_t(k) = \frac{P_m(k|n)}{\sum_{h=k}^{L} P_m(k-1|n)} \qquad (20)$$

where $P_m(k|n)$ is the distribution of number of locks requested by a transaction requesting n locks and was given by equation 1 in Section 2.1. Defining $P_{a1}(k)$ as the probability that k'th lock request is successful (which is derived in equation (35)), the probability of lock acquisition $P_a(k)$ can be obtained as:

$$P_a(k) = (1-P_t(k))\ P_{a1}(k) \qquad (21)$$

The probability of deadlock $P_r(k)$ is then:

$$P_r(k) = (1-P_t(k)-P_a(k))\ P_{r1}(k) \qquad (22)$$

where $P_{r1}(k)$ is the probability that a conflict at k'th lock request causes a deadlock and is represented by the sum of probabilities of deadlocks with different cycle lengths:

$$P_{r1}(k) = \sum_{c=2}^{V-J+1} P_{rr}(c|k) \qquad (23)$$

where $P_{rr}(c|k)$ is the probability of deadlock with cycle length c at a conflicting k'th lock request and is derived in equation (37).

The probability of blocking $P_c(k)$ is simply the complement of the other routing probabilities as follows:

$$P_c(k) = 1 - P_t(k) - P_r(k) - P_a(k) \qquad (24)$$

$P_i(k)$, the probability that an elementary transaction holds k-1 locks, is computed as follows:

$$P_i(k) = \begin{cases} 1/A & \text{for } 1\leq k\leq 2 \\ 1/A \prod_{h=2}^{k-1} (1-P_t(h)-P_r(h)) & \text{for } 2\leq k \end{cases} \qquad (25)$$

where where A is the normalization constant. When there are no transaction restarts due to deadlocks (or the fraction of such transactions is negligible) in the finest granularity of locking, then all transactions request exactly n locks, and:

$$P_i(k) = \frac{1}{n+1} \qquad 1\leq k\leq n+1 \qquad (26)$$

which means that the number of locks held by elementary transactions is distributed uniformly over [0,n].

The mean number of locks held by an Eligible (resp. Blocked) transaction is denoted by L_e (resp. L_b). We have:

$$L_e = \sum_{k=1}^{L+1} (k-1)\ P_i(k) \qquad (27)$$

$$L_b = \sum_{k=1}^{L+1} (k-1) \frac{P_i(k)P_c(k)}{\sum_{k=1} P_i(k)P_c(k)} \qquad (28)$$

For finest granularity of locking with small transactions and low data contention:

$$L_e \simeq \frac{\bar{L}}{2} \simeq \frac{n}{2} \qquad (29)$$

$$L_b \simeq \frac{(\bar{L}-1)}{2} \simeq \frac{(n-1)}{2} \qquad (30)$$

This was observed in simulation studies [11] and can also be argued intuitively [5]. This estimates given by equation (29) and (30) were used with fine granularity locking, in which case equation (27) and (28) confirm the initial estimate. In the case of medium granularity of locking an initial estimate for L_e and L_b was chosen and iteration was used to improve the initial estimate. The iteration was carried out from equations (21) through (28) until L_e and L_b converge.

To derive $P_{ta}(J,I|k)$ {resp. $P_{ra}(J,I|k)$} used in equation (18), we first compute $P_{at}(I|b,J,k)$ {resp. $P_{ar}(I|b,J,k)$} as the probability that I-J of b blocked transactions are unblocked from the Lock-Wait queue when k-1 locks are released due to completions {resp. restarts}. $P_{at}(I|b,J,n)$ and $P_{ar}(I|b,J,n)$ are then computed by the following recursion for $1\leq b\leq V-J$, $J\leq I\leq \min(V,J+k-1)$:

$$\begin{aligned} P_{at}(I|b,J,k) &= P_{at}(I|b-1,J,k)(1-P_o(I-J|k)) \\ &\quad + P_{at}(I-1|b-1,J,k)P_o(I-J-1|k) \end{aligned} \qquad (31)$$

$$\begin{aligned} P_{ar}(I|b,J,k) &= P_{ar}(I|b-1,J,k)(1-P_o(I-J-1|k-1)) \\ &\quad + P_{ar}(I-1|b-1,J,k)P_o(I-J-2|k-1) \end{aligned} \qquad (32)$$

with the initial condition of

$$P_{at}(I|b,J,k) = \begin{cases} 1 & \text{for } I=J \text{ and } b=0 \\ 0 & \text{otherwise} \end{cases}$$

$$P_{ar}(I|b,J,k) = \begin{cases} 1 & \text{for } I=J+1 \text{ and } b=1 \\ 0 & \text{otherwise} \end{cases}$$

where $P_o(q|k)$ is the probability that a blocked transaction following q transactions is unblocked when k-1 locks are released and is computed from (41). The second initialization is different from the first one since at least one blocked transaction is unblocked upon the restart of a transaction. Since we have V-J blocked transactions in the Lock-Wait Queue, then probabilities $P_{ta}(J,I|k)$ and $P_{ra}(J,I|k)$ become:

$$P_{ta}(J,I|k) = P_{at}(I|V-J,J,k) \qquad (33)$$

$$P_{ra}(J,I|k) = P_{ar}(I|V-J,J,k) \qquad (34)$$

We now proceed to compute the basic probabilities: $P_{a1}(k)$, $P_{rr}(c|k)$, and $P_o(q|k)$ when lock requests are mutually exclusive, independent and uniformly distributed over the N locks. The key assumptions in our analysis is that (i) an outstanding lock request by a transaction is conflicting equally probably with all busy locks held by other transactions. and (ii) eligible (resp. blocked) transactions hold L_e (resp. L_b) locks. $P_{a1}(k)$, the probability that the k'th lock request is successful, is obtained by:

$$P_{a1}(k) = 1 - \frac{L_e(J-1)+L_b(V-J)}{N-k+1} \qquad (35)$$

where the ratio is the number of locks taken by other transactions divided by the total number of available locks.

We now proceed to derive $P_{rr}(c|k)$, the probability that a transaction requesting k'th conflicting lock causes a deadlock of cycle c. Consider a deadlock involving three transactions T_1, T_2, and T_3 (c=3), where T_1 is the transaction requesting a conflicting lock. A deadlock cycle of length three is made, i.e., $T_1 \rightarrow T_2 \rightarrow T_3 \rightarrow T_1$, where $T_i \rightarrow T_j$ denotes that T_i is blocked by T_j. $P_{rr}(3|k)$ is then computed by the product of $\text{Prob}[T_1 \rightarrow T_2]$, $\text{Prob}[T_2 \rightarrow T_3 \mid T_1 \rightarrow T_2]$, $\text{Prob}[T_3 \rightarrow T_1 \mid T_1 \rightarrow T_2 \rightarrow T_3]$, and the number of choices to choose T_2 and T_3 among blocked transactions. Note that $\text{Prob}[T_3 \rightarrow T_1 \mid T_1 \rightarrow T_2 \rightarrow T_3]$ is not equal to $\text{Prob}[T_3 \rightarrow T_1]$. $T_3 \rightarrow T_2$ and $T_2 \rightarrow T_3$ can not happen simultaneously since all deadlocks have been resolved before T_1 makes a lock request.

Defining $P_{w1}(k)$, $P_{w2}(k|i)$, and $P_{w3}(k|i)$ as follows:

$P_{w1}(k)$ = Prob[A transaction requesting k'th lock is blocked by a specific blocked transaction | Lock conflict occurred].

$P_{w2}(k|i)$ = Prob[A blocked transaction waits for an eligible transaction which holds k-1 locks | It does not wait for the i other blocked transactions.]

$P_{w3}(k|i)$ = Prob[A blocked transaction is blocked by a specific blocked transaction | It does not wait for the i other blocked transactions.]

$\text{Prob}[T_1 \rightarrow T_2]$ becomes $P_{w1}(k)$, $\text{Prob}[T_2 \rightarrow T_3 \mid T_1 \rightarrow T_2]$ becomes $P_{w3}(k|0)$, and $\text{Prob}[T_3 \rightarrow T_1 \mid T_1 \rightarrow T_2 \rightarrow T_3]$ becomes $P_{w2}(k|1)$. The number of ways to choose T_2 and T_3 from V-J transactions is obtained by (V-J)·(V-J-1). Hence the probability of deadlock involving three transactions when a transaction makes its k'th conflicting lock request is represented as follows:

$$P_{rr}(3|k)=P_{w1}(k)P_{w2}(k|1)(V-J)(V-J-1)P_{w3}(k|0) \qquad (36)$$

The probability of deadlock involving m transactions at k'th conflicting lock request in general is obtained for $2 \leq m \leq V-J+1$ by:

$$P_{rr}(m|k)=P_{w1}(k)P_{w2}(k|m-2) \prod_{i=0}^{m-2} \{(V-J-i)P_{w3}(k|i)\} \qquad (37)$$

$P_{w1}(k)$ is obtained from the mean number of locks held by other transactions as follows:

$$P_{w1}(k) = \frac{L_b}{L_e(J-1)+L_b(V-J)} \qquad (38)$$

Then $P_{w2}(k|i)$ and $P_{w3}(k|i)$ are then obtained by:

$$P_{w2}(k|i) = \frac{k-1}{L_e(J-1)+L_b(V-J-i-1)+k-1} \qquad (39)$$

$$P_{w3}(k|i) = \frac{L_b}{L_e(J-1)+L_b(V-J-i-1)+k-1} \qquad (40)$$

Finally $P_o(q|k)$,the probability that a transaction is unblocked following q transactions when k-1 locks are released, is computed as follows:

$$P_o(q|k) = \frac{k-1-q}{(J-1)L_e+(V-J-1)L_b+k-1} \quad \text{for } q<k-1 \qquad (41)$$

A Graphical Interface for Specification of Extended Queueing Network Models

J. B. Sinclair
S. Madala

Department of Electrical and Computer Engineering
Rice University
Houston, Texas 77251-1892

ABSTRACT

GUIDE is a graphical user interface to a performance evaluation tool based on extended queueing network models. The interface allows a user to specify the structure of a model by creating a graphical representation of the objects in the model and their interconnections. Additional information about the specific objects and/or the model as a whole is input through a set of dialog windows that adapt to the specific context and prior information entered by the user. This enforces the creation of complete models that are syntactically correct. We briefly describe the implementation of GUIDE and its modeling capabilities, and illustrate its usage through a small example.

1. Introduction

GUIDE (the Graphical User Interface and Dialog Editor) is a tool for constructing extended queueing network models. It is part of a simulation-based modeling and performance evaluation package called GIST developed at Rice. [1] In designing GUIDE (and GIST), we had several objectives:

(1) The interface should be easy to learn and simple to use.

(2) It must be powerful in its descriptive capabilities, to allow very complex systems to be modeled.

(3) Users should not be able to create a syntactically incorrect model specification.

(4) The user should be able to easily specify large models (dozens or even hundreds of components).

(5) The interface should be flexible in allowing the user freedom to construct a model with as few restrictions as possible, other than syntax enforcement.

(6) The interface implementation hardware should be inexpensive to make its use practical in an educational environment.

In this paper, we discuss both the implementation and use of GUIDE. We also describe some proposed extensions to the current implementation that will improve its utility and bring us closer to achieving these objectives.

2. Background

Queueing models (QN's) and extended queueing models (EQN's) can be specified in several ways. The most primitive way is to describe them in a conventional programming language such as FORTRAN, C, or PASCAL. This approach offers complete generality but, in the case of simulation, requires that the programmer also construct the mechanism for the execution of the simulation model. To avoid this we can use a simulation language, which is often an extension of a conventional programming language that provides high-level modeling constructs and a run-time environment for model execution. [2, 3, 4, 5, 6]

An alternative to this "language-oriented" approach, and the approach chosen for GIST, is to use an interface tailored to the specification of EQN's. In this "transaction-oriented" approach, the interface deals with the model at the same level of abstraction as the user. Examples of this approach include RESQ, [7] QNA, [8] QNAP2, [9] XL, [10] SNAP, [11] SuperNet, [12] PANACEA, [13] PERFORMS, [14] BEST/1, [15] COPE, [16] PAWS, [17] PLANS, [18] NUMAS, [19] the Performance Analysis Workstation, [20] and STEP-1. [21] There are several advantages to a transaction-oriented approach. Since the tool allows the user to describe the model directly in terms of the abstractions used to construct the model, it is easier to learn and to use the specification tool. It is also easier to insure that the specification matches the model. Some types of errors are avoided completely or can be detected at model specification time. A major advantage is that the model specifications are easier to understand and to modify.

In most cases the user of one of these performance tools interacts with the tool through a textual interface, but graphics interfaces have been proposed or implemented for at least four of them: PAWS, [22] RESQ, [23] the Performance Analysis Workstation, and NUMAS.

3. Description of GIST

GIST allows specifications of EQN models through a graphical or a textual interface and produces executable images to simulate a model of the system under consideration. The EQN models are specified as a network of high level objects drawn from a set of object types. GIST is based on CSIM, a subroutine package that provides runtime support environment for discrete event simulation. [24] The major parts of GIST are two distinct user interfaces that accept specifications from the user, a translator that generates CSIM source code, and a library of object routines written in CSIM to model the various object types (Fig. 1).

3.1. User Interfaces

The two interfaces have similar modeling capabilities, but one is graphics-oriented (GUIDE) while the other (TIDE) is intended for use on terminals without graphics.

3.1.1. GUIDE

A natural way to specify many aspects of an EQN model is graphical. GUIDE allows users to assemble EQNs from elements of a set of icons representing the various object types, interconnected by routing paths. Users can define or edit object specific parameters through the use of "dialog" windows.

CH2345-7/86/0000/0709$01.00 © 1986 IEEE

GUIDE was implemented on a 512K Macintosh personal computer because the window environment, mouse input, and pull down menus provided a friendly, easy-to-learn, easy-to-use interface and the software tool base made the prototype development much simpler. Also, a Macintosh is a relatively inexpensive graphics workstation. GUIDE runs standalone; no host computer is needed during the specification process. This reduces the load on the mainframe that executes the simulation model. The output of GUIDE is a file containing the EQN model specifications. The file is transferred to the host for processing by the translator.

3.1.2. TIDE

The Textual Interface and Dialog Editor (TIDE) is provided as an alternative when a Macintosh is unavailable. [25] It runs on a Unix-based system and is intended to be used with a VT100 or equivalent terminal. It uses the CURSES windowing library routines for efficient screen management.

The user is guided through a series of hierarchically structured menus. A unique feature of this interface is that, unlike the dialog interfaces for some performance evaluation tools such as RESQ, interaction is menu-driven and conducted via overlapping "windows" on the screen. This helps the user maintain a sense of perspective of the current context of the specification process. The output of TIDE is again a specifications file to be processed by the translator.

3.2. Translator

The translator is the link between the user interface and the object routines. Its input is the specifications file created by the user interface and its output includes CSIM source code (see below). The translator produces as output the following files: a main file, a definitions file, a "make" file and optionally a report file. The main file contains code for initialization and calls to the appropriate object routines. The definitions file contains declarations of special CSIM constructs. The "make" file is provided to simplify the task of creating the final executable image. The report file contains a user-readable summary of the EQN model. A parser, generated using the Unix facilities lex and yacc, is used for parsing the user-specified conditions.

3.3. CSIM

CSIM is a subroutine package, written in C, that provides a runtime support environment for discrete event simulation. It is based on the process interaction approach, in which related sets of events are combined into a single process. A simulation specification in CSIM consists of a set of procedures, one for each type of process, and declarations of instances of special constructs such as conditions, semaphores, and state variables. CSIM provides routines to manipulate both processes and these special constructs.

4. GIST Objects

One of the approaches used in attempting to meet the goal of providing GIST users with a high-level model specification capability is the implementation of a set of object types that can be used for realistic and detailed representation of relevant properties of systems of interest. An EQN model can be built from a number of objects, each object of a predefined object type. The object types in a GIST model are briefly described below.

SOURCE: Jobs of a specific jobclass are created at a SOURCE object. The creation of a job may be condition-dependent, or jobs may be created at intervals determined by an inter-generation time distribution.

SINK: Jobs arriving at a SINK object are removed from the network.

ALLOCATE: An ALLOCATE object assigns units of a specific resource to the visiting jobs that request it. Jobs request resources in integer amounts according to jobclass-dependent distributions. Sometimes, a request from a job cannot be satisfied immediately due to an insufficiency of the resource. In that case, the job is delayed until its request is met in accordance with an allocation policy that is followed at the object.

DEALLOCATE: At a DEALLOCATE object, all the units of a specific resource held by visiting jobs are reclaimed and returned to the pool of available resources.

When jobs visit a CREATE object, an integer amount of a particular resource is produced. The amount of resource created is in accordance with a jobclass-independent distribution.

DESTROY: At a DESTROY object, all the units of a specific resource held by visiting jobs are removed, but they are not returned to the pool of available resources.

FORK: A FORK object creates a new job when a job of a specific jobclass visits it. The new job is defined to be either a **child** job or a **peer** job in relation to the visiting job. The created job can have a jobclass different from that of the visiting (creator) job.

JOIN: When a job that has a parent or child relationship with any other job reaches a JOIN object, it waits there until its child or parent reaches there. When the two meet, the child job terminates and the parent job continues through the network. When a job has more than one child jobs in the network, it waits at a JOIN object for the arrival there of its most recent unterminated child job. Jobs that have no child jobs or parent jobs are unaffected by a visit to a JOIN object and are not delayed there.

PROBE: A PROBE object collects user-specified statistics from the visiting jobs. The jobs themselves are unaffected by visit to a PROBE object.

SWITCH: SWITCH objects perform job routing. The routing decision made at a SWITCH object can be based on a condition-evaluation, stochastic selection, or a static, jobclass-based routing specification. A SWITCH object does not delay the jobs that visit it.

QUEUE, SERVER: The two functions, queuing and service, of a QUEUE object in a QN model can be performed separately by QUEUE and SERVER objects in a GIST EQN model. QUEUE objects perform only the queuing function (without service). Jobs joining a QUEUE object wait there while service is unavailable. Jobs at a QUEUE object conform to that object's **queuing discipline**, a policy which determines the order in which jobs become eligible to leave the object. The next job eligible to leave is said to be at the **head** of the QUEUE.

QSERVER: A QSERVER object in an EQN model is equivalent to a QUEUE object in a QN model. It is an object where both the queuing and service functions are performed. It is computationally more efficient to use a QSERVER if the generality provided by separate QUEUE and SERVER objects is not required in an EQN model.

We will use the term QUEUE to refer to the EQN model object. If the discussion concerns a QUEUE object type as in a QN model, we make the context explicit.

5. Implementation of GUIDE

EQN models are characterized by a network of objects and their interconnections. An analyst almost always draw a pictorial representation of an EQN model before actually specifying it to a typical modeling tool. Such representations or block diagrams are much more readable than textual information accepted by EQN modeling tools. Then the analyst in effect manually translates the graphical representation, augmenting it with additional information, into a form recognized by a modeling tool or programming language. The translation process is time consuming and is a potential source of errors. An obvious way to bypass this step is to provide the user with an interface that directly accepts graphical specifications. However, certain information associated with EQNs is necessarily specified textually. Examples of such information include the attributes of each object such as parameters of probability distributions, names of objects, and initial conditions. The graphical interface shields the user from implementation details and minimizes the possibility of errors during the specification process. It lets the user concentrate on the model specification rather than on the tool itself.

GUIDE is written in the C language, using the Stanford University Mac C (sumacc) development software. [26] It is tailored to the Macintosh and presently is not portable to other computers/graphics terminals. Users familiar with some typical Macintosh application programs can learn to use GUIDE in a few minutes. Provision has been made to give on-line help about the various objects of GIST and about GUIDE itself, but at present this feature is unimplemented.

The minimum hardware requirements for the graphical interface are a high resolution display, sufficient memory to specify large models, and a graphical input device such as a mouse, trackball or digitizing pad along with a keyboard. Several workstations and personal computers satisfy the above requirements. We chose the Macintosh computer primarily because it was the least expensive system which meets these minimum requirements, and is more widely available at Rice than more sophisticated (and more expensive) workstations. Moreover, the Macintosh has an excellent library of graphics routines and a well defined standard user interface that reduced our implementation effort considerably.

The software for GUIDE can be divided into two parts, the graphical input package and a set of specification routines. The input package allows the user to create a graphical representation of the network topology, i.e., the objects and their interconnections. It also handles all generic system functions such as saving partial or complete specification files, and opening existing files. The specification routines allow the object-dependent data to be entered in windows tailored to each object type. These routines have been implemented in a modular fashion, making it easy to modify existing object types or add new object types.

GUIDE presents the user with a set of menus, a working window and an options window (Fig. 2). The working window is the region of the screen displaying the part of the larger work area in which the user is currently creating the model. The work area can be scrolled horizontally and vertically in the working window to aid in specifying large models. The options window contains graphical representations (icons) for each object type available in GIST, as well as an interconnect option. The icons for the object types are given in Fig. 3.

There are seven pulldown menus: 1) the apple menu, 2) the file menu, 3) the edit menu, 4) the help menu, 5) the specify menu, 6) the transfer menu, and 7) the debug menu. Moving the cursor over any menu item and pressing the mouse button results in the display of a set of items grouped under this menu. Any item within the menu can then be selected by moving the cursor over it and releasing the mouse button. The apple menu is common to most Macintosh application programs. The transfer and debug menus will not appear in future implementations of GUIDE and will not be discussed.

The file menu lets a user invoke the following functions: open a new file, open an existing file, close the current file, save the current specifications in a file, save the current specifications in a different file, revert back to the last saved version of the specifications, check for partial correctness of specifications, and quit the program.

The edit menu allows a user to delete objects or interconnections. Other items in this menu are the standard cut, copy and paste items found in other Macintosh applications. These items at present work only with concurrent mini-applications (Desk Accessories) that are invoked via the apple menu.

The help menu is used to invoke on-line help. Currently this feature is not implemented.

The specify menu lets users specify initial jobs, runtime parameters, and initial quantities of passive resources. In addition, it lets user view information about job classes and objects.

6. Example of the Use of GUIDE

We shall now illustrate the usage of GUIDE through a small example. Consider a computer system which services jobs of two different classes, batch and interactive. Batch jobs arrive from the external world, receive service from the system, and depart. Interactive jobs continually circulate in the system between terminals and the CPU. Both classes of jobs contend for primary memory before they receive service and release the memory allocation after service. The system consists of two processors, a "fast" cpu and a "slow" cpu. In the interest of high throughput the batch jobs are processed on the fast cpu, while the interactive jobs are processed on both processors, pre-empting the batch jobs whenever necessary to reduce response time.

This system can be modeled using the GIST object types SOURCE, SINK, ALLOC, DEALLOC, QUEUE, SERVER, SWITCH and PROBE. The SOURCE and SINK objects model arrival and departure of batch jobs, the ALLOC and DEALLOC objects model acquisition and release of primary memory by both classes of jobs, the QUEUE and SERVER objects model the waiting jobs and the two processors, and the SWITCH object models job routing.

The model might be specified using GUIDE as follows. Positioning the cursor over an icon in the options window and pressing the mouse button selects and highlights the icon by inverting it. We now can specify a new object of the selected type by moving the cursor into the working window without releasing the mouse button (Fig. 4). During this "dragging" process an outline of a box enclosing the icon follows the cursor movement.

After some or all of the required objects have been dragged into the working window we can specify the interconnections between them using the interconnect option in the options window. The cursor changes shape to a cross to keep the user aware of this option. To interconnect two objects we click first on the source icon and then on the destination icon. The source icon represents the object from which jobs depart and the destination icon represents the object to which jobs are routed. In Fig. 5 the source icon and the destination icon represent the SOURCE type object and the ALLOC type object, respectively. During this process an "elastic" line anchored at the source object tracks the motion of the cursor. Interconnections with more than one line segment can also be specified by clicking in succession on the source icon, intermediate points that define the line segments, and the destination icon. The completed EQN model diagram for the example appears in Fig. 6.

Object type specifications for an object can be entered at any time after the icon for the object has been placed in the working window. Clicking twice in succession (double clicking) on an icon brings up a "dialog" window specific to the object type represented by that icon. These windows contain boxes to accept object names, items that permit selection among a number of alternatives, items that accept yes/no options and items that start immediate actions.

As an example, double clicking on the SOURCE icon in Fig. 6 brings up the SOURCE specification dialog window in Fig. 7. This window contains text boxes to accept the name of the object, the class of jobs to be generated by this SOURCE and initially boxes for distribution parameters. The interface is designed to hide as much irrelevant detail as is possible from the user. If the conditional generation option is chosen, the distribution related items disappear and a text box to accept a condition appears in their place.

Other items in the dialog window allow the user to specify the statistics that can be collected at this SOURCE. Clicking on the OK button confirms the specifications for the object. This closes the dialog window and takes the user back to the working window. Alternatively, clicking on the Cancel button undoes all changes made to this object's specification and returns the user to the working window. This undo feature is available in all object specification dialog windows.

A noteworthy feature of the interface is that the dialog windows adapt to different interconnections in the model being specified. For example, the appearance of the QUEUE specification dialog window depends upon the number of SERVER type objects to which the QUEUE type object is connected. The dialog window for the upper QUEUE of Fig. 6. ("Interact queue"), which is connected to two SERVER type objects, is shown in Fig. 8 and differs from the dialog window for the lower QUEUE ("Batch queue") shown in Fig. 9, in that it has additional items for specifying server selection. Clicking on the "Edit" button brings up another dialog window (Fig. 10) for the specification of server selection. GUIDE's context-dependent syntax is again illustrated in the dialog windows for the two SERVER objects (Figs. 11 and 12).

Modifying an already existing model specification is relatively easy with GUIDE. Objects and interconnections can be added or deleted at any time during the specification process. It is not necessary to have all the objects and interconnections ready before specification for some of the objects can begin. Some checking is done during additions and deletions so that internal data structures remain consistent at all times. Icons can be moved on the working area at any time, even after they have been connected to other icons, and the connections will be maintained. Multiple-segment routing paths can be manipulated by moving the point at which any two segments join.

Details which are not object-specific but are pertinent to the model as a whole, such as passive resources, run time parameters and initial jobs, can be specified in other dialog windows that are invoked by selecting items from the "Specify" menu. The Runtime parameters dialog window is shown in Fig. 13.

When specification of the model is complete, it can be saved in a file and transmitted to the host computer for processing by the translator component of GIST.

7. Summary and Discussion

GUIDE has only recently been made available for general use. However, even our limited experience with it offers some basis for judging how well our objectives have been achieved. We believe that it is extremely easy to learn to use for anyone with an understanding of extended queueing network models. The icons are similar or identical to those found in the literature. Virtually all of the object types that are typically found in EQN models are supported by GUIDE and by GIST, although in some cases the semantics of the objects have been modified. These include objects for modeling active and passive resources, concurrency, and open networks. New object types (principally the QUEUE, SERVER, SWITCH, and PROBE objects) provide additional modeling capabilities and/or make model specification easier.

The user cannot construct a complete model that is syntactically incorrect. By complete we mean a model in which all object inputs and outputs are connected to other objects. At any point in the specification process, GUIDE requests and a user can only enter information that is appropriate for the context. Menus for entering object information adapt to user responses.

Support for large models is currently limited to the ability to scroll within a large virtual screen. This causes an undesirable "peephole" effect, in that a user can only see a part of the model at one time. The problem is made more severe by the small size of the working window, which in turn is due to the small screen size of the Macintosh computer.

The user has a great deal of flexibility in creating and editing model specifications. Objects can be inserted into the model at any time. Information for an object can be entered when the object is inserted or later, and all of the information does not have to be entered at the same time. Icons and connections between icons can be deleted at any time, and icons (even with connections) can be moved around in the virtual workspace. The model specification can be saved for later additions and/or modification.

The major deficiencies of GUIDE are in the area of large model specification. Currently, GUIDE has no concept of a submodel, and hierarchically structured models are not possible. Scrolling is useful, but forcing the user to always see every part of the system at the same level of abstraction may result in an amount of detail that confuses rather than clarifies the nature of the model and the interactions among its components. Also, each model must be completely constructed from the set of GIST primitive objects. The user should be able to use previously specified models as higher level abstractions when constructing new models, and nesting of model definitions should be possible. The most important extension that we plan for GUIDE (and GIST) is the inclusion of single-input, single-output submodels.

Another useful feature for modeling systems, especially large ones, is that of a replicated object. That is, a user should be able to declare an instance of an object and then specify that the object is to be replicated several times. For instance, in a model of an interactive computer system, the set of all terminals/users could be modeled as a single replicated QSERVER. Enhancements to CSIM currently under way will make the task of implementing this feature easier and the result will be more efficient than it would be under the current CSIM implementation.

Overall, GUIDE offers an interesting and efficient alternative to more traditional methods of extended queueing network specification. We are in the process of gaining experience with its use in both courses and research and we will use that experience to identify other enhancements that will increase its utility.

ABSTRACT

The development of computer programs for evaluating the performance of resource contention systems such as computer, communication, and manufacturing systems, represents a significant software development effort. This effort can be very costly in terms of the work required to evaluate the results of these programs and to build, verify, modify, and maintain the programs themselves. In the paper we discuss our current efforts on design, development and implementation of an integrated, interactive, high-level, graphics-oriented environment for constructing and evaluating extended queueing network performance models of resource contention systems. The RESQ modeling language provides the foundation for the capabilities provided by the environment.

1. Introduction

Evaluating the performance of resource contention systems such as computer, communication, and manufacturing systems is a critical and complex step in the design, planning and evaluation process for such systems. Fortunately, the difficulty and complexity of this step can be considerably reduced by providing the performance analyst with an appropriate set of software tools to aid in the performance evaluation process.

Traditionally, the notion of an "appropriate" software tool has meant a declarative language in which a performance model may be specified and then evaluated (either numerically or through simulation). General purpose programming languages such as PASCAL or FORTRAN and general purpose simulation languages such as GPSS, SIMULA and SIMSCRIPT have often been used in the performance evaluation process. More recently, special-purpose modeling languages such as RESQ [Saue82] [Saue84], PAWS [IRA81] and STEP-1 [Trip84] have been developed. The languages in this latter group provide the modeler with a rich set of programming constructs or "modeling elements" which can be easily used to specify the objects and actions actually found in the modeling domain. At this level of abstraction, performance models can be easily and rapidly constructed, evaluated, and verified; the analyst's productivity and effectiveness thus increase dramatically.

With the recent widespread availability of relatively inexpensive, graphics-oriented workstations, the development of a *performance evaluation workstation environment* has become possible. At the heart of such an environment is the notion of a *graphical* representation of a performance model [Mela85]. We believe a graphical representation is the most natural form in which to express a performance model; indeed, there has always been a very strong pictorial flavor even in textual modeling languages such as RESQ and PAWS [Saue84]. Perhaps more importantly, the graphical representation of a model creates the opportunity to provide a single, uniform interface for *all* aspects of the modeling and performance evaluation process, and the environment can thus provide the analyst with an integrated set of software tools for use throughout the modeling lifecycle. A model may be graphically constructed, edited, and documented. In the case of simulation the solution may be animated. Performance results can be displayed, manipulated and examined together with the performance model itself in a single and integrated manner. We believe that the ability to easily create such a natural expression of performance models together with the ability to easily access all the modeler's software tools through a uniform and integrated interface will result in yet further increases in an analyst's capa-

bilities and productivity.

In this paper, we discuss our current efforts in developing an integrated, graphics-oriented performance evaluation workstation environment for constructing, maintaining, revising, and evaluating performance models of resource contention systems. The RESQ modeling language provides the foundation for the capabilities provided by the environment. This language provides the modeler with a rich set of high-level modeling primitives with which a performance model may be constructed, multiple methods (both analysis and simulation) for solving these models, and sophisticated statistical techniques for evaluating performance results.

We believe our RESQ modeler's workstation environment offers several important advantages over other related efforts; indeed, we adopted what we have found to be the most promising aspects of this previous work and have drawn on the modeling experience and methodology of RESQ users (including ourselves) in designing the environment. We believe that the use of a *single* graphical description of the performance model throughout *all* phases of the modeling process is central to the development of a truly *integrated* modeler's workstation environment. We contrast this with the approach taken in SIMVISION and CINEMA [Heal85], which provide graphical animation of *textual* specifications of SIMSCRIPT II.5 [Russ85] and SIMAN [Pegd85] performance models, respectively. We also note that, since the RESQ language provides an extremely rich set of modeling primitives, our environment offers greater modeling power and flexibility than are available in other environments such as [Mela85] [Sinc85].

In the following section we provide an overview of the RESQ modeling language. In section 3 we describe the hardware and software configuration of the performance modeler's workstation environment. In section 4, we discuss the process of constructing and revising the model, solving the model, and displaying the output performance results. A sample modeling session is used to illustrate these ideas. Section 5 summarizes this paper and discusses directions for future work.

2. The Research Queueing Package (RESQ)

In this section we provide a brief overview of the RESQ language, since it forms the foundation upon which our performance modeler's workstation environment is built and demonstrates the wide range of modeling capabilities that must be supported by the environment. For a more detailed discussion of RESQ, the reader is referred to [Saue82] [Saue84].

The RESQ modeling language provides the analyst with a rich set of high-level modeling primitives with which performance models of resource contention systems (such as computer, communication, and manufacturing systems) may be *specified* and *evaluated*. At the highest level, a RESQ model consists of

- a population of jobs,
- a set of queues,
- a set of nodes,
- rules specifying how the jobs circulate among the nodes and queues,
- additional modeling constructs, and
- information concerning the solution of the model.

Queues typically represent resources in the system being modeled; jobs represent the objects in this system which require the use of these resources. The purpose of the model is typically to analyze this contention for resources and its effect on the flow of jobs through the system.

RESQ provides two type of queues: *active* queues and *passive* queues. Active queues have servers which provide service to a job. An active queue might be used to represent, for example, a computer's central processing unit, a communication link in a network, or an assembly station in a flexible manufacturing system. A job arrives at an active queue, waits until it is selected for service (according to the user-selected service discipline), receives service, and eventually leaves the queue. Passive queues allow for a more general notion of resource use and provide a natural mechanism for modeling phenomena such as simultaneous resource use and blocking. A passive queue consists of a pool of tokens, where each token typically represents a distinct unit of some resource (e.g. a buffer or a block of memory). A passive queue additionally consists of a set of nodes at which the passage of a job may cause a user-specified number of tokens to be allocated, deallocated, created or destroyed. A job may hold tokens from a passive queue as it visits other nodes or (active or passive) queues in the model.

Additional nodes are provided by RESQ in order to model phenomena other than strict resource contention. For example, if there are external arrivals or departures to/from the system being modeled, *source* and *sink* nodes (respectively) can be used to model these effects. *Set* nodes permit values to be assigned to variables associated with the simulation. *Split* nodes allow a job to create an independent copy of itself. *Wait* nodes cause a job to be delayed until a specified Boolean condition becomes true. These and other additional auxiliary nodes are described in [Saue82].

A *chain* specifies the route or path that a class of jobs will follow through the queues and nodes in a model. These routing decisions may be fixed, probabilistic, or dependent on the current state of the simulation (e.g., dependent on the number of jobs at a given queue). In an *open* chain, new jobs may be created at source nodes and jobs may leave the chain at a sink node. In a *closed* chain, an essentially fixed number of jobs circulates among the nodes in the chain.

RESQ also provides numerous modeling constructs in addition to those discussed above, such as symbolic constants and parameters, and arrays of nodes. Another important modeling construct is the *submodel*, which may be used to define a parameterized template of an interconnected "subnetwork" of nodes and queues. This submodel may then be *invoked* several times (much the same way that a macro may be invoked several times in a programming language) to create multiple instances of that subnetwork. We note that submodels provide an important mechanism for constructing modular, hierarchically-structured models of large and complicated systems.

The final component of a RESQ model concerns the solution itself. RESQ can both simulate and, in some cases, analytically solve for the various performance measures requested by the performance analyst. In the case of simulation, the analyst may specify information regarding the desired length of the simulation run, a method for generating confidence intervals, tracing parameters, and other simulation-related information. Resource utilization, throughput, average queue length, queueing time and queue length distribution are typically requested performance measures. Several methods are provided by RESQ for generating confidence intervals, including "independent replications", the "spectral" method, and the "regenerative" method [Saue82].

3. An Overview of the Modeler's Workstation Environment Configuration

In this section we provide an overview of the physical and logical structure of the performance modeler's workstation environment. A detailed description of the functioning of each of the major software components together with a sample modeling session is described in the following section.

The hardware and software configuration of the modeling environment is shown below in figure 1. The workstation currently in use is a personal computer connected to the mainframe with an all points addressable graphics display and a character display. The graphics screen is considered the primary display device, and a pictorial representation of the network model is visible to the user at all stages of model construction, evaluation, and output analysis. The analyst controls the modeling process by selecting menu items and pointing to objects on this display. The graphics display is programmed using the Virtual Device Interface (VDI) provided by the Graphics Development Toolkit.

The character screen is used for:

- entering the attributes of the elements in the RESQ model (e.g the service discipline of a queue, the number of jobs in a closed chain),
- specifying the parameters for model runs (e.g., service times, interarrival times),
- choosing the multiple performance measures to plot and specifying the non-default viewing attributes of output graphs (e.g., color, axis intervals), and
- displaying tutorial-like help.

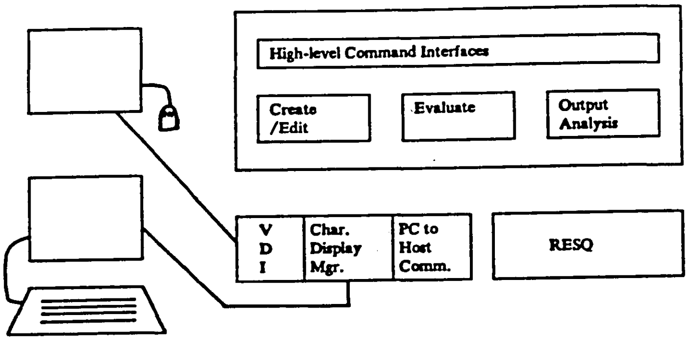

Figure 1: Input/Output Hardware and Software Configuration

The textual information is entered via the keyboard into dynamic forms on the character display.

Our decision to employ two screens was influenced by the work of [Gilb85] and motivated by our experience that complicated, real-world RESQ models may require a significant amount of textual attribute information to be specified. Since we desired to display a significant amount of graphical information at all times (to display the appropriate context for a given modeling element) as well as use the graphics display to cue the attribute specification process, a two-screen mode of interaction was a natural selection.

As shown in figure 1, the software divides broadly into three modules (model creation and editing, model evaluation, and output analysis); the functionality provided by each of these will be described in the following section. For now we note that uniform access is provided to each of these modules by a high level graphical command dispatcher. We also note that each of these modules directly relies upon portions of previously developed components of RESQ [Saue82].

The PC-to-host connection provides the best of two worlds; we may simultaneously exploit the processing power of the mainframe for execution of large RESQ models and the interactive graphics capability of the PC for constructing the model and viewing the graphical results. This allows the user through a consistent interface on the PC to iteratively create the model, view the simulation results, revise the model based on the output, and view comparative results for families of models. The user is presented with one workstation interface, making the PC-to-host connection transparent to the user.

4. System Modeling Using the Performance Analysis Workstation Environment

4.1 Introduction

In this section we describe the functionality provided by the RESQ performance modeler's workstation environment. Using a simple model of a time-shared computer system as an example, we trace the analyst's interaction with the environment from model construction to solution, to the display and manipulation of the performance results.

Let us suppose that the computer system to be modeled consists of a fixed number of terminals at which users enter jobs for execution. The computer itself consists of a single CPU, memory, a fixed disk, and a floppy disk. The purpose of the model is to analyze the contention for the memory, CPU, and I/O resources. The system operates as follows. Once a job is submitted to the system, it must first be allocated a single memory partition from the fixed number of partitions which comprise the computer's active memory. The "execution" of a job then consists of some random numbcr of rcpetitions of a CPU burst (of random length) followed by an I/O operation (also of random length). A job thus cycles some random number of times between the CPU and the I/O devices before terminating execution and returning results to a terminal. Once a job terminates, the user then waits some random amount of time before submitting the next job for execution.

Our RESQ model of this system — which we shall call CSMTM, for "central- server model with terminals and memory" — will be a variation on the well-known central server model [Saue81] for timesharing systems. The I/O devices will be represented by first-come first-served active queues with exponentially distributed services times; the CPU by an active queue with a processor-sharing service discipline. A special type of active queue known as an infinite server queue will be used to model the terminals, and the service time at this queue will be an exponentially distributed user "think time". A passive queue which contains a fixed number of tokens will be used to model memory contention, and each token will correspond to a memory partition. Finally, a fixed number of jobs (equal to the number of users in the system) will circulate among these various queues. A job waiting at the infinite server queue models the thinking user seated before a terminal; a job circulating among the CPU and I/O devices may be thought of as "executing".

4.2 Layout of the Graphics and Character Screens

Upon entering the workstation environment, the analyst is presented with the main command menu in the lower left of the graphics screen and a screen-management menu along its right border (see Figure 2). The main menu permits selection among the three subsystems of the environment: create/edit, evaluate, and output analysis. It also contains items to display help screens and to permit the redefinition of global default options. Based upon the user's selection, additional menus will pop up to display the more detailed suboptions. In particular, selection of one of the three subsystems first brings up a submenu containing a list of models currently available in the user's library or database, and the option "Other" for a textual specification of a model name.

The screen-management menu, which is visible throughout all three subsystems, has options for zooming in or out and panning the view of the model, for locating a particular model element by name, for traversing levels of a hierarchically structured model, and for toggling the visibility of the other menus. With the other menus visible, the modeling area is restricted to the upper 3/4 of the display, and a single-line prompt describing the action expected from the user appears just above the menus. When they are turned off, the modeling area expands to fill the entire screen.

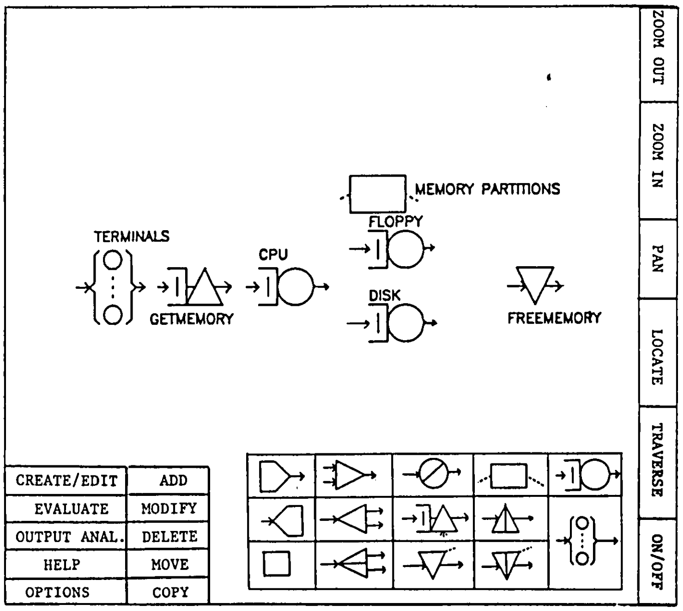

Figure 2: Graphics screen showing a partially completed RESQ model

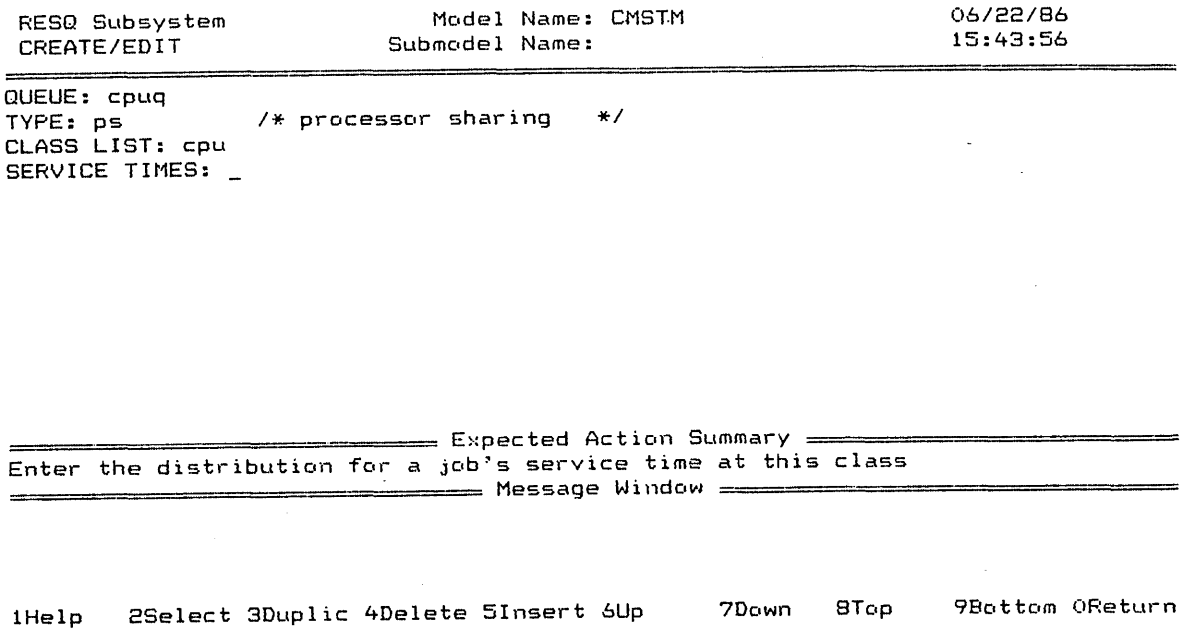
The display on the character screen is divided horizontally into four sections (see Figure 3). The top section contains the name of which subsection of the environment is active, and the name and version (date and time) of the model which is being worked on. The second section is used for the dynamic forms controlling the entry and manipulation of textual information. The third section repeats the expected action prompt, also visible on the graphics screen. The final section provides space for messages from the environment to the user and summarizes the current meanings of the function (PF) keys. Initially, all of these sections except for the expected action window are blank.

4.3 Graphical Model Construction and Specification

When the analyst selects the model create/edit command, "Create/Edit" appears in the top section of the character screen and the environment prompts for the name of the model. Once this has been specified, the graphical representation of the model is displayed in the modeling area, and the menu of create/edit commands pops up in the lower portion of the graphics screen; any existing model element attribute specifications are also parsed at this point. If a new model is being defined (as we will assume in this example), the graphical display will be blank and no attribute definitions will be available to be parsed.



```

Figure 3: Character screen showing a partially completed form for a modeling element

The first time the modeler selects the "add" option from the create/edit menu, a palette of the available RESQ icons pops up. The graphical RESQ model is constructed by picking icons from the palette using a graphics pointing device (typically a mouse or a joystick) and placing these icons in the modeling area. Each icon consists of a stylized drawing of the RESQ modeling element it represents within a rectangular color-filled background; an icon's fill color is used to cue the modeler on the "state" of that modeling element. When a palette icon is picked, it is highlighted in red and connected (via a rubberband) to the graphics cursor until the icon is placed in the modeling area. Once in the modeling area, the icon's fill color is set to yellow to indicate that its attributes have not yet been specified. Figure 2 shows the icon palette, the main and "Create/Edit" command menus, and the seven model elements in our central server model. (Due to the reproduction process for this paper we are unable to show the fill colored background and thus have simply shown the stylized drawing of the elements).

Once an icon has been placed in the modeling area, that instance of the icon is considered an element of the model and its textual attributes can be defined. These attributes are specified in a context-sensitive form on the character display. The overall attributes of the model itself (specifically, the model parameters, numerical constants and maximum size information) are typically specified as a first step in the model construction process. Attributes for the other modeling objects may be entered or modified at any point in the model construction process. Figure 3 shows a partially completed attribute form in which the queue name, service discipline, and class name have been specified.

General information about the current model is displayed above the form. The form itself closely resembles the "dialogue file" definition of an element in the text-only version of RESQ. Each line in the form contains a "prompt" and a field in which the "reply" to the prompt is to be specified by the analyst. As the analyst moves the text cursor from one of these reply fields to another, a message concerning the information to be entered in the current reply field is dynamically displayed below the form in the Expected Action Window. Certain fields (such as the service discipline for a queue) may contain one of only a fixed number of possible replies. In such cases, the analyst simply scrolls through the various possible replies until the desired reply is displayed. Finally, we note that these forms must be *context sensitive* in the sense that a reply to one prompt may change the remainder of the form. For example, if the analyst had selected (through scrolling) a priority service discipline for the disk queue, prompts for the priority information would also have dynamically appeared in the form. The forms mechanism also supports the repetition or deletion of prompts (or sets of prompts) and the extension of a reply field over several lines.

Once the analyst completes an attribute form, the form is immediately parsed for syntactic and semantic correctness. A correctly completed form causes the background color of the icon to change from yellow to green. An incorrect form causes error messages to be displayed below the form and turns the background color to red. The analyst may correct the form either immediately or at some later point. The completed set of attribute forms for the central server model is given in Appendix A.

After the analyst has correctly specified the attributes of a set

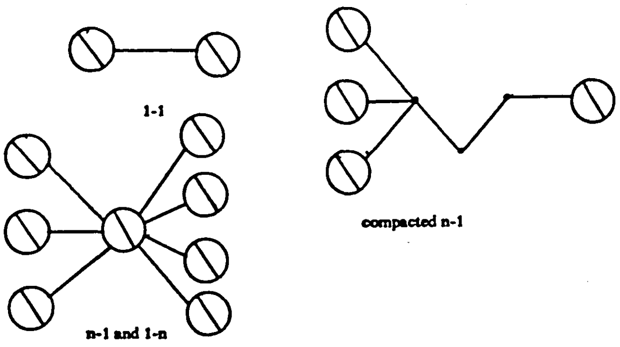

Figure 4: Line Drawing Types

of graphical elements in the modeling area, it is time to specify the routing of jobs which defines how they should flow "from" one of these elements (nodes) "to" other nodes in the model. The environment provides extensive support for this routing definition process. The routing between nodes is accomplished using the pointing device. As the analyst graphically defines the routing with the pointing device, a textual description of the routing also appears in the attribute form for the routing chain currently being defined.

In order to define the routing between nodes, the user first graphically picks a group consisting of one or more "from" nodes. A group of "to" nodes is then selected, and the environment connects the "from" nodes and "to" nodes using straight lines (except as noted below). If another set of "to" nodes is immediately selected, the previous "to" nodes are implicitly used as the set of "from" nodes; this considerably reduces the amount of work required in the routing specification.

Examples of the different types of line drawing supported by the environment are shown in figure 4. As discussed above, straight lines are automatically drawn by the environment. However, a user may alter a straight line by picking a point along the line, inserting a vertex, and then moving the vertex to another point in the modeling area; this permits lines such as the one immediately below the disk queue in figure 5 to be drawn. We note that the existence of a vertex in a line has no syntactic or semantic meaning in the RESQ model itself. Finally, a "compacted" line may be used to define a 1-N or N-1 routing, as shown in figure 4.

The above discussion has focused on the initial construction of a model. In addition to the capabilities (adding elements, panning and zooming) described above, a modeler may also delete, move, copy, modify, annotate, print and plot any portions of the graphical model description. Finally, we note that the environment provides direct graphical support for the use of submodels. Each submodel is defined on a different graphical "plane", and the *traverse* command is used to move the modeler from one plane to another. We believe this approach greatly encourages a top-down, hierarchical, and structured approach towards model development.

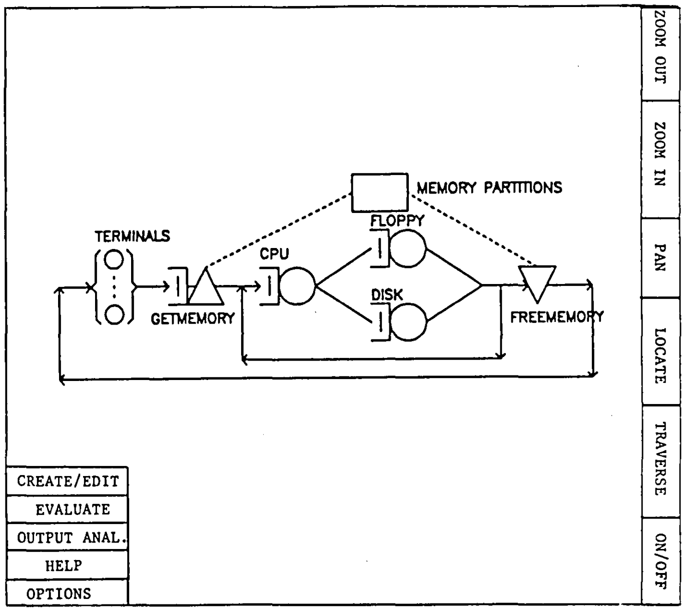

Figure 5: Graphical Display after Model Construction

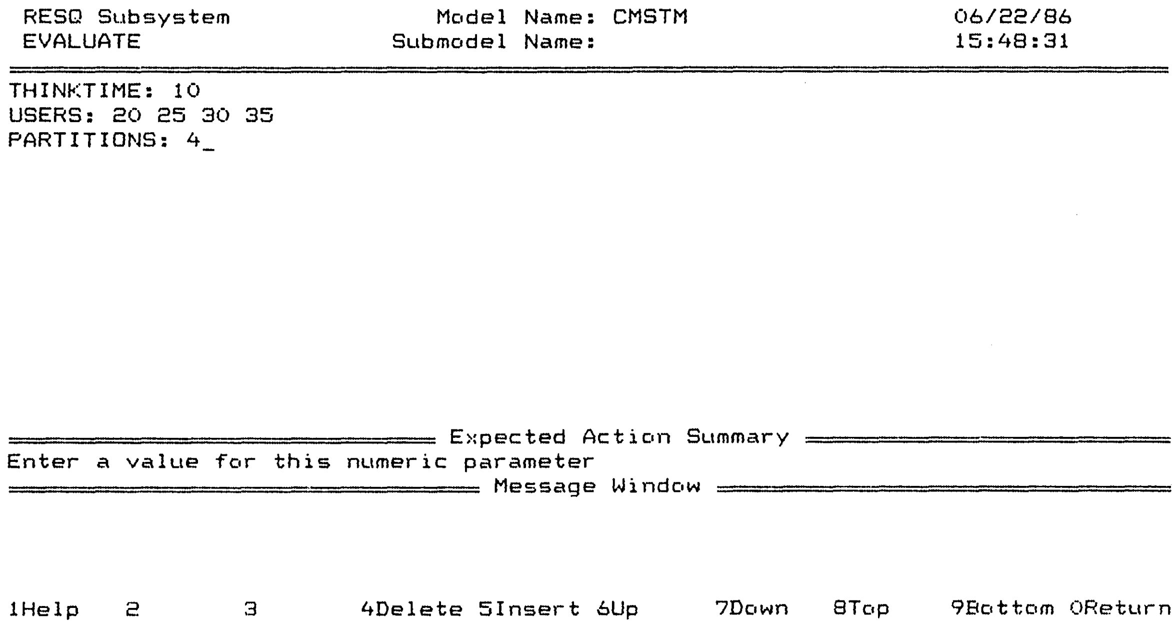
Once a model's elements, the routing, and the simulation-dependent information (if any) have been specified, the model can now be solved.

4.4 Model Solution

The Model Solution component of the workstation software allows the analyst to specify run parameters (such as think time, number of users, and number of partitions in our CSMTM model example) and then to evaluate the model and produce the output statistics for analysis. In our workstation architecture, the parameter specifications and run commands are uploaded to the host where the model is executed. While the RESQ model is executing on the host, the analyst can continue to work on the PC to construct and modify models and to evaluate output statistics from previous runs. The analyst can check the progress of the host batch run and, when the model's run is completed, can directly view its results on the PC. The upload to the host of commands and parameters and the subsequent download to the PC and accompanying EBCDIC to ASCII translation of RESQ results are handled by the model solution software, transparently to the user. The analyst selects "Evaluate" on the main menu and need not be aware that there are host/PC communications and translations being done automatically for him.

When the analyst wants to evaluate his model, he selects "Evaluate" from the main menu on the graphics screen (see figure 5) and chooses the name of the model to execute. The template on the character screen then displays the parameters to be specified for that model. The analyst provides the values of the parameters for each run desired (see figure 6), and the model is then solved on the host. In the CSMTM model example, parameter values are input for four runs of the model with the number of users varying



```

Figure 6: Parameter Specification for Evaluate on the Character Screen

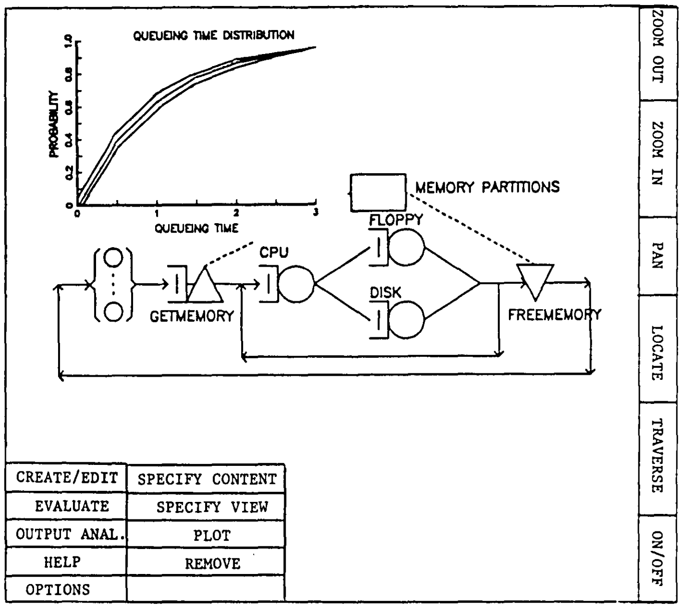

Figure 7: Graphics Display During Output Analysis

from 20 to 35, with think time fixed at 10 and partitions fixed at 4.

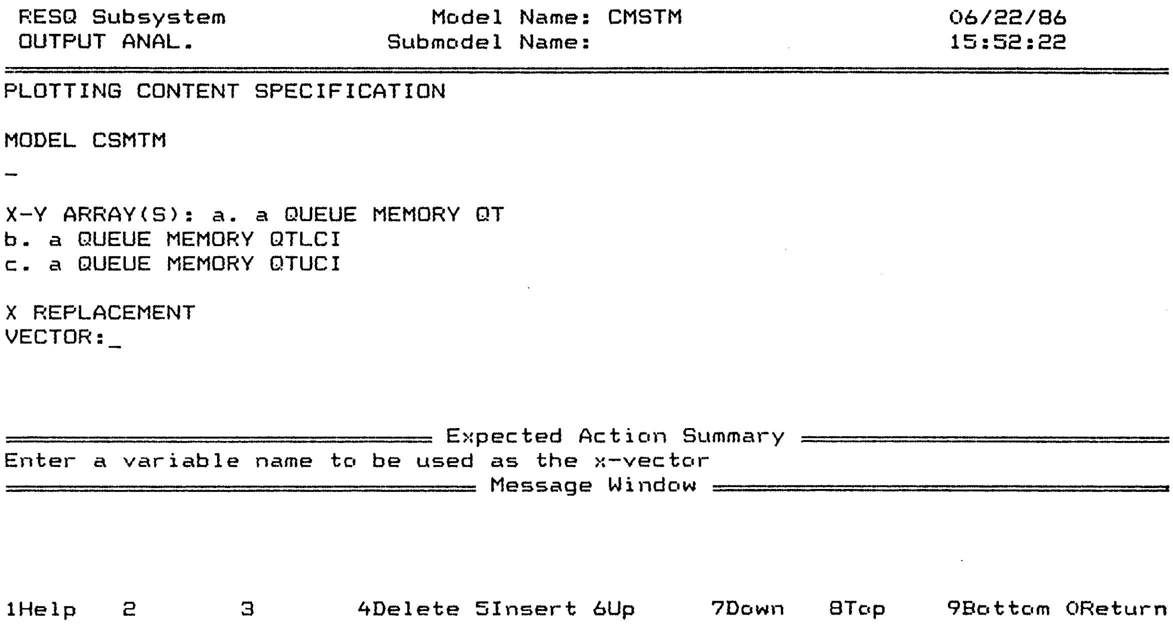
When the evaluation run has been completed, the output statistics are downloaded to the PC, and the performance measures are stored for output analysis.

4.5 Output Analysis

The Output Analysis component of the workstation software provides the analyst with the capability of viewing graphically all the performance measures of the simulation. The analyst selects the contents and form of the graphs to suit his purposes, such as for model verification, determination of transient phase, comparison of runs, or investigation of alternatives. Decisions based on this analysis can then be immediately translated into direct modification of the model diagram, re-running of the model, and the resulting production of the next version of performance measures. This cycle of model construction, execution, and output analysis is performed by the user without switching modes; all actions are accomplished from the one workstation environment.

Selecting "Output Analysis" from the main menu creates a submenu for providing plotting specifications. This submenu (see figure 7) provides the analyst with the ability to specify the content, location, and form of any graph, to plot the graph, and to remove it from the display screen. The latest content, location, and form are remembered by the system, so that the analyst can produce graphs without further specifications or, if desired, can change any specifications to tailor the next chart to his needs.

The following illustrates the use of the Output Analysis submenu to produce graphs of performance measures. For example, marking a node or group of nodes by pointing to them on the model diagram and then selecting the menu item "Specify Content" would provide the analyst with a list of output variable names associated with the marked area of the model. Each output variable name represents a vector of x-y value pairs that can



```

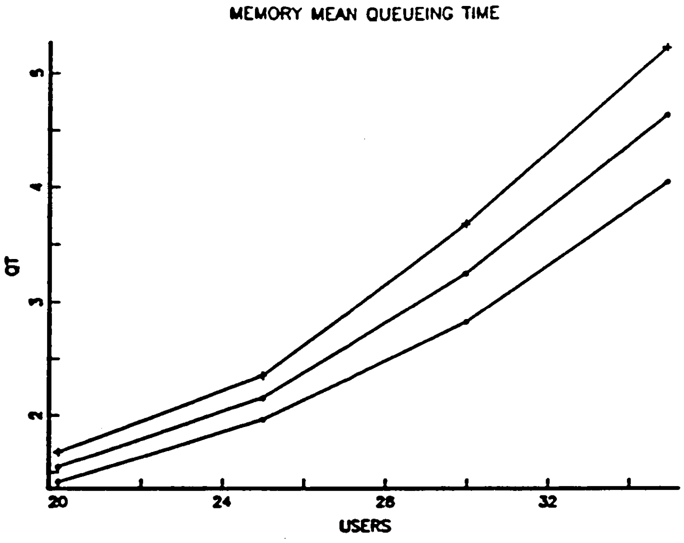

Figure 9: Plot of Mean Queueing Time

be plotted. Selecting one of the variable names and pressing the menu item "Plot" will immediately produce the plot with the latest default values for window position, size, x- and y-axis intervals, etc. In particular, pointing to the memory node in the CSMTM model, selecting the variable name "Queueing Time Distribution", and pressing "Plot" will produce the graph in figure 7, showing the queueing time distribution with its confidence interval for the memory queue. The analyst can also choose to display several variables on the same graph, or to substitute the y values of variable v' for the x values of variable v, or to fit a curve, or to request a projection. These specifications are made by filling in the template for Plotting Content Specifications on the character screen. Figure 8 shows the template to plot the mean queueing time of the memory queue in the CSMTM model with its confidence interval. Completing the template with the variable name for the number of users in each run and selecting "Plot" would produce the graph shown in figure 9.

Independently of content specification, the analyst can specify the form of the output graph by choosing "Specify View" in the Output Analysis submenu. He can choose the graph type, such as line graph, bar chart, histogram. The analyst can place the graph at any point on the modeling field. The analyst points to the desired spot on the graphics screen for one corner of the output window. A rubberbanding box allows him to view the resulting window location as he tacks down the opposite corner. Selecting the "Plot" menu item will produce the graph in this window using the remaining default values for its form. The analyst can use the Plotting Attribute Specifications template on the character screen to change the form attributes, such as the x- and y-axis tick marks, the axis labeling, graph colors. Selecting "Plot" will produce a graph of the latest specified performance measures in the form just specified. Selecting "Remove" will remove the graph and redraw the underlying portion of the model.

5. Summary and Future Directions

We have discussed an integrated graphics-oriented workstation environment for the specification, evaluation, and output analysis of network models. The environment provides a uniform interface for all aspects of the performance evaluation process. The model is constructed and modified by creating and editing the model diagrams on a graphics display and by entering textual information on a character display. Model specification and modification can be performed in various orders to accommodate the working styles of different analysts. In the evaluation phase, the user assigns values for any parameters defined in the model for one or more solutions, and the model is sent to the host for evaluation. The workstation is then free to be used for any other purposes. When the solution is complete, the output analysis phase permits the graphical and tabular display of any desired results. The graphical facility provides a flexible mechanism for plotting multiple performance measures. This will allow the user, through a consistent interface on the PC, to iteratively create the model, view the results of the analysis or simulation, revise the model based on the output, and compare results for families of models.

Future work is planned to extend the capabilities of the graphical performance modeler's environment. This work will include

- a tutorial facility to teach users about the structures and features of RESQ in a programmed-learning environment,
- an "include" facility to permit the user to extract segments from completed models as building blocks for new models,
- higher-level modeling by permitting the design and use of "smart" icons to represent particular models or submodels,
- animation capabilities to display the movement of jobs on the model diagram and the accompanying changes in performance measures,
- a database component to manage the storage and manipulation of models and permit the merging of results from solutions of related models,
- an experimental-design facility to aid the analyst in optimizing model designs through appropriate parameter-search techniques.

Acknowledgments

We would like to express our appreciation to Richard Gilbert for a number of fruitful discussions, which significantly influenced our choice of the design features of the environment.

THE PERFORMANCE ANALYSIS WORKSTATION: AN INTERACTIVE ANIMATED SIMULATION PACKAGE FOR QUEUEING NETWORKS

B. MELAMED

AT&T Bell Laboratories
Holmdel, NJ 07733

ABSTRACT

The advent of low cost high powered intelligent workstations equipped with high resolution displays is gradually changing the practice of performance analysis. Exciting new visual tools are now emerging at research laboratories and in the marketplace.

A typical visual tool combines text and graphics in a user-friendly interface. The interface supports three main functions: system specification (editing icons and parameters), performance evaluation (simulation or analysis), and displaying statistics (time-series, histograms and summary reports). Visual tools reward users with higher productivity, ease of communication and a vastly more pleasing work environment when compared to traditional programming tools.

This paper describes a visual simulation tool dubbed the Performance Analysis Workstation (PAW), currently under development at AT&T Bell Laboratories. PAW enables a user to draw a queueing network model on a CRT screen with a mouse, parameterize the model by filling out forms from a keyboard and then make animated simulation runs displaying traffic flows and evolution of statistics.

1. THE ENTERPRISE OF MODELING

A model is a simplified representation of an entity. A model purports to capture certain behavioral aspects of the modeled entity (see [1-2]), and is only as good as its success in reproducing select behavior of the modeled entity. Examples are: a scale model of an airplane in a wind tunnel; a set of equations describing the state evolution of a queueing network; a computer program describing a protocol across a communication line.

The enterprise of modeling consists of building models, checking for their goodness, and using them to generate predictions. The utility of models lies in their predictive power; the modeler is interested in the value added of new information gleaned from models, and the subsequent scientific and economic benefits engendered by it. Since a model is used to understand and predict the behavior of complex systems, it must combine and balance the opposite requirements of faithfulness and simplicity. Consequently, the process of modeling is often tedious, complex and error-prone. It requires both knowledge and intuition, and often proceeds in cycles of "try and modify", backtracking and refinements. In many cases, modeling is more Art than Science, and good performance analysis is often the domain of experts.

The modeler starts with a conceptual model which is invariably a verbal description of the modeled entity's structure, rules of behavior and numerical parameters. The conceptual model must often be further reduced to a form that can be "solved". Models and their solution methods can be grouped into two broad categories: analysis and simulation. This paper will concentrate on Monte Carlo simulation and the role of workstations in hosting visual computer tools to aid users in simulation modeling.

2. SIMULATION VS. ANALYSIS

A Monte Carlo simulation is a computer program used to generate sets of conceivable system histories. Data collected from those histories are cast into statistics which serve as estimates of system performance. Random phenomena are driven by pseudo random number generators, thus conjuring up the chance experienced by gamblers at that ultimate casino of Monte Carlo.

The statistical approach, so central in simulation, contrasts sharply with analytic methods where mathematical tools (equations, etc.) are used to compute performance measures of sample aggregates (means, probabilities, etc.). An analytic approach rarely addresses transient phenomena or individual histories; rather, it usually deals with systems in steady state.

The trade-off between an analytic approach and a simulation approach can be summarized as follows:

A tractable analytic solution often requires stringent assumptions on the model to be solved. However, if those assumptions can be validated, the analytic method used is likely to require a fraction of the computer time consumed by a corresponding simulation program. Simulation models can be used validly for a far larger class of conceptual models. A lesser degree of abstraction can be employed in their construction because a simulation program can mimic the behavior of the conceptual model more directly. However, a simulation can be extremely costly to run or plainly infeasible due to the computer time or memory necessary to achieve satisfactory statistical confidence.

All in all, it is harder on balance to develop a valid solvable analytic model, and deriving a solution where none is known can require considerable mathematical skill. In contrast, a simulation approach is engineering-like in nature, imposes on balance fewer restrictions on models, and the problem of how to derive an "unknown solution" never arises.

3. MODELING WORKSTATIONS

The advent of affordable workstations with ever increasing computational power and rapidly improving graphics has recently rendered the concept of a simulation workstation an attractive and reachable goal. I argue that an animated simulation approach to solving models meshes neatly with a workstation environment where the user interacts with a graphics screen, keyboard and pointing device. Points supporting this argument are:

a) A workstation is a dedicated resource. Model building is inherently incremental, evolutionary and subject to cycles of "try-modify-test repeat." A workstation setting being a dedicated resource can allow the process to proceed swiftly and smoothly, through uninterrupted interaction between Man and Machine. Experimentation is thus encouraged and facilitated.

b) A workstation has graphics capabilities. Model simulations, particularly network models, have fundamental and inherent visual components. These include displaying a pictorial representation of the model and its statistics, and generating animated sequences which represent the model in operation (traffic flows, state changes and statistics evolution).

c) A workstation can support a user-friendly interface. It lends itself to object-oriented programming where icons depicted on the screen are directly manipulated by clicking the buttons of a pointing device. Models that can be manipulated visually appear more natural and concrete to the user.

As a result, the user community of modelers could gain in two professional segments. First, engineers will find modeling easier because of the reduced need for abstraction. For them, a simulation workstation fulfilling a CAE (Computer Aided Engineering) function would be a familiar and accessible tool. Second, mathematically-oriented users who are not proficient with computers could find the burden of interaction alleviated by a good user-interface shielding them from inessential programming detail.

The above discussion must not be construed as advocating the replacement of analytic methods by Monte Carlo simulation, or that analytic methods have no place in modeling. Quite to the contrary. Analysis and simulation are in fact complementary and each approach should be used where appropriate and economical, often on the same problem. A good modeling workstation should ideally use *both* simulation and analysis for cross validation and to obtain well-rounded understanding of the system under study. The point is, though, that a simulation approach has the most to gain from the visual capabilities of a workstation environment.

4. OVERVIEW OF THE PERFORMANCE ANALYSIS WORKSTATION (PAW)

The Performance Analysis Workstation (PAW) is a visual modeling tool with both simulation capabilities and interfaces to analytic tools, currently under development at AT&T Bell Laboratories [3]. A number of visual modeling tools have preceded PAW or are contemporaneous with it. Noteworthy commercial packages include SEE WHY^{TM} (by BLSL Inc.), RESQ^{TM} (by IBM; work is in progress [4]), IDSS^{TM} [5] (by Pritsker and Associates, Inc.), Model Master^{TM} (by GE), PAWS^{TM} (by Information Research Associates) and SIMAN^{TM} [6] (by Systems Modeling Corporation). SIMAN has a particularly nice graphics package called CINEMA^{TM} which allows users to draw a realistic-looking simulation scene complete with color and semantic icons. Recently, PC-SIMSCRIPT was enhanced with visual capabilities by a program called SimVision^{TM} [7].

Hardware and Software

PAW runs on a Teletype Dot Mapped Display 5620 terminal (DMD for short) in conjunction with a host computer running under the UNIX^{TM} operating system. A UNIX host is required for file operations because the DMD has no peripheral memory. The DMD has 1MB memory and is equipped with a keyboard and a three button mouse (a pointing device). PAW is available to the public from AT&T through the UNIX System Toolchest.

PAW is written in C and assumes that the host computer has a UNIX operating system. The user interface is menu driven with pop-up menus appearing on the screen so as to allow the user to make a selection with the mouse. The style of interaction with the user interface is object-oriented. Icons on the screen represent concrete objects (nodes, transactions, statistics, etc.) and the user refers to them by pointing (placing the mouse cursor in an icon) and depressing, releasing or clicking a mouse button (to specify a selection or cause an action). Mouse button functionality is programmed in software.

Human Factors

PAW was designed with the user in mind. A basic design decision was to trade off generality and modeling scope for simplicity and ease of use. PAW is self-teaching and requires little reference to its documentation in the course of a session. To achieve this goal, a special subwindow on the screen is dedicated to communication with the user (see Figures 1-3). Called the Reporter Corner, this subwindow is updated after every key stroke or button action with three messages:

1) PREVIOUS ACTION FEEDBACK: informs the user of the outcome of the most recent action. Erroneous actions are also accompanied by a double beep to draw the user's attention.

2) CURRENT MODE: reminds the user of the current operation mode. This is helpful to novices attempting to navigate the menu tree.

3) EXPECTED ACTION: details a suggested sequence of actions. This is particularly helpful in graphics operations.

In addition to placing a good deal of ready "help" function in the Reporter Corner, PAW will also place needed information in a reminder window, but only when necessary.

PAW extends the user a one step grace period following any text or graphics deletion operations. This allows the user to recover text and graphics deleted by mistake.

Error checking throughout PAW is extensive with detailed error reporting (PAW stores some 16K bytes worth of messages). Error localization is carried out as soon as possible, even in the middle of lexical tokens. Most errors are checked for in the editors as information is being entered, and very little is left to be checked in the simulator.

PAW recovers from user errors with default values inserted whenever missing or erroneous information is encountered. Thus, a model description is maintained consistent and error-free from PAW's point of view. Of course, high level modeling errors cannot be discovered by PAW, but rather by the user observing PAW. Consistency is not guaranteed only when PAW runs out of memory.

5. PAW's WORLD VIEW

PAW's world view is a queueing network. In this regard it is an extension of Jackson, BCMP and Kelly Networks [8-10]. PAW's simulator is a discrete event simulation system operating in a world of queueing networks.

PAW Entities

PAW's world consists in the main of two fundamental entities: nodes (geographical sites in a network) and transactions (jobs, customers, etc.) which circulate among nodes.

A node has associated with it a queue whose positions can accommodate (hold) transactions. A queue capacity can be finite or infinite, but it has to be strictly positive. Queue positions are ordered 1,2,... from head to tail. A block of contiguous positions starting at the head (position 1) can have servers associated with them. There must be at least one server, but obviously the number of servers cannot exceed the queue capacity. Nodes have incoming and outgoing paths so that a queueing network can be thought of as a directed graph.

A special kind of nodes called *environment nodes* represent the "outside" environment of the network; all other nodes are called *regular nodes*. An environment node that feeds into a regular node is called a *source*; an environment node fed by a regular node is called a *sink*. Regular nodes can be freely connected, but any two environment nodes *cannot*. Unlike regular nodes, environment nodes have no queues.

While nodes are static entities anchored to particular network locations, transactions are dynamic entities that circulate and move from node to node. Each transaction has two fundamental attributes associated with it: a *class tag* and a *family membership*. A transaction class tag is a dynamic attribute assigned to the transaction whenever it enters a regular node. Typically, class tags are used to denote the "state" of a transaction during the course of its life in the network. A node and class dependent priority can be specified by the user for transactions. All transactions with the same class tag at a given node will exhibit the same probabilistic behavior as regards external arrivals (from a source), service delays and routing decisions because they all have the same priority and share the probability distributions governing that behavior. A transaction may change class (and consequently priority) on routing to another node.

In contrast, family membership is a static attribute that cannot be changed. PAW keeps track of the total number of each family's members in the system by incrementing or decrementing appropriate counters whenever transactions are created or destroyed respectively. Note that there is no motivation to do the same for classes because transactions with the same class tag but in different nodes may well be conceptually unrelated. Family members, on the other hand, are conceptually related and they can "recognize" each other even when they reside in different nodes and carry different class tags. The family concept is motivated chiefly by situations where a transaction is split (spawns a batch) and the batch members must be eventually joined to "recover" the original transaction (e.g., messages which are split into interleaving packets that must be reassembled at their destination). Family membership can propagate and expand by further splitting.

In PAW, there are no special types of transactions. For example, a transaction modeling a token will have its service time set to infinity with probability one, but otherwise it appears like a normal transaction (a token is a transaction resource that cannot move in the network on its own; rather, another transaction must move it around through the so-called yanking action to be described later). Passive queues can be modeled in PAW, but they do not exist as such, because conceptual "token" transactions are allowed to mingle freely with "non-token" ones. Specialized modeling constructs are embodied in the various types of nodes supported by PAW, to be described next.

6. PAW NODES

The regular nodes in PAW fall into several categories: standard nodes, SPLIT nodes, JOIN nodes and YANK nodes. The list above is ordered in increasing specialization.

Standard Nodes

All PAW nodes are variations on the standard node mechanism. Transactions may be created dynamically at any source node during a simulation run according to a user defined *arrival interval distribution*, or statically at any regular node directly by the user. At arrivals times, transactions may arrive in batches according to a user defined *arrival batch distribution* or singly (batch size one); batch size of zero is also allowed, in which case no arrival occurs.

On arrival at any regular node, a transaction is assigned a user defined *class* and *priority*. It then attempts to seize a server position. If successful, its status changes to *busy* and it is said to join the *busy queue*. A service time is sampled for it by a user defined *service time distribution*, and the transaction will stay in the busy queue until its service time requirement is satisfied. If all servers are occupied (busy), the incoming transaction has its status set to *idle* and it is said to join the *idle queue*. Transactions in the idle queue have no service dispensed to them; rather, they queue up until a server becomes available at which point in time they switch from the idle queue to the busy queue. A user specified mechanism called the *queueing discipline* governs this behavior. A transaction may move from the busy queue to the idle queue if the queue discipline permits preemption; in this case, PAW will automatically keep track of the residual service time of the preempted transaction.

Eventually, the transaction will finish service and attempt to route to another node according to a user defined *routing rule*. If the destination node is a sink node, the routing always *succeeds*. However, if it is a node with finite capacity, the routing may *fail* for lack of queue space. At this point, the transaction can have another shot at an *alternate routing rule*, provided the user had defined it (alternate routing is optional). If the alternate routing fails or if it is undefined, the transaction status changes to *blocked* and it is said to join the *blocked queue*. In this case, the transaction remains in its origination queue and waits there until a free queue position becomes available at its destination node. The server of the blocked transaction remains unavailable throughout the blocking period. Eventually, a queue position may become available at the destination queue. The transaction will then *unblock* by moving to the destination node where it will be assigned a new class and priority. The process then repeats itself.

A transaction is destroyed when it leaves the network by entering a sink node. A transaction attempting to enter a full node from a source is not blocked but immediately destroyed; such transactions are said to be *lost*.

PAW maintains in each node three contiguous disjoint subqueues. These are (from head to tail) the blocked, busy and idle queues. Within each of them, PAW implements queue ordering as follows:

1) Blocked transactions are ordered from head to tail by blocking clock time; that is, those that blocked earlier precede those that blocked later.

2) Busy transactions are ordered from head to tail by residual service time; that is, transactions with shorter residual service time precede those with longer residual service times.

3) Idle transactions are ordered from head to tail according to the node queue discipline within priority sets; that is, higher priority transactions precede lower priority ones.

The queueing disciplines supported by PAW at standard nodes are:

- FCFS = First Come First Served (within priority sets). Also commonly called FIFO.
- LCFS = Last Come First Served (within priority sets). Also commonly called LIFO.
- PS = Processor Sharing. Here the set of transactions with the highest priority share the (single) server. If n are present, their service is being completed at rate $\frac{1}{n}$.
- IS = Infinite Server. Every transaction in the node is guaranteed a server immediately on entering the node.
- PR_SRT_FCFS = Preemptive Resume, Shortest Residual Time, First Come First Served. Same as FCFS, except that preemption is allowed in which case the busy transaction with the *shortest* residual service time is selected for preemption.
- PR_LRT_FCFS = Preemptive Resume, Longest Residual Time, First Come First Serve. Same as PR_SRT_FCFS, except that the busy transaction with the *longest* residual service time is selected for preemption.
- PR_SRT_LCFS = Preemptive Resume, Shortest Residual Time, Last Come First Serve. Similar to PR_SRT_FCFS, except that the idle queue is LCFS.
- PR_LRT_LCFS = Preemptive Resume, Longest Residual Time, Last Come First Serve. Similar to PR_LRT_FCFS, except that the idle queue is LCFS.

SPLIT and JOIN Nodes

SPLIT nodes are essentially FCFS nodes with infinite queue capacity. However, on service completion of a transaction at a SPLIT node, that transaction (called the *parent*) samples a batch size from a user defined *split batch distribution* and spawns the sampled number of transactions (called *children*). If the distinction between parent and children is unimportant, they are collectively called *siblings*. The children may or may not have the class tag or family membership of the parent. All transactions involved in the split event then attempt to route out of the SPLIT node according to their prescribed routing rules.

PAW supports the following SPLIT nodes:

- CL_SPLIT = Class-Split. All transactions involved in the split event are guaranteed to have distinct family memberships. In particular, each child forms a singleton family.
- FM_SPLIT = Family-Split. All transactions involved in the split event (parent and children) are guaranteed to belong to the same family.

JOIN nodes perform roughly the opposite function of SPLIT nodes. The first transaction (in a batch to be joined) to arrive at a JOIN node samples a batch size from a user defined *joined batch distribution*. The transaction class and sampled batch size specify a *join demand* which is then posted at the JOIN node. The first transaction and subsequent ones (which arrive in due time) wait idly until the sampled batch size is met. At that point all batch members are collapsed into a single transaction. The resultant transaction changes status to busy and assumes a user defined class tag; it then proceeds to be served by one of the node's infinite number of servers, before routing out as usual. Busy and blocked transactions are excluded from further batching and join events at the JOIN node. Multiple batching of disjoint batches may take place simultaneously. Joining like splitting may involve transactions of the same class or same class and family.

PAW supports the following JOIN nodes:

- CL_JOIN = Class-Join. Transactions of the same class are batched for joining. Infinite batch size is allowed, but in this case that batch will never join; in effect, the batch will behave like tokens (passive resource).
- FM_JOIN = Family-Join. Transactions of the same class and family are batched for joining. The effective batch size used by PAW is always the minimum of the sampled size and the total family size in the system. Infinite batch size is allowed but it simply means that joining occurs when all family members congregate in the JOIN node and all carry the same class tag.

SPLIT and JOIN nodes can be used to model the following phenomena:

1) Transaction generation: SPLIT nodes provide an alternate means of complex transaction generation. In particular, a SPLIT node can be conveniently used to model the simultaneous arrival of multiple transaction

batches each having a different class. In this case, a generator transaction enters a SPLIT node repeatedly (via a feedback path). On each visit it enters the node with an appropriate class tag and spawns the requisite batch (after spending zero time in service).

2) Assembly operations: Class-JOIN nodes can be used to model factory assembly operations where finished products are assembled from various parts.

3) Synchronization points: Family-JOIN nodes provide a natural way to model synchronization points, especially situations where a parent job spawns subjobs which must all be completed before the parent job is allowed to proceed. The family-JOIN node is necessary to group precisely the subjobs that were spawned by a given parent.

YANK Nodes

Yank nodes are special nodes where a transaction is allowed to yank some other transaction from another node and route it elsewhere. In effect, yanking is an extreme case of preemption followed by rerouting. Unlike preemption, the status of the yanked transaction does not matter; while preemption only applies to busy transactions, yanking applies to blocked, idle or busy ones. Furthermore, yanking does not have the resume aspect of preemptive-resume; rather, the yanked transaction is "restarted" at its destination.

The yanking mechanism is non-trivial and operates as follows. A transaction entering a YANK node may or may not have a *yank targets distribution* specified for it. If none is specified, that transaction is considered a *pass-through* transaction and routes out of the YANK node without delay. Otherwise, that transaction samples a *target node* from which to yank, a *target class* to be yanked and a *batch size* which together specify a *yank demand.* It then posts the yank demand at the target node and attempts to satisfy it. A yanking action is executed as follows. Each member of the target batch is moved from the target node to a destination node. PAW determines the destination node by appeal to the routing rules of the yanked transactions at the YANK node. Each yanked batch member may have its class changed on entry at the destination node where it is considered an ordinary arrival. If a yanked transaction gets blocked, it will stay blocked at the YANK node. A yank event is said to *succeed* if the posted yank demand can be satisfied by transactions on hand; otherwise it is said to *fail.* If the yank event fails and the yanking transaction has no alternate routing defined for it, then that transaction will wait at the YANK node until its yank demand is completely satisfied. If, however, the alternate routing rule is defined for it, that transaction will invoke it without completing the yank action. When a yank event succeeds, only the routing rule is invoked for the yanking transaction.

A YANK node may yank from another YANK node but not from itself. Like splitting and joining, yanking can be programmed for class alone or for family and class; the family to be yanked is implicitly that of the yanking transaction. When specifying a class to be yanked, the user may specify a single class or the keyword "all" meaning "yank regardless of class".

It is common for multiple yanker transactions (possibly at distinct YANK nodes) to attempt to yank the same target transactions from a common target node. Such situations model contention for transaction resources (as opposed to contention for server resources which occurs within a standard node). In particular, if a YANK node targets a JOIN node, then yanking and joining demands may coexist in contention. PAW resolves contention for transactions by ordering the incoming demands first by priority (of the yanking and joining transactions) and then FIFO by the time the demands were posted.

The discipline of satisfying a yanking demand comes in two flavors: first-fit and immediate. In both cases, a demand list is scanned head to tail. If a first-fit yank demand is encountered, it will be satisfied only if its posted batch size can be met by transactions on hand. In contrast, an immediate yank demand may be partially satisfied by any number of transactions on hand, and the corresponding posted batch size is accordingly reduced.

PAW supports the following YANK nodes:

- FF_CL_YANK = First-Fit Class-Yank. First-fit yanking is carried out for target transactions in a prescribed class or regardless of class.
- FF_FM_YANK = First-Fit Family-Yank. First-fit yanking is carried out for target transactions in a prescribed class or regardless of class, but only if they belong to the same family as the yanker transaction.
- IM_CL_YANK = Immediate Class-Yank. Same as FF_CL_YANK except that immediate yanking is employed.
- IM_FM_YANK = Immediate Family-Yank. Same as FF_FM_YANK except that immediate yanking is employed.

YANK nodes can be used to model the following phenomena:

1) Multiple resource possession: Token transaction are placed in a node representing a pool of available tokens. A transaction requiring multiple resources enters a class-YANK node and attempts to yank token transactions from the pool of available tokens to another node holding all unavailable tokens. Eventually that transaction will release the resources by yanking token transactions from the pool of unavailable tokens back to the pool of available tokens. Transactions that cannot find tokens to yank from the pool of available tokens must wait until they become available.

2) Finite queues: Although PAW admits finite queues in standard nodes, it is sometimes required to restrict the entrance of certain transaction classes into a standard node with an infinite queue. For example, in a machine breakdown model, a preemptive-resume node with infinite queue represents the machine, low priority transactions represent the product worked on by the machine and high priority transactions represent breakdowns. The infinite queue is necessary to allow any breakdown transaction to enter the machine node without blocking. However, product transactions can enter the same only when buffer space is available. This can be implemented via the token scheme described above.

3) Time-out: To restrict the time a target transaction may spend at a node, a time-out transaction is created in a family-SPLIT node and proceeds to be delayed, say, in an infinite server node. The time-out transaction then enters a YANK node and attempts to yank the target transaction. If successful, that means that the target transaction has timed out; otherwise, the target transaction has beaten the time-out "clock" and will usually proceed to destroy the time-out transaction by yanking it from the delay node to a sink. A similar setup can restrict the time a transaction is allowed to spend in a set of nodes (subnetwork).

7. PAW STATISTICS

PAW permits statistics collection in the background or in the foreground (in a statistical window). All statistics are displayed up to date on every screen refresh. PAW statistics are packaged in three formats: summaries, time-series and histograms.

A summary maintains eight numerical statistics: number of observations collected, the most recent observation, minimum observation, maximum observation, average, variance, standard deviation and coefficient of variation. A time-series is a pictorial representation of observations and the times they were collected, displayed as a sequence of bars. A histogram is a pictorial representation of an empirical distribution computed from collected observations. Both time-series and histograms also display the respective summary statistics, space permitting (see Figures 1-3). PAW will automatically redisplay updated pictorial statistics whenever the display window is reshaped or refreshed.

Once the user selects the statistics format from a menu, the particular statistical aspect to be collected can be chosen from a menu of fourteen items:

1) Server utilization
2) Total queue length
3) Idle queue length
4) Busy queue length
5) Blocked queue length
6) Total input interval
7) Total output interval
8) Lost arrival interval
9) Node sojourn time
10) Node idling time
11) Node service time
12) Node blocking time
13) Network sojourn time
14) Network cycle time

Utilization and *queue length* statistics are computed as time integrals. The *total input interval, total output interval* and *lost arrival interval* are respectively the time intervals between successive arrivals, departures, and losses at a node; they can be used to obtain traffic rates (e.g. throughputs). *Node sojourn time* is the total time spent by a transaction in a node during a visit. *Node idling time* and *node service time* are the time periods a transaction is idle or busy respectively during a node visit; they are of interest in preemptive resume or processor sharing nodes. *Network sojourn time* is the total time spent by a transaction in the network, while *network cycle time* is the time elapsed between a transaction's departure from a node and its next return to it (useful for collecting "response time" observations). In any given node, statistics can be customized to be collected only for particular classes, as well as for all classes.

8. PAW ARCHITECTURE

PAW software is made up of four components: graphics editor, text editor, Monte Carlo simulator and utilities. The menu mechanism allows the user to quickly and easily walk among components.

The Graphics Editor

The creation of a new model must always begin in the graphics editor. Using the mouse, the user draws the individual nodes of the network, and then specifies the topology by connecting nodes as necessary. "Node drawing" is in fact a simple process because the node icon has been preprogrammed; by moving the cursor, the user merely changes the node size and orientation in the plane. Nodes can be deleted from the screen, in which case all node information is automatically purged from the model. A node icon can also be moved around on the screen. This is done by placing the cursor in a node icon, pressing a button, "dragging" the icon to its requisite place on the screen and then releasing the button. Every node may have a source and a sink. However, all source and sink nodes denote the same "environment" node. A distinct label is generated and associated with each regular node. Node labels can be made to appear and disappear on the screen and can be changed in the text editor.

To reserve screen space for statistical displays, the user sweeps out rectangular areas called *windows*. Statistical windows can also be moved around or deleted. PAW allows the user to bind a statistic to a window (an operation called *pegging*), to clear a window of a statistic or to delete the window altogether. The last two operations never delete the statistic itself; rather, statistics collection is moved from the foreground to the background.

The Text Editor

PAW's text editor is used to parametrize a model and define its statistics. All text data are entered in captioned fields of appropriate forms. The user can scan, enter data or delete data while moving among the form's items in a wrap-around manner. The advantage of form entry is that the user has almost no syntax to remember. On the other hand, this necessarily limits the expressive power of the system. Still, PAW can model a respectably large class of queueing networks.

PAW's text editor checks every input token thoroughly for lexical and some semantic errors. For example, node and transaction labels are checked for validity and uniqueness; routing is checked for discrepancies with the drawn topology; discrete distributions are checked so as not to exceed one, etc. Error localization occurs at the first erroneous character; a double beep sounds and the offending character is rejected or an appropriate default is used.

The Monte Carlo Simulator

PAW's simulation activities are largely controlled from the simulation panel and its nine windows located at middle bottom of the screen (see Figures 1-3):

1) Stop window: when highlighted, the simulator is stopped.

2) Continuous window: when highlighted, the simulator is running in continuous mode.

3) Step window: when highlighted, the simulator is running in step mode.

4) Current window: current simulation time.

5) Interval window: simulation time interval since last screen refresh.

6) Reset window: simulation time to reset all model statistics.

7) End window: simulation end time.

8) Realtime window: real time delay between screen refreshes.

9) Snapshot window: simulation snapshot interval. When zero, every event is animated; when positive, successive snapshots are displayed at the specified time granularity.

PAW supports a variety of run modes and options to suit the requirements of various stages in the modeling process. When a model is first constructed and debugging gets under way, the modeler wants to examine the detailed (microscopic) behavior of the model. As confidence in the model builds up due to modifications and bug removal, the modeler's interest turns to more global (macroscopic) behavior. Finally, when the model is deemed valid, the modeler often makes long production runs and collects final statistics with few or no intermediate snapshots. This last stage rarely requires interaction and is preferably launched in batch mode.

In PAW, the user can set the snapshot window to any nonnegative value. To examine the simulation event by event, the user sets the snapshot window to zero. In this case, screen animation displays the shuttling of transactions among nodes, their creation and destruction and more complicated behavior such as splitting, joining and yanking. For added convenience, the user can elect to step through events or to run the animation continuously, somewhat like a movie. When the snapshot window is set to a positive value, the screen is refreshed every snapshot interval to give a time lapse account of model behavior at the specified time granularity. Again, snapshots can be stepped through or run continuously. Finally, to launch production runs in batch mode, the user can select the upload option and specify an output file. The model on the DMD screen is then uploaded to the host, a batch run is initiated and the final state of the model will be saved in due time in the designated output file. The user can later download the output file from the host to the DMD and look at the final state and statistics. Uploading simulations is particularly desirable when the host has floating point hardware because of the speedup gains (the DMD has all floating point in software).

Uploaded PAW simulations can be run outside PAW under UNIX. In a typical scenario, the user runs the DMD under the *layers* program [11] which supports multiple windows. The user downloads PAW in one window, and launches one or more batch simulations of an already debugged model. To track the progress of a simulation run, the user may interrupt it at any time. PAW arranges to save a model snapshot on the nearest event boundary. The user can then download the snapshot and look at it at leisure. The run itself can be restarted either from the saved snapshot or from the downloaded one, etc. Alternatively, the user may investigate a snapshot's microscopic behavior by running it on the DMD and perhaps later resume it in batch mode.

In a more complicated situation, the user may wish to run replications, step through a model's parameters for a sensitivity analysis, or compare multiple models. To facilitate these kinds of activities, PAW provides a host programming environment that allows the user to access and change model parameters through an interface package. The user writes a control program in C that takes one or more PAW models, modifies them as necessary and calls the PAW simulator to produce the requisite runs. The user is then responsible for processing summary statistics such as confidence intervals, $x-y$ plots or statistical tests. Only when using the host programming environment do users assume the responsibility for any programming bugs resulting from their code; on the DMD, they are only responsible for "high level" errors.

Utilities

PAW provides an array of utilities, mostly involving file manipulation and translation.

In PAW, models are always created on the DMD; but because the DMD lacks peripheral memory, models must be saved on the host. A PAW model is always saved with its full state, including the random number generator seed. Consequently, a PAW simulation can be stopped at any time, a model snapshot saved in a file and later read back into the DMD (or the host) to resume the simulation from where it left off.

PAW models are saved in binary (machine-readable) form for the sake of efficiency. Another set of utilities produces human-readable printouts of PAW models. The user can get a listing of an entire PAW model or save a screen image in a file and print it as a hard copy. Individual statistics can be blown up on the screen and similarly printed.

PAW is envisaged as a single point of contact with multiple modeling and analysis tools for queueing networks. Currently, PAW includes interfaces to two analytical packages: PANACEA (which uses asymptotic expansion to solve large steady state queueing networks [12]), and QNA (which generates an approximate analytical solution for steady state queueing networks based on the first two moments of each modeling distribution [13]). Both tools were created in AT&T Bell Laboratories, but expect different source formats. PAW merely provides translators which take a PAW model as input and generate as output the source files in the requisite format. As usual with simulations, the modeling scope of the PAW simulator subsumes that of PANACEA and QNA by a wide margin.

Most PAW utilities can be invoked either from PAW (in which case they apply to the model on the screen), or from outside PAW (in which case they can be applied to arbitrary files). In particular, the upload facilities and the host programming environment of PAW enable the user to run simulations without being confined to the PAW screen environment. Downloading and uploading can be freely mixed in any combination. Listing, screen hard copy and translation utilities can also be invoked directly from UNIX in order to save the overhead of file transfer between the DMD and the host.

9. INTERACTING WITH PAW

A typical interaction scenario with PAW has a distinct pattern, extending possibly over multiple sessions. The following stages sketch the broad outline of a typical PAW modeling and simulation scenario.

1) The user always begins in the Graphics Editor. At this stage, nodes are created and connected, their labels placed on the screen and statistical windows are swept out.

2) The user enters the Parameters Editor. Form entry is used to specify and edit mostly numerical data describing the behavior of nodes and transactions.

3) The user enters optionally the Statistics Editor to define statistics and display them in statistical windows.

4) The user enters the PAW Simulator to verify the PAW model (i.e., to ascertain that it represents the conceptual model) and sets the windows of the simulation panel. Testing and debugging runs usually start in step mode and progress to continuous mode with the snapshot window set to zero. The user observes sequences of event-by-event animations and notes the flow of transactions, the sequence of clock values and the evolution of select statistics. Later, the user sets the snapshot window to a positive value and proceeds to observe sequences of model snapshots at increasing time granularities. Any discrepancy noted between the PAW model and the conceptual model requires the user to loop back to any of the previous stages to modify the PAW model's topology, parameters or statistics.

5) If a real system gave rise to the conceptual model, then model validation is called for to ascertain that select aspects of the real system are in sufficient agreement with their counterparts in the PAW model. To this end the user launches production runs with few snapshots, or may elect to upload simulation runs to the host to attain additional speedups. The statistical summaries obtained from such runs are then compared to those of the real system. If agreement is not satisfactory, the user may loop back to earlier stages for further rounds of model modification, verification and validation. If possible, PAW's interfaces to the analytical packages may also be invoked to cross-check the simulation and thus aid in validation.

6) Finally, when the PAW model is verified and validated, the user has finally reached the point where the model's predictive power may be used to gain new information. The user can elect to step through model parameters, different topologies, etc., and make production runs to answer "what-if" questions. The host programming environment can be used for these activities as well as statistical post-processing (confidence intervals, hypothesis testing, comparison plots, etc.).

The above scenario sketch only gives an idea of the interaction between the user and PAW. It glosses over the important interactions among analyst colleagues or between analyst and client. Inter-user communication is greatly facilitated by PAW since phenomena can be jointly observed on the DMD screen rather than merely talked about.

10. AN EXAMPLE: A PAW MODEL OF PACKET VOICE

In a transmission system, multiple sources feed streams of packetized voice into a high speed line. The conceptual model is designed to capture the bursty nature of human speech. A voice source is either on (active) or off (silent), corresponding to a customer talking or pausing respectively. When on, the voice waveform is sampled, and a voice packet is generated every 16 ms. A voice burst is assumed to be exponential in length with mean 352 ms. When off, the voice source is silent for an exponential time with mean 650 ms. The time to transmit a packet on the high speed line is .333 ms. The PAW model in Figures 1-3 is designed to model only the traffic flow of packets in the system.

To initialize the simulation model, (see Fig. 1) the user need only introduce the requisite number of voice sources. This is done by putting a set of transactions (in this case 100) with class tag *src* at node INIT. Because PAW allows the user to create transaction batches directly at any regular node, initialization requires just one action. Note that only six transactions are displayed in INIT - the first five and the last one. The gray area separating them is the "fog" covering all undisplayed transactions.

When the simulation is started, each *src* transaction in the family-SPLIT node INIT splits into a family of two siblings. One sibling goes to node SILENCE with class tag *gen*, and the other to node DELAY with class tag *idl*. Class *gen* transactions model the packet generation process by forever shuttling between nodes SILENCE and GENERATOR. When at node SILENCE, they have an infinite service time thus representing a pause in the speech pattern. However, while at the class-SPLIT node GENERATOR, a class *gen* transaction will keep spawning a class *pkt* transaction representing a voice packet every 16 ms. Each *pkt* transaction is routed immediately to the HSL node (representing the high speed line) for transmission before exiting the system. The parent *gen* transaction retains its class tag and simply loops back to GENERATOR for the next packet generation. A class *gen* transaction is delayed (16 ms) before each split, and packet generation by multiple class *gen* transactions proceed in parallel with no queueing interference, because GENERATOR has infinite servers.

The switching on and off of the packetizing process is governed by the sibling of each class *gen* transaction. Initially, that sibling resides in node DELAY with class tag *idl* for the duration of the silence period; again multiple sources co-exist there without interference because DELAY is an infinite server node. When the silence period ends, the class *idl* transaction is routed to the family-YANK node ON_OFF. From the ON_OFF node it seeks and finds its sibling in node SILENCE, and yanks it to node GENERATOR thereby inaugurating an active period during which packets are generated at GENERATOR and sent to the high speed line HSL. The yanker sibling is routed to node DELAY where it assumes class tag *act* and times the duration of the active period. When it is time to switch the line off, the class *act* sibling moves to node ON_OFF to yank its sibling from GENERATOR back to SILENCE. The process will then repeat indefinitely.

Figures 1-3 depict three snapshots in the evolution of the model. They were obtained with the DMD's screen copying utility and show the entire screen (note the Reporter Corner and simulation panel located below the model area).

In Figure 1, the initial state at time 0 is shown with all transactions in the INIT node. Two statistics are collected in the foreground: a time-series of the number of active lines (bottom left) and a histogram of packet delay at node HSL (bottom right). Summary statistics are shown at the right margin of each.

Figure 2 depicts the state just after initialization. All *gen* transactions are in node SILENCE and all their siblings appear as *idl* transactions in node DELAY. This state represents a "cold start", i.e., all channels start in silence mode. To get rid of startup conditions, the reset window has been set to 1000.0; consequently, all statistics will be reset after a warmup period of 1000 time units. A pilot run can be used to gauge a reasonable reset time. Because initialization takes zero simulation time, the simulation clock is still 0. Note that the simulator is in step mode (step window is highlighted).

In Figure 3, the network state has already evolved considerably. The snapshot shows that at time 7185.687, a buildup of active channels is causing some idling time delays of packets at node HSL (see right hand histogram). The time-series on the left shows that 33 channels are now active (and by implication 67 are idle). Although a small queue of *pkt* transactions is present at HSL, a dynamic view of the model (through event-by-event animation) reveals that those queues are intermittent; they build up to moderate size and then disappear periodically. An *idl* transaction is shown in node ON_OFF poised to yank its *gen* sibling from node SILENCE to node GENERATOR. Note that the simulator is stopped and that the second line in each statistics window reflects the fact that all statistics had been reset at time 1000.0.

11. CONCLUSION

The modeling constructs of PAW allow a quick and efficient modeling of a wide variety of systems and phenomena. For example, the split/join mechanism can model message packetizing, product assembly, process forking, job synchronization and more. The yank construct was found to be surprisingly powerful. With it one can model inventories, time-out, flow control, polling, multiprogramming level control, and general phenomena involving token manipulation such as gating, and multiple simultaneous resource possession.

Within AT&T, PAW has been used in dozens of projects and in a wide variety of applications including voice and data communications, computer systems and manufacturing. The response has been positive; users appreciate the ease of use and efficiency of modeling provided by PAW.

PAW is not yet a completely general purpose modeling tool. The fact that it lacks a general programming language, while often a strength, is sometimes a weakness. In particular, predicates are not supported beyond the built-in ones (for example, PAW supports a limited number of state-dependent routing rules). Nevertheless, PAW is adequate for modeling a large class of queueing systems. Where it can be used, PAW is quite effective. It is hoped that future enhancements will further increase PAW's expressive power and consequently its modeling scope.

Acknowledgements

I wish to thank Robert Morris and Harry Heffes for reading and commenting on this paper. Robert Morris participated in the design of PAW and, in particular, in developing the notion of YANK nodes. The PAW model of packet voice is included here courtesy of Harry Heffes.

AN OVERVIEW OF THE CAPACITY MANAGEMENT PROCESS

Kenneth W. Kolence

Kolence Associates, 3591 Louis Road, Palo Alto, CA 94303

ABSTRACT

This paper provides an overview of the general capacity management processes used to assure reliable on-line response times for large production oriented IBM systems operating under MVS or MVS/XA. The other survey papers in this series focus on the techniques and tools used in these processes, such as analytic modeling, work load management, and software performance engineering. Taken together, this set of papers is an attempt to review the history of capacity management and its current state of the art capabilities. Finally, in this paper, the relationships between the field of capacity management and the academic disciplines of computer science and software engineering are commented on in the context of Ferrari's recent paper, "Considerations on the Insularity of Performance Evaluation".

INTRODUCTION

It is often said that computers have ushered in the Information Age over the last two decades, and this has been reflected in not only what we do, but how we do it. Just as the period we now call the Industrial Revolution was characterized by major changes in the means of organizing business endeavors, so too have computers caused radical changes in the business processes which characterize the modern corporation. While the development of broad corporate data bases ultimately lies at the heart of this new organizational revolution, the outward manifestation is most often in the form of an on-line system. Such systems fit smoothly into the natural pace of work of the business processes only if their response times are both reasonably fast and reasonably consistent.

For major production systems, one of the most consistently vexing problems of on-line systems is how to reliably provide such response times at a reasonable cost. Perhaps because the focus of concern is on production environments, this issue and its means of solution have received relatively little attention in either the academic world or the IEEE and ACM professional literature. However, the problems are of great practical concern, and as such have given rise to a large and vigorous community of professionals dedicated to establishing the relevant theory and practice.

The purpose of this paper is to provide an overview of the history and current state of the art of this field, and to partially address the academic implications of the technologies and viewpoints that have evolved. Other survey papers presented in the Capacity Management sessions at this FJCC Conference consider the major technological issues and provide rich bibliographies of the available literature. (BUZE86, HOWA86, LO86, SMITHB86, SMITHC86)

BACKGROUND AND HISTORY

In this set of papers, the term capacity management has been used to refer to the general collection of processes concerned with assuring on-line response time and batch service time requirements are reliably met at reasonable cost. Both the day-to-day processes and the planning and design processes are included as part of the general capacity management process, since the latter must fully support the former.

The term capacity management was originally intro--duced in the mid-1970s. (KOLE74, KOLE76) This was about the time on-line applications were first being widely placed in use, and slightly before analytic modeling concepts were made available in a generally usable product form. At that time, the major activities were tuning systems to improve utilization and throughput, reducing the run times of batch applications, and equipment planning. The importance of response times, and especially the difficulties in reliably providing required response times, were then only beginning to be fully appreciated. Had the field been named slightly later, a more properly descriptive term, such as service management, would probably have been chosen. Although the tuning activities are still a major aspect of capacity management, the focus is now more on response time and service, along with equipment planning.

Capacity management is almost uniquely identified with large mainframe production environments, and in particular IBM and IBM compatible systems running under the MVS and/or MVS/XA operating systems. Partially this is because these systems are highly multiprogrammed and typically configured with several 308X and/or 309X central processors using a common pool of disks and tapes. Significant cost and throughput benefits accrue when an

CH2345-7/86/0000/0741$01.00 © 1986 IEEE

ɔngoing tuning activity is applied to such an environment. The key reason though is that in modern corporations, these systems usually act as the underlying engines which drive many vital business processes. As such, response time and batch service reliability is of sufficient organizational importance to justify the costs and manpower involved in developing and maintaining service reliability.

As a conservative estimate, well over 10,000 DP professionals in the U.S. are involved in some aspect of capacity management, many if not most on a full-time basis. Worldwide, the number certainly exceeds 15,000.

The growth of capacity management capabilities in this environment was not paced by the equipment vendors. The existence of the potentially large and easily accessible MVS marketplace encouraged the entrepreneurial spirit in many individuals, resulting in a large variety and number of capacity management oriented software products being made available for the MVS environment. Contrariwise, the relatively small and unaccessible marketplaces for other large mainframe manufacturers discouraged independent product development, and much less choice is available to these users. The even smaller budgets for mini and supermini installations, as well as their relative lack of a production orientation, has resulted in an almost complete absence of such products or even capabilities. For example, the UNIX 4.3 system released from a group at U.C. Berkeley contains only one or two of the most basic types of measurement tools. Thus, it is probably quite fair to say that the evolution of the current state of the art in capacity management has been driven by a combination of corporate needs for production response time and service reliability and the entrepreneurial spirit.

Any group of professionals as large as that involved with capacity management will normally be involved in one or more professional societies related to their work. In general, however, these people belong neither to the ACM nor IEEE and have little interest in the broader interests of either group. Because of the homogeneity of interest centered on large IBM operating systems and work loads, the IBM SHARE and GUIDE organizations were more natural loci of interest. Also, in the early 1970s the most universally used products were offered by a company named Boole & Babbage, Inc. A user's group based on these products was founded in 1971. Because the attendees also represented almost all of the users of other products as well, it quickly outgrew the limitations of a single vendor orientation. To reflect this, it was formally incorporated in 1975 as a non-profit organization called the Computer Measurement Group, Inc., or CMG.

At the time of incorporation, CMG member interests were almost solely limited to problems associated with tuning systems and applications, and with charge-back methods. To some extent, this was because available software products were limited to these functions. The more general concepts and methods of capacity management were popularized by a company called the Institute for Software Engineering, Inc., beginning in early 1976. This same company also published a book called "An Introduction to Software Physics: The Meaning of Computer Measurement". (KOLE76, KOLE85) This theory permitted the unification of the many different measurements in use, and postulated the basic structure of the capacity management process to identify where to focus further research in and application of the theory. A variety of courses and publications, and the International Conferences on Computer Capacity Management (ICCCM) were used to inject these concepts into the CMG community.

Almost concurrently with the activities of the Institute, another company called BGS Systems, Inc., was founded to exploit the techniques of analytic modeling in the form of a software product called BEST/1. At that time, modeling was an unproven technique in the eyes of most practitioners, and was initially met with considerable skepticism. However, the combination of an available product to predict response times, the problems of managing on-line systems response times, and the concepts of capacity management quickly resulted in genuine acceptance of both analytic modeling and the capacity management subprocess called capacity planning.

In effect, the development and use of the product provided the empirical proof of the concepts of analytic modeling. This undoubtedly contributed greatly to the relatively widespread academic interest in these techniques.

By about 1980, a relatively balanced emphasis on tuning (or performance management) and capacity planning had emerged at CMG. By this time also, installation management had begun to formally organize capacity planning functions as well as the older performance management activities. Often, this was done at the direct instigation of senior management above the DP group, because of the serious need to provide reliable response times for the major on-line systems used by the corporation.

The planning and tuning activities of capacity management are now generally accepted within the community of large IBM MVS production sites, at least in the U.S. and Europe, and probably all of the other continents as well. This has been reflected in a dramatic growth of the CMG membership and U.S. conference attendance. For example, the 1982 CMG conference attracted 550 people; 950 attended in 1983, growing to 1,200 in 1984 to over 1,600 in 1985. The 1986 conference in December of this year is expected to draw close to 2,000.

In addition to its annual conference, CMG has a large number of Regional Chapters. Typically, these groups meet monthly and present one-day technical programs.

In Europe, a private organization sponsors an annual conference called ECOMA. It is roughly equivalent to a CMG conference. For various reasons, however, local CMG organizations in some of the European countries have begun to form and can be expected to eventually merge with or replace the ECOMA organization. For example, the first U.K. CMG organization was formed in January of 1986. It held its first conference in late May. Over 250 people attended, and the quality of the papers and presentations was excellent. During the same period of time, a less formal meeting of CMG Italy attracted about 100 attendees. Going to the other side of the world, Australia has a very active national CMG with several regional chapters.

The relationships between the various national CMGs is currently quite informal and based mostly on personal relationships. However, the problems to be solved are essentially the same worldwide for everyone who uses large MVS systems. For this reason, one can always expect to see considerable cooperation between the national CMGs, and perhaps some form of international confederation will evolve over the next several years.

Clearly, the vitality of CMG reflects the economic value of the capacity management activities within the sponsoring DP organizations. However, it should also be pointed out that the drive and energy of many individuals have contributed both to the field and to CMG itself. CMG is probably also unique in the degree of support it receives from the vendors of capacity management products, although this is generally in the form of personnel commitments rather than money.

AN OVERVIEW OF CAPACITY MANAGEMENT

The Major Subsystems

The most general definition of capacity management is that it is the collection of processes by which the response time and batch service requirements of applications software are consistently and reliably provided, at all times and at a reasonable cost. In practice, capacity management breaks into two major subprocesses. The first, often called performance management, is concerned with those processes which use existing configuration capacity with existing systems and applications software, and provide real response times and real batch service to real transactions at some load level. That is, performance management operates in the current time frame and is charged with meeting user service requirements with the means at hand. To emphasize it is a major subprocess of capacity management, performance management is often referred to in this paper as the Current Time Frame (CTF) capacity management subsystem.

The second major subprocess is typically called capacity planning. Because the term implies the process is limited to equipment planning, it is considered by the author to be a serious misnomer. More generally, the objective of this second major process is to assure the means required by the performance management process to provide actual service within requirements are in fact delivered at the appropriate points in the future time frame. For this reason and others, this second major subprocess is referred to in this paper as the Future Time Frame (FTF) capacity management subsystem. It should be understood that the FTF subsystem fully includes capacity planning as the term is currently understood.

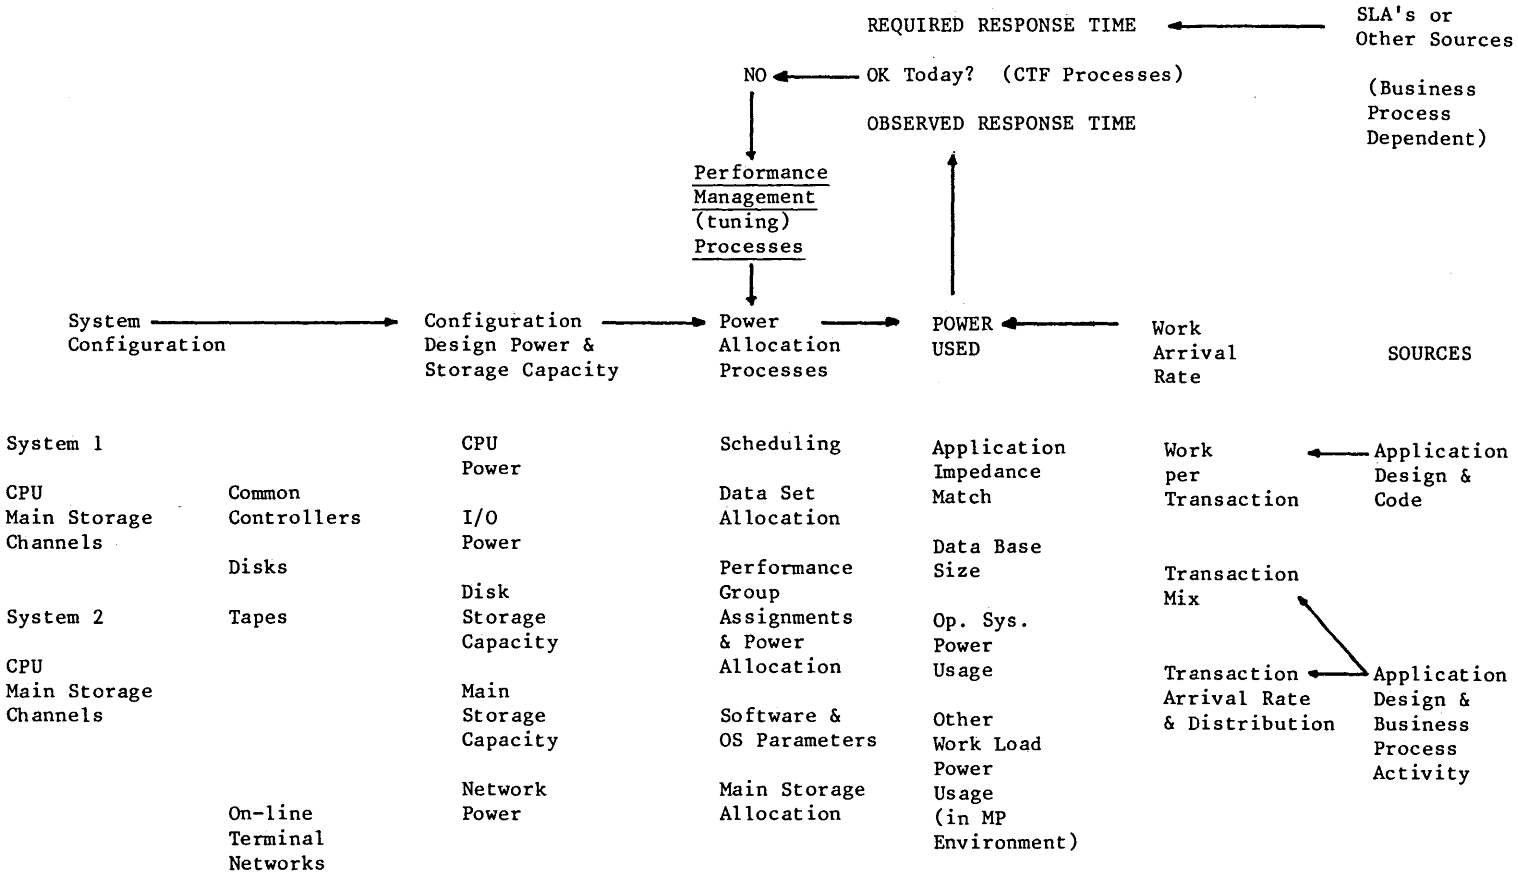
Since physically real configurations, work loads, and service times only exist in the current time frame, the FTF subsystem must develop and use representations of reality to determine what will be required, and then must obviously implement the solutions proposed. As a result, much of the FTF subsystem is concerned with the processes of work load classification, work load characterization, transaction arrival rate and batch volume projection, service and response time projection, and equipment and configuration design. Analytic modeling software products are widely used in this subprocess for the equipment (capacity) planning subfunction.

The emerging discipline called Software Performance Engineering is part of the larger FTF process, and as such is a major reason for discarding the term capacity planning to represent the more comprehensive FTF process. Software performance engineering is concerned with the problem of assuring new systems and applications software have inherently good quantitative properties, both service and utilization/cost. While less well recognized, it is also concerned that such software properly interfaces to the other capacity management processes. Although still in a very early stage, Software Performance Engineering will probably become the major bridge bringing together the capacity management and the computer science and software engineering academic communities.

The responsibility of the FTF capacity management process is to deliver what is needed by the CTF process to provide actual response and service times which meet the required levels. Thus, it is useful to consider the characteristics of a typical MVS installation, and the real processes which result in the observed service characteristics. Figure 1 is a simplified schematic of these characteristics and the basic processes at work. Since the word capacity figures prominently in this diagram, the software physics interpretation of the term will be discussed first.

Capacity and Power

The term capacity generally can refer to either the quantity of available storage (disk, main storage, etc.) or to processing power. The most general definition of processor power is simply bytes per second transferred to a storage medium (including CPU registers), taking into account the full execution time of the processor. (KOLE76, KOLE85) It has been shown in general that processor power defined in this manner is a function of a variety of software and resource allocation parameters in addition to the raw hardware speeds. Thus, the processor powers available from a system depend partially, and sometimes largely, on how these parameters are set.



A Software Physics Analysis of CTF Response Time
Characteristics and Processes

Figure 1

The most commonly used approximations to power are MIPS (Millions of Instructions executed Per Second) for central processors, I/O rates (Number of I/O's per second) for DASD (disk) and tape subsystems, and messages per second for networks. Since power is generally defined as work per unit time, the corresponding units of work in this system of measures are Millions of Instructions Executed (MIE's), Number of I/O's, and Number of network messages. However, on any given CPU it is more normal to measure and refer to CPU work in terms of CPU seconds.

In general, the amount of work required by a unit of systems or applications software to process a given quantity and mix of data is invariant. (However, the work may be quite sensitive to changes in the quantity and/or mix of data.) In particular, the average work per transaction in on-line systems, and the transaction mix in conjunction with the transaction arrival rate, defines the processor powers required to provide any given level of service and response time.

The work per transaction (or per record in batch systems) is a vector quantity, and the ratios of work required by different processors (e.g., CPUs and DASD systems) are fixed for given data. As a result, the application software can only use available capacity in proportion to the work vector requirements. For example, assume one million instructions and 50 I/O's are required to process a transaction. If a ten MIPS CPU is being used, and the I/O system and data set allocation is such that the application can only get 50 I/O's per second, then the application can only use one-tenth of a CPU second per elapsed time second. And, the minimum obtainable response time for the transaction will be close to one second plus the network service time.

In large MVS and MVS/XA systems one typically finds more than one central processor (308X or 309X) with a common pool or network of DASD and tapes. Within the I/O network, strings of drives are attached to controllers or storage directors, and these in turn are attached to one or more channels on one or more central processors. The major reasons for this common I/O pool are reliability and storage accessibility. That is, if a CPU or channel or controller fails, another I/O path and/or CPU can be used to continue processing of critical systems.

The exact manner of connecting I/O devices through controllers and CPU channels is the design of the I/O subconfiguration. In conjunction with the physical drive speeds and storage characteristics, the configuration defines the I/O processing power available overall, and to each of the central processors. In large MVS systems, the overall I/O design capacity is usually considerably less than the sum of the I/O capacities available to each CPU. In Figure 1 the capacity identified as configuration design capacity includes total CPU, I/O, and network power as well as main and secondary storage capacity.

The allocation of design capacity occurs in several ways. First, the scheduling of applications onto various CPUs results in the allocation of each system's total MIPS power and main storage among temporally concurrent applications. In an operational mode, MVS further dynamically allocates CPU power and main storage according to "performance groups and classes", to which each of the applications is assigned.

An important form of power allocation is done by the DASD space allocation process. There are only a limited number of independent or non-interfering I/O paths within the DASD channel-controller-drive network. If data sets from temporally concurrent applications (and the operating system) are allocated space on the same path, interference can occur and DASD service times increased and made more variable. In effect, the I/O power which the application can draw from the design capacity is often significantly reduced. Within a single application, the degree of I/O concurrency between data sets on the same path and other space allocation factors such as head movement and block size can further reduce the actual ability of the application to draw I/O power from the system.

The work vectors for applications require CPU, I/O, and network power be drawn from the system in fixed proportions. In many ways, the problems of allocating processor power to an application correspond to electrical impedance load matching problems. In both instances, mismatching leads to a situation in which less than the design power of a system is usable. In the capacity management context, this means increased unit costs and increased service and response times. It can also mean wide variability in response times when the mismatch occurs as a result of interapplication interference. This is a particularly undesirable situation in most if not all on-line production systems.

The Performance Management Subsystem

The performance management function is usually performed within the computer operations group, often in the group called technical services. They are essentially overconstrained in terms of the means available to them to assure required service levels are consistently provided. At any given time, the equipment and thus the design capacity they use is fixed, the work per transaction is an inherent property of the application, and the transaction arrival rates are determined by the business processes being supported.

Performance analysts are thus limited in capability to adjusting power allocations, and to improving the "impedance match" through data set allocation and placement and by interapplication data set isolation techniques. In addition, they can also improve the available power of the system by adjusting various operating system and application system parameters, particularly those involving main storage management and paging activities.

In general, such activities are referred to as "tuning the system", and indeed performance management is basically limited technically to improving and maintaining the ability of the overall system to deliver as much of its design capacity as possible to the applications.

It should also be mentioned that a considerable amount of effort by performance management personnel is spent in monitoring on-line response times and analyzing problems to determine their causes and possible solutions. Because of the high degree of multi-programming found in MVS systems, along with huge transaction volumes, this is often a very difficult task. It is also not easy to determine the most effective action to take, or indeed even if a given action will completely solve a given problem. As a result, there have been recent proposals that analytic modeling software products be developed and used in conjunction with direct measurements to detect problem causes and quantify potential solution options. In fact, early results have been quite encouraging and a rapid evolution of this new application of analytic models can be expected.

In addition to response times, the performance management group monitors utilizations, work load volumes, and so forth. Various management reports and historical trends are prepared and maintained. Much of the input to the capacity planning function is thus provided by the performance management activity. Typically, these two groups are separate. The day-to-day orientation of performance management and the longer range viewpoint of capacity planners have not been found to mix well organizationally.

Future Time Frame Subsystems

Figure 2 is a schematic of the FTF capacity management subsystem corresponding to the structure of Figure 1.

Service Level Agreements. All of the capacity planning activities clearly require a quantitative definition of what "required response time and batch services times" are. In practice, only certain critical applications (normally, just the on-line systems, but some batch systems are also critical) have formal response time requirements set for them. These are typically stated in the form of Service Level Agreements, or SLAs. These are agreements between the Operations and user departments that a minimum response time will be guaranteed some percentage (typically 95%) of the time.

The guarantees in SLAs are generally difficult to fulfill, and may be even more difficult to negotiate. As a result, formal Service Level Agreements and the associated "Service Level Management" systems are far from universal. In the less sophisticated large MVS installations, the problem of establishing required response times for capacity planning purposes is sidestepped by Operations setting response time objectives without formal user consultations. Still, if this is recognized as a primitive form of service level management, then it is reasonable to say that all MVS installations require a service level management activity.

The Capacity Planning Subsystem. The performance management system must match the available capacity to the actual work load to provide the required response and service times. The FTF (Future Time Frame) capacity management subsystem therefore is, among other things, charged with the responsibility of assuring the required capacity is available when needed and in fact can be allocated as required.

To do so requires several things. One is a set of work load projections grouped into applications and other work which correspond to the scheduling of the various physical configurations in the installation; i.e., IMS, TSO program development, production batch, etc. Typically, only peak loads are projected and so a means for identifying and projecting the peaks of various applications is also required. Another requirement is a means of projecting the response and service times to be expected at these peak loads using the existing configurations and also using alternative equipment and configurations. The activities associated with developing these forecasts and determining when and what equipment changes are required are generally called the capacity planning function within a typical MVS installation.

The papers by Buzen, Lo, and Brian Smith review the evolution and current state of the art of the major capacity planning activities (BUZE86, LO86, SMITHB86). While analytic modeling techniques and products have been a boon to capacity planning practice, these papers demonstrate that current capabilities are not yet all that are needed. In particular, a more direct linkage between models and the various power allocation processes would be useful to provide the performance management process with directions on how best to accomplish this in the current time frame.

Software Performance Engineering. The importance of reliable and consistent response times to the successful operation of the basic corporate business is being increasingly recognized at senior non-DP management levels. Considerable pressure is thus being brought to bear for the use of formal SLAs. The importance of the performance management function, which is also usually charged with the resultant day-to-day service management responsibility, is increasing in response to this pressure. Similarly, the importance of the capacity planning function, and especially work load forecasting, is also increasing. However, taken together, both functions are limited in terms of their technical methods of assuring proper response times to simply providing more computing power, more effectively. The other two determining technical factors, work per transaction and transaction arrival rates (in some mix), are currently left largely uncontrolled. This failing probably represents the most significant unresolved area in the field of capacity management.

A Software Physics Analysis of the FTF Capacity Management Subsystem

Figure 2

Ultimately, the transaction arrival rate characteristics of an on-line application are determined by the level of activity of the corporate business processes being supported. One is thus tempted to say that arrival rates are in fact inherently uncontrollable, and move on to the question of how to adequately project arrival rates given business plans. Certainly this is the basis of one of the major technical thrusts in work load forecasting methodology. However, the arrival rate of logical, as opposed to physical, transactions is a function of the application design, which in turn is a function of the basic business process design. In other words, the actual transaction arrival rate required to support a given level of corporate activity is determined during the design process. Obviously, this is similarly true of the third independent variable determining response time, the work per transaction.

The field of software performance engineering is concerned with assuring that applications and systems software have the quantitative and functional attributes required to meet required response and batch service times, at reasonable cost. It is therefore a process of basic importance within the overall capacity management process, with interfaces to all of the other capacity management subprocesses; e.g., performance and service management, work load forecasting, and capacity planning.

Software performance engineering currently has only a tiny number of proponents and practitioners compared to the other capacity management functions. A major hurdle to the growth of the field is that the practitioners really need to be the applications development and maintenance people within a company, and historically such groups have been outside of the mainstream of capacity management.

An oft-repeated development philosophy is to develop first and then "tune" if necessary. Painful experience has proven this approach is not only grossly wasteful of computing capacity, but much worse, is operationally unacceptable in the context of any company whose business is paced by its computer systems. The basic initial hurdles faced by software performance engineering are thus twofold: (1) to understand the technical methods of designing applications with the desired quantitative and functional capacity management properties, and (2) to encourage the adoption and use of such methods within the application life cycle.

Today, the basic focus of software performance engineering research is on developing an understanding of the technical principles which should be applied in order to reduce the work per transaction characteristics of applications. As with the other capacity management processes, these efforts are proceeding in the classical scientific way by combining empirical efforts with a search for underlying patterns and principles. Good progress appears to have been made in understanding what these principles may be. (SMITHC/UP) However, they can be difficult to apply in the context of applications development systems developed in ignorance of these principles.

For example, information hiding and data base navigation are typical properties of the so-called fourth generation data bases, languages, and systems (such as FOCUS and IBM's DB2). The functional generality of these properties come at a high cost in terms of work per transaction, and in some instances this work may be highly variable. Neither the means to understand a design decision in these terms nor methods for controlling the work per transaction are easily available to the designer, using such systems. So, the problem of encouraging the adoption and use of technical methods of software performance engineering may be more formidable than developing the technical aspects of the discipline.

There are other major obstacles to extending the concepts and techniques of software performance engineering into the applications design and maintenance processes, at least relative to the problem of controlling the response time and work per transaction characteristics. Essentially, they all center on two facts: (1) qualified development personnel are a scarce and expensive resource, and (2) a large backlog of applications requirements exist in a typical MVS installation. While software performance engineering can easily be shown to be highly cost-effective over the life of an application, it is perceived as requiring more personnel and more development time. In many if not most development efforts, especially where considerable tuning is required, this is not true. Nonetheless, this misperception hampers the acceptance of the process.

It should be noted that the other aspects of software performance engineering, such as those concerned with interfacing applications directly to the other capacity management functions, have not been explored in any significant manner. It would appear they could be solved in some form amenable to productization. The history of the growth of capacity management functions corresponds closely with the general availability of product.ı to support functions. The likelihood then is that once such products become available, these other aspects will quickly become important.

Another area of software performance engineering that would benefit from the availability of additional software product tools is applications tuning. In the earliest days (circa 1970), such tools were able to lead quickly and easily to quite significant improvements in most batch applications. However, these tools have not been extended and adapted to current software as well as could have been hoped. Properly upgraded capabilities of this type would be of direct value to the performance management area. They would also identify coding methods and styles which have pos:tive and negative impacts on response time and service. This in turn would lead to enhanced awareness of the value of software performance engineering in the applications development area.

ON THE ISSUE OF INSULARITY

The presentation of this collection of survey papers at FJCC '86 is to a large extent a direct response to, and in support of, Ferrari's recent paper entitled "Considerations on the Insularity of Performance Evaluation". (FERRA86) In it Ferrari observes that the topics of performance evaluation (here called capacity management) have primarily evolved outside of the academic disciplines of computer science and software engineering. He also points out that in general there is a great lack of academic interest in the quantitative concepts and methods exemplified by the field of capacity management. He then argues this is no longer an acceptable state of affairs, both because scientific and engineering disciplines are classically quantitative, and because the quantitative properties of computer-based systems are of great concern in all major projects. Ferrari also fully recognizes that such quantitative concepts and methods cannot be treated as a separate discipline. Rather, they need to be permeated into the very fabric of both computer science and software engineering. Finally, Ferrari suggests several areas of both research and action to assist and support the process of fully integrating capacity management with the academic disciplines.

Ferrari's paper closes with the statement that a small group of people have kept ". . . the esoteric cult of performance evaluation . . . alive but relatively secret for twenty years." While true with regard to the academic community, it is untrue in the context of the community of capacity management professionals. Thus, an anomalous and, as Ferrari argues, perhaps unique situation has developed. A strong and vigorous profession exists, it is deeply wedded to quantitativeness and scientific empiricism, and it is without representation or support in the corresponding academic disciplines.

It would perhaps be easy to argue that this condition has arisen due to the "insularity" of either or both groups, and to a certain extent these arguments would carry a ring of truth. Still, the existence of the thriving professional society, CMG, with a rich technical literature certainly implies openness. Beyond that, CMG's highest award, the A. A. Michelson Award, celebrates the famous experimental physicist and thereby sets his accomplishments in science as a model for the capacity management professional. Moreover, the 1985 award winner was Dr. K. M. Chandy, an academician who, in his acceptance speech, spoke on the same basic issues as Ferrari. So the academic community is in fact represented in and recognized by the CMG community. What then are some of the problems?

The focus of attention of capacity management has been and is large IBM systems under MVS, and such systems are not easily learned nor accessed by academicians. Second, the major topics have been systems tuning, capacity planning, and other production oriented concerns. Again, these are not areas academicians would normally become involved in. Products, often specialized to MVS and MVS application systems, play a major role in the basic activities of a capacity management professional. Although a few academics have been involved in the design of such products, products are not generally transportable to the systems, such as UNIX, which are favored in the universities. Even if they were, the production orientation of most of them would render them useless and uninteresting. Finally, as Ferrari points out, art is fun, but scientific empiricism is often hard, tedious work. The game must be worth the candle, and little in the way of financial, intellectual, or "fashionable" support or reward is available to academicians who venture into this area.

In the author's opinion, part of the solution to dissolving the insularity Ferrari observes is to recognize that the types of problems of interest to the academician and to the practicing capacity management professional only appear to be quite different. There are many instances where great commonality of interest exists. For example, as Ferrari again correctly argues, practice would benefit greatly from improved theory. In the author's opinion, the direction and form of the required theory must relate to the needs of practice as, for example, the general problem of quantitative work load characterization. Such work clearly would, and undoubtedly will, lie at the heart of a discipline of software performance engineering. While other examples can easily be given, perhaps it is simplest to say that a part of the solution to bringing the practical and the academic disciplines together is to recognize where and in what manner their interests overlap.

To be turned into reality, commonality of interest needs to be turned into a commonality of importance and support. This part of the solution involves many things, but the most important is simply to develop proper funding sources and intellectual acceptance and support within the academic community. Opening much broader and meaningful lines of communication between academics and practitioners, perhaps initially through professional society activities, would be important, too. But of the most basic importance, it will take people to make all of these things happen. It is to be hoped that Ferrari's paper, and this set of FJCC papers, will encourage the necessary personal commitments in both communities.

AN OVERVIEW OF PERFORMANCE PREDICTION IN MVS SYSTEMS AND SNA NETWORKS

Dr. Jeffrey P. Buzen

BGS Systems, Inc.

ABSTRACT

Analytic models based on the theory of queueing networks are used extensively in capacity planning applications involving mainframe computer systems. The mathematical theory which provides the backbone for such models has been extended recently to deal with SNA based telecommunications networks. This paper surveys the use of analytic models in both host and network capacity planning. Some of the important differences between analytic queueing models for host systems and telecommunications networks are then discussed. Finally, the paper reviews the operation of relevant SNA mechanisms including polling, half and full duplex protocols, slowdown mode, and the parameters MAXIN, MAXOUT and PASSLIM.

INTRODUCTION

The problems caused by an overloaded data center are all too familiar to many users. As workloads grow, response times for online applications can increase dramatically, creating numerous difficulties. These include long lines at automated banking machines, sluggish response for order entry and customer information systems, and reduced productivity among programmers, data entry clerks and word processing personnel.

The process of planning hardware upgrades to avoid such overloads is generally referred to as capacity planning. Although it is an essential function, capacity planning is not an easy task. One problem is that the processing demands on most data centers are continually varying and shifting. In addition, evaluating alternative upgrade strategies has become substantially more difficult as systems have increased in complexity. For example, it is not easy to determine whether a faster CPU, more processor storage, or an additional telecommunications line represents the most cost-effective solution to an overload that is expected to arise three months in the future.

Despite these difficulties, every data center manager does -- in fact -- employ some method for dealing with the capacity planning process. The simplest but least satisfactory approach is to be purely reactive: that is, to wait until a serious problem arises and then react by ordering additional hardware. This creates obvious problems such as disrupting normal business operations and frustrating both external customers and internal users. In addition, management must still address the important technical problem of deciding exactly what hardware is required to resolve an existing overload condition. The simplest approach here is to rely purely on intuition and experience. However, as already noted, it is difficult for human intuition to keep pace with increasing system complexity. As a result, relying on intuition can become a costly trial and error process that generates overexpenditures in certain areas as well as further delays in restoring satisfactory performance.

One obvious way to improve the capacity planning process is to employ predictive techniques that can indicate: 1) how much longer a system can operate before an upgrade is required; and 2) what the most cost-effective upgrade will be at that time. Since response time is the primary indicator of system performance in most installations, predictive techniques employed for capacity planning must provide information about response time. Queueing theory is a branch of mathematics that deals directly with the prediction of response times, and as a result queueing models have become important tools for capacity planning. Before discussing queueing models in more detail, it is useful to present an overview of the major response time components in MVS/SNA systems.

MANAGING RESPONSE TIMES IN HOSTS AND NETWORKS

As shown in Figure 1, the response time for a typical transaction can be divided into three major components. The first,

CH2345-7/86/0000/0751$01.00 © 1986 IEEE

inbound network response time, is the length of time needed for the user's transaction to travel from a remote terminal to the host computer. Host response time, the second component, is the time required to process the transaction at the host. Finally, outbound network response time is the time necessary to transmit the transaction results back to the end user.

In many organizations, responsibility for maintaining acceptable network response time (inbound and outbound) is assigned to the manager of the telecommunications department. The data processing manager is then responsible for maintaining acceptable host response time. Conceptually, this separation of responsibility is appealing because of the clean hardware interface and reasonably clean software interface between the host computer and the network. Furthermore, the substantial quantity of specialized information needed to manage the host computer and the communications network can be separated under this scheme, considerably reducing the complexity of the overall management problem.

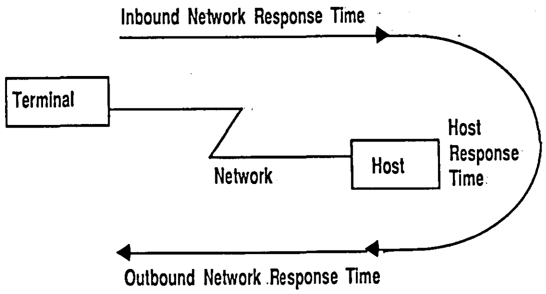

Figure 1: The Components of On-Line Response Time

Despite the advantages of dividing the responsibility for host and network response time, it must be remembered that the end user of an online application sees no such separation. The user is concerned only with total response time (inbound plus host plus outbound) and is satisfied only if the sum of the three components meets expectations.

Traditionally, total response time is controlled by establishing formal or informal "service contracts" between the host data processing department and the network management department. For example, the host data processing department might commit to providing a two second host response time for a particular class of order entry transactions. Based on the assumption that this will be true, the network management department can then configure its telecommunications lines and network processors to meet the total response time requirements of the remote offices that it serves. At the same time, the host data processing department can plan its hardware and software upgrades to meet the two-second requirement as the total load increases. This host oriented planning can be done without concern for network response time.

Although there are several advantages to this division of responsibility, there are certain disadvantages as well. Specifically, without an overall view of host/network interaction, time and effort can be wasted trying to optimize the wrong component. For example, rather than adding higher speed lines to handle increased traffic from a distant city, a more economical approach may be to reduce host response time by increasing the speed of the paging subsystem. Such trade-offs are difficult to see when the responsibilities for telecommunications and host capacity planning are assigned to separate organizations.

Another problem with dividing the responsibility is that certain interactions between host and network work loads may be hidden. For example, as the number of remote users increases, the network traffic and host processing loads increase, and there may be feedback effects resulting from the interaction and interdependencies of the network and host system. These effects can be difficult to account for without direct links between the models used for host and network capacity planning.

A further consequence of the traditional approach to capacity planning is that advances in the analysis techniques of one area may not be fully communicated to the other. The evolution of performance modeling tools during the past five years is a case in point.

PERFORMANCE MODELING

A performance model allows the capacity planner to assess how performance will be affected by changes in a system's external workload and internal hardware and software components. For example, a model can be used to predict the effect on response time if the transaction volume from a remote site increases by 75 percent and a faster host CPU or telecommunications line is installed.

Figure 2 illustrates a very simple queueing model known as the single server queue. It is assumed in this model that a stream of "customers" are arriving at the "server", which is represented by the circle in Figure 2. Each customer requires a certain amount of processing or "service time" at the server. If a customer arrives at a time when the server is idle, the customer receives service immediately. Otherwise, the customer joins the queue of waiting requests, which is represented by the rectangle in Figure 2. When the server completes processing for an individual customer, the queue is examined; if there are customers waiting at this point, one of them is selected and is immediately placed in service.

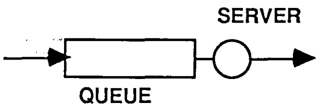

Figure 2
Single Server Queue

One of the most important quantities that analysts consider when analyzing a single server queue (or almost any queueing model) is the response time of a typical customer. Response time includes both the time spent by a customer while waiting in the queue and the time spent receiving service. In general, if server utilization is low (i.e., if the server is idle much of the time), the majority of arriving customers will not have to wait at all in the queue. Thus, average response time should be approximately equal to service time. As server utilization increases, it becomes more likely that arriving customers will encounter a busy server. This will increase queueing delays, which in turn will increase response time. Figure 3 illustrates the way response time typically varies as the utilization of the server increases from 0% to 100%.

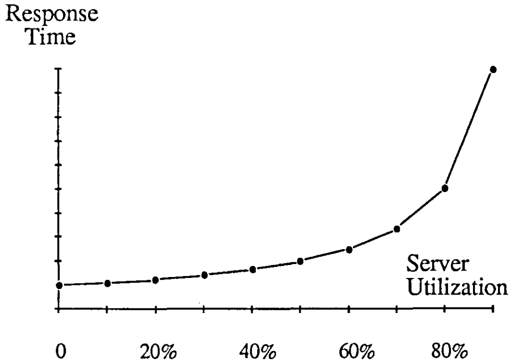

Figure 3
Response Time Function

Note that the curve in Figure 3 has a steadily increasing slope. Thus, the increase in response time that occurs when server utilization changes from 30% to 40% will always be less than the corresponding increase for a 40% to 50% change in utilization, and this in turn will be less than the corresponding increase for a 50% to 60% change in utilization.

Many performance analysts try to make predications of future response time by generalizing upon historical observations of the relationship between previous changes in utilization and their associated effects on response time. For example, an analyst might note that last year utilization increased by 10%, and response time increased by 15%. If another 10% increase in utilization is anticipated next year, the analyst might conclude that there will be another 15% rise in response time as well.

The steadily increasing slope of the response time function implies that this intuitively plausible procedure will almost always underestimate actual response time. The errors that arise when applying simple intuitive reasoning to response time prediction provide one of the principal motivations for the development of queueing theory. The importance of obtaining accurate response time estimates explains why queueing theory is now such an indispensible tool for capacity planners and computer performance analysts.

MODELS FOR MAINFRAME COMPUTER SYSTEMS

When developing a model of a mainframe computer system, the single server queue illustrated in Figure 2 can be regarded as a basic building block which is used many times in the overall model. For example, to model the CPU in a uniprocessor (UP) system, analysts generally use a single server queue in which the "server" represents the CPU itself, the "customers" represent programs that have instructions ready to execute, and "service time" corresponds to the amount of time it takes the CPU to execute these instructions for each program.

Similarly, to model an I/O device such as a disk or drum, an analyst would use another single server queue in which the "server" represents the I/O device, the "customers" represent programs that have I/O operations (reads or writes) ready to be initiated, and "service time" corresponds to the amount of time it takes the device to perform the I/O operation.

In typical computer systems, an arriving program begins by requesting a burst of processing at the CPU. The initial CPU processing request completes when the program generates an I/O request such as a read operation to a data file or a page-in request to a page data set. At this point, the program proceeds to the appropriate I/O device where it will wait in a queue (if necessary) and then perform I/O processing. Once the I/O transfer is complete, the program returns to the CPU queue and begins the next CPU-I/O cycle.

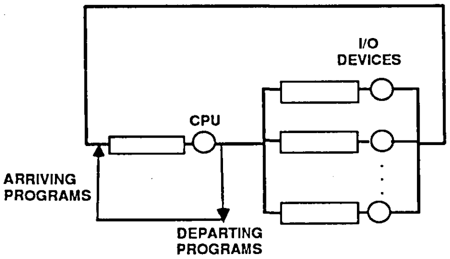

Figure 4
Central Server Model

Figure 4 illustrates the overall flow of programs (customers) in this model. Since the model contains a network of interconnected queues and servers, it is referred to generically as a queueing network model. In particular, Figure 4 presents an example of the "central server" queueing network model [9,10], which has proven extremely useful in analyzing mainframe computer systems. It should be noted, of course, that in order to provide satisfactory analyses of complex MVS systems, the basic central server model in Figure 4 must be extended in a number of ways. The next section of this paper surveys some of these extensions.

MVS MODELING CONSIDERATIONS

One important extension to the central server illustrated in Figure 4 is the representation of multiple customer classes (multiple workloads). The discussion in the preceding section implicitly assumed there is a single class of customers (programs) circulating through the network. This class is represented by a set of parameters that represent the average processing demands that programs make at each server as they circulate. Suppose, however, there are two or more workloads being processed by an MVS system (e.g., batch, TSO, IMS, CICS). In this case a single workload model could be used to approximate performance, but the set of parameters that represent the processing demands at each server would be averaged across all workloads. In addition, predicted response times and throughput rates could only be provided for the single (average) workload. This is clearly unacceptable in cases where separate performance objectives are defined for batch, TSO, IMS, CICS, etc.

To provide this additional detail, the single class queueing network solutions developed by Jackson [22,24] were extended by Baskett, Chandy, Muntz and Palacios [5] to deal with multi-class (multiple workload) networks. Shortly thereafter, the computational algorithms originally developed by Buzen [9,10] for single class models were extended by Reiser and Kobayashi [28] to handle multi-class models. The development of alternative algorithms that provide improved numerical stability in certain cases or improved speed through the use of various approximations continues to be an active area of research [2, 3, 15, 17, 25, 29, 30, 31, 32]. Additional papers on this subject will appear soon in the *Journal of the ACM* and the *ACM Transactions on Computer Systems*.

Another important extension needed for realistic models of MVS systems is an analysis of the delays programs experience before entering memory. Note that the "memory queue" is different from the queue at a CPU or I/O device since memory is not an active server that processes a program for a short burst and then allows the program to proceed to another server. Instead, memory is a "passive resource" that a program must acquire before proceeding to the active job mix and being allowed to compete with other jobs for CPU's, I/O devices, and other conventional servers.

Memory queueing is beyond the scope of the exact solutions developed in [24] and [5]. However, a number of approximations have been developed based on the idea of decomposition. Brandwajn [7] presented one of the earliest analysis of this type. Work by Courtois [18] and Chandy, Herzog and Woo [14] clarified some of the theoretical assumptions involved, and subsequent papers by Menasce [27] and Lazowska and Zahorjan [26] proposed additional approximations to deal with multi-class extensions.

Other problems that must be addressed to develop realistic models of MVS systems include the modeling of preemptive priority scheduling at CPU's and the modeling contention within the I/O subsystem for channels, control units and heads of string. In general, these problems have been addressed by analyzing individual servers or sets of servers in these solutions into complex network models via transformational techniques [1]. The use of operational analysis [11, 19] has facilitated the development of some of these approximations and also provided new theoretical insights into why queueing models work well in practice [33].

It is important to note that the end user of an MVS modeling tool is insulated from these mathematical details in the same way that a programmer using a high level language is insulated from machine language instructions. Thus, the literature on the use of analytic models in capacity planning has shifted from early papers stressing basic feasibility [12] to more recent descriptions of how the models are used to solve everyday problems [6,16,20,21,23].

MODELS FOR TELECOMMUNICATIONS NETWORKS

The basic objectives of a queueing model for a telecommunications network are to predict the response time for various classes of messages: in particular, for "inbound" messages which originate at user terminals and are destined for the host computer system, and for "outbound" messages which originate at the host computer system and are destined for a user terminal. This problem would appear to be well suited for a queueing theoretic analysis since it involves response time prediction for customers that correspond naturally to inbound and outbound messages.

Having identified the customers, the next step is to specify the servers, the service times, and the sources of queueing delay. Consider a very simple case in which a set of user terminals communicate with a host system over a single transmission line as shown in Figure 5.

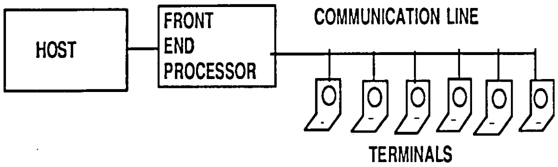

Figure 5
Simplified Layout of a Communication Line

Assume that only one message can be in transmission on the line at any time. In this case the communication line corresponds to the server in a single server queue, messages correspond to customers, and the service time for a customer corresponds to the time it takes to transmit the associated message from the terminal to the host or vice versa.

In this simple case, service time is a reasonably straightforward function of total message length (both data and overhead characters) and the bandwidth of the line (the number of characters per second the line can transmit). Essentially, service time in this case is equal to message length divided by bandwidth.

In reality, queueing models of communication lines are seldom this simple. An important complication arises because of the nature of inbound messages. These messages are prepared at terminals, where they must wait until the line becomes available for the next transmission. Since these messages are not all in one centralized location, it is difficult to arrange things so the "next" message begins transmission as soon as the transmission of the current message completes. In fact, it even takes some special synchronization mechanisms to prevent one message from attempting to use the line at a time when another message is already in transmission.

Note that these synchronization and coordination problems do not arise in the central server queueing model shown in Figure 4. This is because each queue in the central server model contains only local (rather than remote) customers. Thus it is easy for the software that manages each queue to determine exactly when one customer completes a service request, and to dispatch the next customer waiting in the queue without significant delay.

In contrast, the queue of inbound messages waiting for a communication line contains a geographically distributed set of remote customers. Any analysis of such a queue must account for the significant delays that occur between the completion of one service request and the initiation of the next. Because they include queues with remote customers, the mathematical models developed for telecommunications networks differ in important respects from the central server models used to analyze mainframe computer systems.

Systems Network Architecture, or SNA, is the hardware and software architecture employed in most IBM communications networks. Because it must support different types of communications hardware, SNA supports several alternative families of algorithms for managing message traffic between remote terminals and host computers. The next few sections of this paper discuss some of the more important algorithms and architectural concepts incorporated into SNA. The discussion will consider basic functionality as well as implications for performance modeling.

EFFECT OF POLLING

A number of techniques exist for controlling a transmission line to prevent attempts to transmit two or more messages at the same time, and to allow the "next" queued message to begin transmission once the line becomes free. The technique selected for use in SNA networks is known as polling.

To implement the SNA polling algorithm, a front-end processor (e.g. 3705) is placed between the transmission line and the host computer as shown in Figure 5. Conceptually, this processor tests the status of each terminal on the line in succession by sending a test message (a poll) to each. When a terminal receives a poll, it responds by either transmitting a message (if it has one ready) or by transmitting a "null response" indicating that it has no message ready. Once the front end processor has received a response from one terminal, it proceeds to the next terminal on the list. When the end of the list is reached, the polling algorithm in the front end processor returns to the beginning of the list and starts the next polling cycle. The list that controls the polling algorithm is known as the service order table.

Note that the simple queueing model in Figure 2 is no longer directly applicable since the sending of polling messages and null responses takes additional time, thus introducing additional delays between successive message transmissions. Suppose the service time per message is increased to account for these additional delays. That is, suppose the delays are added to the "basic message transmission time" in order to create a larger "effective message transmission time" for use in the model in Figure 2.

At a minimum, the additional delay is the time to transmit and propagate one polling message. However, there could also be several other polling messages, each followed by a null response, before an actual message is finally sent. Moreover, the number of null responses between actual messages will vary as a function of the total load on the line. That is, as the load increases, the expected number of null responses between actual messages will decrease. All these considerations make it difficult to determine the correct "effective service time" to use for the transmission line (the server) when attempting to apply the simple queueing model of Figure 2.

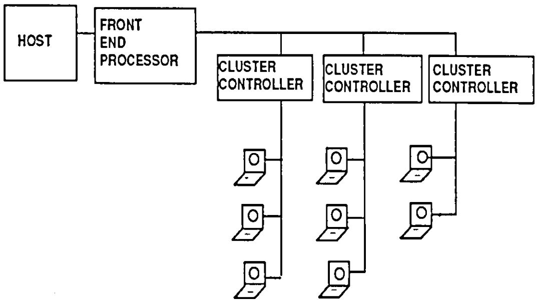

Figure 6
Position of Cluster Controllers

EFFECT OF CLUSTER CONTROLLERS

There are many other factors to consider when developing realistic models of SNA communications networks. For example, Figure 5 is somewhat simplified in that it shows each user terminal connected directly to the transmission line. In fact, a set of terminals is typically connected to single cluster controller, which is then connected to a line as shown in Figure 6.

The point here is that the polling messages generated by the front end processor are, in fact, sent to the cluster controllers rather than the individual terminals. This is more efficient since a single poll can now be used to test the status of several terminals. Hence, there will be less polling overhead and fewer null responses in each complete polling cycle. However, there is now an additional source of delay since the messages queued at terminals on the same controller must be transmitted sequentially. Thus, one of the messages at the controller will begin transmission as soon as poll is received, but all other messages present will experience additional delays prior to transmission. These delays are comparable in nature to the simple queueing delays in Figure 2, but must be combined with the polling delay described above for a complete analysis.

OUTBOUND MESSAGES

The original motivation for polling has just been presented for the case of inbound messages. In principle, outbound messages are simpler to deal with since they are queued together in the front end processor and are controlled by an algorithm executing on that processor. In SNA networks, this algorithm is conceptually similar to the inbound polling algorithm in that use of the transmission line is allocated to messages destined for each cluster controller by cycling through a fixed list (service order table). However, because the queue of outbound messages resides locally in the front end processor, the time to send polls and null responses is negligible. Thus, outbound message traffic is more naturally treated as an ordinary queueing process with local customers of a type illustrated in Figure 2. There are, however, a number of complicating factors, some of which are discussed below.

HALF AND FULL DUPLEX LINES

The transmission line connecting terminals with a host commputer must, in general, be able to handle both inbound and outbound messages. A half duplex line can only handle one message at a time, and thus must switch back and forth between inbound and outbound traffic, further complicating the polling processes described above.

In the case of a full duplex line, there can be one inbound messsage and one outbound message in transmission at the same time. This would appear to decouple the inbound and outbound traffic, allowing each to be analyzed separately. In fact, things are not this simple because there are interactions between inbound and outbound traffic even on full duplex lines.

One obvious interaction arises because of the interference between polling messages and normal outbound messages. Polling messages generated by the inbound polling process are transmitted on the same transmission lines as ordinary outbound messages. Thus, a model of the inbound polling process must account for the delay incurred when a polling message is being transmitted on the outbound message line. Similarly, a model of the outbound message process should include the effect of additional load due to polling messages. Some of the more subtle interactions between inbound and outbound polling processes are discussed below.

EFFECT OF MAXOUT, MAXIN AND ACKNOWLEDGEMENT MESSAGES

Data integrity considerations make it essential that all messages sent on a transmission line be checked for correctness at their destination. If the message passes appropriate tests (e.g., checksum OK), an acknowledgement is transmitted to the message originator. If there is a problem, a negative acknowledgement may be sent to request message re-transmission. Messages will also be re-transmitted automatically after a time-out period if no response is received by the message originator.

Complete messages in SNA networks are divided into a series of fixed length packets or frames (BLU's) prior to transmission. Each frame is tested for correctness at its destination, but to reduce overhead there are provisions for accumulating a batch of test results and sending only one acknowledgement per batch. The number of frames that are accumulated between each acknowledgement is specified by the parameters MAXIN and MAXOUT, which are always greater than or equal to one. MAXIN controls inbound messages, and MAXOUT controls outbound messages.

Suppose a total of MAXOUT frames have been sent to a cluster controller. No additional outbound frames will be sent until an acknowledgement is received. However, the acknowledgement represents an inbound message, and it cannot be transmitted by the cluster controller until the inbound polling process reaches it. Since the inbound and outbound polling processes operate asynchronously in a full duplex line, the outbound process typically experiences a delay at this point while it waits for the inbound process to catch up. In addition, the inbound acknowledgement messages generate overhead that interferes with the normal inbound message traffic. These factors must be included in any complete analysis of full duplex SNA networks.

EFFECT OF PASSLIM

Suppose a very long outbound message (comprised of many frames) is queued for transmission in the front end processor. If the entire message is transmitted when the appropriate entry is reached in the service order table, the line could be tied up for an extended period of time. To prevent this, the parameter PASSLIM is used to limit the number of outbound frames transmitted to a cluster controller each time it is encountered in the service order table. That is, once a total of PASSLIM frames have been transmitted, the polling process moves on to the next entry in the service order table even if there are more frames to send.

PASSLIM also limits the total number of frames that can be transmitted to all the terminals attached to a single cluster controller each time an entry for that controller is encountered in the service order table. For further analysis of PASSLIM, see [34].

It should be noted that an additional level of control is available in SNA since the number of times each controller appears in the service order table is user specified. Thus, if there are three entries for a given controller, the maximum number of outbound frames that can be transmitted to that controller per complete polling cycle is three times PASSLIM. Multiple entries also affect the inbound polling process, but in this case the main consequences are a reduction in polling delays prior to message transmission and an increase in apparent polling frequency.

EFFECT OF PAUSE

Suppose a complete scan of all the entries in the inbound service order table results in very few (or no) inbound messages. This indicates that line traffic was light during that polling cycle. Assuming that line traffic will remain light in the near future, it is not essential to begin a new polling cycle immediately.

The advantage of "pausing" before initiating the next polling cycle is that the front end processor's load will be reduced. This is helpful if the front end processor has other work to do, such as polling other lines for inbound traffic or managing the flow of outbound traffic.

The SNA paramater PAUSE is used to achieve this result. If the inbound scan time falls below the value of PAUSE, an appropriate delay is automatically introduced so that the time between successive scan cycles never falls below PAUSE. Proper setting of the PAUSE parameter is important for good SNA performance [34].

EFFECT OF SLOWDOWN MODE

The front end processor maintains buffers that are used to store messages waiting for outbound transmission to terminals or inbound transfer to the attached host. If line traffic is heavy, the buffers may fill up, making it impossible for the front end processor to accept additional inbound or outbound messages.

When this point is reached, the front end processor will devote all its capacity to clearing out its buffers. In the case of SNA networks, the front end processor is said to enter SLOWDOWN mode.

While it is in SLOWDOWN mode, the network will be unresponsive to users at terminals who are attempting to send new messages to the host. The additional delays that users experience at these times must clearly be considered when making a complete analysis of an SNA network.

CONCLUSIONS

The theory of queueing networks has advanced substantially in the past fifteen years. Much of the impetus for this expansion has come from the practical need to develop realistic models of mainframe MVS systems. With approximately one thousand MVS sites now using analytic modeling tools for capacity planning, it is clear that the gap between theory and practice has in fact been bridged. Recent advances in analytic models for SNA networks have enabled network capacity planners to take advantage of comparable performance prediction tools.

A Survey of the State of Art and Practice In I/O Subsystem Modeling and Analysis

Brian J. Smith

International Business Machines Corporation
General Products Division
San Jose, California

Abstract

This paper presents a survey of I/O Subsystem Modeling practice as seen in large IBM mainframe installations. It discusses state of the art techniques, but focuses on real problems, real techniques, and discusses the gap between art and practice.

The planning problem for I/O subsystems is a special case of the more general problem of system-wide capacity planning. Basically the problem is to predict the future behavior of a system from observation of its current behavior. There are two subproblems: the capacity planning problem for a particular installation and the system/subsystem design problem. The two problems are related, but the differ with respect to workload characterization. A particular installation can, presumably, measure and characterize its workload. System design problems must deal with typical or average or representative workloads rather than an actual workloads. Furthermore, the potential changes and variations in future workloads make the challange even greater for the system designer.

The approach to capacity planning or system/subsystem design being described involves measurements of existing computer systems to determine workloads. Modeling of the hardware configuration explains the behavior observed in the measurements. There are two distinct parts to modeling computer systems: 1) the system model describing the hardware, configuration, and algorithms controlling the system; and 2) the workload characterization which is imposed on the basic model. A significant factor in this approach is validation of the model -- making sure that the hardware model and workload characterization adequately explain the current state of the system behavior.

One approach to capacity planning or design trade-off studies uses Monte Carlo simulation. The performance analyst creates a model to simulate the detailed behavior of the hardware, drives it with workload descriptions and observes the system behavior. There is one fairly well known, though not generally available, tool based on such a simulation. It is called SNAPSHOT and described in [INGRA85]. Another approach is to use analytic queueing models. CRYSTAL is a modeling tool based on queueing equations. There is a very readable discussion and comparison of CRYSTAL and SNAPSHOT in [INGRA85].

For I/O subsystems, the models typically are based in simple queueing theory, though detailed simulation models work as well. If queueing theory is used to describe the behavior of the I/O subsystem, then the behavior of the hardware is transcribed into the primitives of queueing theory, namely arrival rates and service times. Arrival rates fall into the category of workload description, so the hardware part of the models involve more or less detail about the service time distributions or the size of waiting rooms in the system. The model must include such things as the number of I/O devices, number of data transfer channels, algorithms which control the hardware, such as path selection algorithms and whether or not the I/O devices use rotational position sensing (RPS). Other characteristics of the hardware such as the access times of the I/O devices must also be captured by the model. So the models are essentially collections of equations which describe the behavior (throughput and response time) of the hardware under various workload conditions.

The workload is described in units of work demanded of the system. First is usually the access rate. Some queueing models derive access rates from other input assumptions (such as multiprogramming level), but for most purposes we can assume the access rate for each device is an input assumption. The workload further includes such items as the number of bytes of data to be transferred (blocksize), and perhaps additional parameters involving seek times or other factors of interest. Estimates of these parameters for large IBM mainframe production systems can be found in [SMITH81].

The proportion of the access rate to each device is a very interesting piece of the workload description. Expressed as a probability distribution vector, we call this the I/O skew. Many of the examples in the literature assume a uniform arrival skew -- meaning all the devices do about the same amount of work. Of the input parameters for I/O subsystems, few have as much influence on the answers

CH2345-7/86/0000/0760$01.00 © 1986 IEEE

as the skew. It is fortunate that the arrival skew is routinely reported by most system monitoring reports, unfortunate that real skews are so seldom studied.

Many of the interesting articles in the literature focus on configurations, algorithms in the operating system, or microcode in pieces of the system. For example, multipathing considerations, RPS phenomena, and dynamic path reconnect are current topics of investigation. Cached DASD subsystems is an additional item of current interest. Performance models need to capture the operational characteristics of the microcode and data pathing implementations in order to adequately distinguish one product design from another.

Chapter 10 in the text by Lazowska [LAZOW84], provides a good introduction to I/O subsystem modeling. It discusses RPS phenomena, dynamic reconnect, and includes an introduction to cache modeling, as well. CMG '85 Conference Proceedings include a number of interesting case studies. Two which illustrate current topics are "Analysis of Device Level Select in IBM 3380 Disks" [BUZEN85] and "DASD Performance Analysis Using Modeling" [BERET85].

The text [LAZOW84] shows that analytic techniques are applicable to a broad range of problems in capacity planning and system evaluation. The mathematics has developed impressively, capturing the effects of several queueing disciplines and multiple classes of customers. These techniques have been implemented in a number of packages, such as BEST/1 and CRYSTAL from BGS Systems, MAPS from Amdahl Corp., and CMF from Boole and Babbage. SNAPSHOT and DCAT are IBM internal tools with similar capabilities, and VMPPF is an IBM program for capacity planning in the VM environment.

Simulation technology has also progressed over time. The IBM Research Queueing package (RESQ) is an example of a general simulation strategy with features particularly suited to the analysis of computer systems, capacity planning and system design questions [SAUER80].

After one develops a model of the hardware, the next step is to characterize the workload on the hardware. Workload parameters are usually estimated from software monitors. Examples of these monitors for large IBM systems include RMF for MVS, VM MAP for VM, and DOS/PT. Additional data is sometimes available from key subsystem facilities. For IBM products these include things like IMS Log, Database 2 Performance Monitor, and GTF Trace. Some applications lack adequate software instrumentation, which makes workload characterization difficult. For a good discussion of these issues, I suggest "Establishing Performance and Capacity Planning in a Conversion Environment," by Greene and Simon [GREEN85].

If one reads the articles mentioned in this survey, it becomes clear that capacity planning tools are plentiful and powerful. There is good progress and capability in analytic modeling. If the problems are important enough and too difficult for analytics, simulations can help provide the answers. Workload characterization is made feasible by software performance monitors. The goals and process of capacity planning are well understood, and are handled by several papers in the current session.

Most importantly, complete packages are available to do the job. They extract workload information from a running system, build a model of the configuration, and validate the model and workload characterization against the measured data. The performance analyst can use the model to study changes in hardware and/or workload. This does not mean that all the problems are solved. The "what if" studies still require experience and insight by the analyst. The amount of data involved in capacity planning studies can be enormous. Data entry and data manipulation is a problem. The current tools for for handling such data and system information are epitomized by SAS and MICS [CHEN85]. They foreshadow fourth generation database and data manipulation techniques.

Finally the whole process suggests knowledge-based or expert systems. The proceedings of CMG '85 have a representative collection of papers which capture the current state of this development ([ARTIS85], [HELLE85], [LEVIN85], and STROE85]). The essence of such systems is a combination of rules of thumb for good performance, combined with inferences based on the analysis of queueing models. Nevertheless, there is a considerable gap between what is possible and what is easy to do. [SMITH85] is an excellent dicotomy between the (largely unrealized) potential of the mathematical techniques and the problem of a friendly, flexible user interface.

Facing the Challenge of Other Problems

In the area of system/subsystem design, the difficult problems are a result of the long time frame involved. Real and potential changes to hardware must be evaluated, along with changes in software to exploit new hardware or simply to offer better function. The performance analyst is required to extrapolate far enough into the future to see where the system is likely to break or bottleneck. The job is to effect a change to the system design to avoid such s bottleneck. The system designer must stretch the capabilities of existing systems, thus establishing new rules of thumb for the system. This implies that a knowledge-based system for capacity planning will have to assimilate new rules over time.

Predictions as much as 2-5 years in the future rely on properly characterizing the workload and how it may be changing. From the perspective of a system designer, the problem is predicting the change in the workload. To be precise, the job is to design the change in the workload resulting from a change in the system design. Even simple modifications like a different number or type of devices in the I/O subsystem have potentially large impacts on the workload. As an example, consider a recent problem in capacity planning. What happens to the average seek time in an I/O subsystem when an installation migrates to a new, larger capacity device? It happens that there is nearly enough measurement data to predict the answer to this question, so it is surprising how many studies make simplyfing assumptions only to arrive at partial conclusions. This particular question is studied from real data in "The Impact of 2-to-1 Volume Folding on Seek Time" [MCNUT85].

But I/O subsystem workloads have many more elements in their characterization than seek times. There is connect time, disconnect time, including latency and RPS misses, as well as seek time. There is the access skew to the devices. For cached DASD there are hit ratios, read to write ratios. Even if you measure them in your current subsystem, how do you predict what happens to all of them when you make a change?

Another technique is to hold many study parameters arbitrarily constant while we change a few to study consequences. This specifically denies the possible interactions of several simultaneous changes. All this works well enough for capacity planning and its time frame, but the system design problem, with its longer time horizon, requires that more effort be spent to study possible interactions.

Other problems arise in the characterization and validation of a model. Consider a simple model of an I/O subsystem as a collection of M/M/1 servers. Each device is represented by a server with Poisson arrivals and exponentially distributed service times. Theory then predicts that at 50% device utilization, the response time for a device is twice the service time, or the wait time is equal to the service time. What does the measured data say? Measured data says that many devices have little or no queueing -- that is, the queue lengths are much less than most queueing equations predict. This is most easily understood by imagining the common situation in which exactly one task in the system is using the disk device. No matter how hard the task uses the device, there will be no waiting line when the task wants issues its I/O. Even so, M/M/1 queueing theory provides a lot of insight into the qualitative behavior of I/O subsystems. The problem, of course, is that as computer scientists, we want, expect, even promise quantitative descriptions of the behavior. So we apply the scientific method and try to improve our models.

What can we do to improve the predictions of wait time for I/O devices? We try M/G/1 equations, finite population models of one type or another, separable queueing equations [BUZEN73], even detailed simulations. But in the end there is always some system phenomenon which was not modeled -- which we handle by saying that the models are abstractions, and that the effects they ignore are second order effects. Examples include system design features that exploit parallelism in the I/O subsystem (such as the page/swap subsystem in MVS) or memory and lock contention in databases.

Usually they are second order, but not always. In many ways, the situation is similar to Newtonian physics versus relativistic physics. The simple models are adequate as long as you don't try to extrapolate their results too far beyond the range of current measurements. Trying to use more sophisticated models introduces additional complexity that may make it harder to decide about simple questions at hand. Using more complex models to attack the discrepancies on queue lengths adds extra parameters to the analysis -- parameters like multiprogramming levels, or variance of the service distributions. Often these new parameters cannot be extracted from existing monitors. As mathematically attractive as closed system models with nonhomogenous workloads may be, it is difficult to use an RMF report to apportion paging activity to different workload classes. For I/O subsystem models, it is hard to beat simple queueing theory augmented by heuristics to deal with new or unique features in hardware or microcode.

The problems are hard, but not insurmountable. So it is discouraging to see the simplistic answers that pass for computer science. It is discouraging to see performance studies use superficial techniques to predict disaster, but never check the assumptions against real data. If the workloads are characterized carefully, if the effects of change are given some thought, then the modeling techniques actually suggest ways to avoid disaster. Personally, I believe some performance analysts have more fun predicting disaster, especially if they can appeal to mathematical arguments to make the case that much more plausible.

On the other hand, models may suggest solutions which simply don't work in real systems. Queueing theory can be used to show the profound advantages of uniformly spreading I/O requests across all the I/O devices. But on systems like MVS or VM, the mechanisms which cause skew prevent us from easily modifying the skew toward uniform activity across devices. And in real systems it may not even be desirable. The busiest devices often have the least queueing because only a single task owns and uses the device. The mechanisms which spread activity across volumes would "probably" introduce queueing (wait time) where there was none. The operable word is probably. That is because there is no real program of experimental computer science to address these types of questions. There is not enough data to make scientific hypotheses to be tested by further measurements.

Right now, the mathematical techniques available to the capacity planner or the system designer are ahead of our willingness to collect and analyze data about real systems. We are unwilling to bear the costs. Better measurement techniques are possible, even advocated, but there is no systematic program of experimental computer science where a group is willing to put up money and facilities. Such a facility could be comparable to a physics research program. In part, this is because systems and technology are still evolving too rapidly for the performance engineers to evaluate every trade-off. Ferrari states other reasons for this phenomenon [FERRA86].

The Prognosis

The use of capacity planning techniques is widespread. Data processing shops are known to use sophisticated techniques, and the computer manufacturers apply similar technology to the design and evolution of their systems. Of particular promise are packages which measure a system, characterize its workload, construct a model of the hardware configuration and validate the model against the real system. Such systems are easy enough to use for them to become powerful tools for attacking capacity management problems -- they suggest tuning alternatives in the short term.

Traditionally, much tuning is trial and error. These modeling tools can now be used in a diagnostic mode to show where performance problems might be hiding. They can also use simple deductions based on queueing theory to suggest solutions to the potential problems. Admittedly, there are difficulties in this technique. The models need to be enhanced to deal with more complex workloads. There must be a way to incorporate some common sense into their recommendations. But you see the way this will evolve.

Already we read about expert systems for computer performance. Knowledge based systems to operate, tune, and design systems are receiving much attention. They will undoubtedly be a boon to the performance analyst in time. And as these systems become common and proficient, another development will occur. Systems will incorporate the same techniques to tune themselves. This is a natural evolution of operating systems and I/O subsystems. There are elements of computer systems which already exhibit this trend. The paging supervisor in MVS (VM too), the subsystems which allocate scratch and spool data sets on disk devices, and to some extent, the capabilities of cached I/O subsystems already exhibit the characteristics of self-tuning subsystems. So it is most fitting that the subjects of capacity management and capacity planning are topics of this particular joint computer conference dedicated to "Exploring the Knowledge-Based Society."

THE EVOLVING ROLE OF SOFTWARE PRODUCTS IN CAPACITY MANAGEMENT: A SURVEY

Phillip C. Howard, Editor

EDP Performance Review, P.O. Box 9280, Phoenix, Arizona 85068

Abstract

A great many tools have evolved over the years to aid in the capacity management area. In this paper, seven different tool categories are defined and described, including job accounting systems, hardware/software monitors, operations management, communications management, data management, simulation and modeling, and integrated systems. The types and functions of tools are described for each area, including their role in capacity management.

Introduction

There is no shortage of tools to aid capacity planners in doing their jobs, although the sheer numbers of those tools presents its own problem in terms of selection and training. There is no tool which can be said to be the perfect solution for capacity management. Probably those which fall in the general class of simulation and modeling come the closest. That is, they are primarily intended for predicting future capacity requirements based on given workload data, although their predictions are only as good as the forecast data entered into the model and the validity of the model itself. In short, there is no perfect answer to the capacity management problem in terms of software tools, but there are many which can help to make the planner's job easier.

No attempt at capacity management can be successful unless grounded on a firm base of measurement data which accurately portrays the present actual operating environment in terms of both workload and resource utilization. For that reason, a number of tools must be included which are primarily performance measurement-oriented, but which are critical in terms of supplying capacity planners with good measurement data about present operating environments.

Performance measurement or management, as differentiated from capacity management, generally refers to the measurement of existing systems for the purpose of tuning or optimization. However, because capacity management is so dependent on good measurement data, we view performance measurement as a subset of the larger function of capacity management for the purposes of this paper.

The Role of Products

For the most part, the entire capacity management profession has developed from the tools introduced by private companies, mostly entrepreneurial ventures that evolved from advances in the systems programming area. Although the tools market is dominated by IBM MVS offerings, the same capabilities are available for all mainframe vendors, albeit in smaller numbers. Nevertheless, it is probably safe to say that the technology has generally been based on IBM operating system software.

In most fields, academic research is the driving force behind the development of a technology. Except possibly in the area of queueing-based modeling, where the initial work was begun in a university environment, nearly all of the tools were developed in entrepreneurial settings. Several examples come to mind: the contributions of Dudley Warner to the field of hardware monitoring; Ken Kolence's early development of a software monitor and founding of Boole & Babbage; Jeff Buzen's development of the first modeling package for commercial use and his part in the founding of BGS Systems; and Mario Morino's contributions to the collection and archiving of performance data. There are certainly many other examples of individuals and companies which have contributed to the growth of this field.

The principal professional organization in the field, the Computer Measurement Group, has by and large grown up around the tools and technology offered by these types of companies, as opposed to developing around a strict academic discipline. In short, it is the tools and their application, plus the expertise in hardware and software that is found in the many small companies which make up this field, that accounts for much of the growth and success of capacity management.

In this survey, we have covered seven categories of software tools which are in general use in the performance management/capacity management field. Only the simulation and modeling category is really dedicated to the capacity planning problem. Most of the rest are primarily measurement or optimization tools. Both job accounting and software monitors provide almost exclusively measurement capabilities. The operations management group is more oriented toward optimization and making life easier for the operator, but scheduling packages, for example, may have a simulation capability to test the impact of introducing new applications. Both the communications management and data management categories focus primarily on measurement and optimization, but within each there are packages to aid in configuration and space management. The integrated systems typically offer a variety of capabilities, often with an interface to a modeling package.

Job Accounting Systems

Most advanced operating systems keep statistics on internal operations and collect that data in a file or data base. Numerous software packages have been written to process such "job accounting files", both for the purpose of billing resource use back to customers and summarizing the information into meaningful performance reports. It is the use of job accounting files (such as SMF and RMF in the IBM environment) as the primary source of input which uniquely characterizes this category of software tools.

In most cases, the activity data is collected at the termination of a specific event such as a job step, a transaction, a TSO session or other work unit. There are literally hundreds of specific measures or facts which may be collected, depending on the specific system, but the most common are metrics relating to CPU utilization, disk

CH2345-7/86/0000/0764$01.00 © 1986 IEEE

utilization, I/O requests, memory usage, paging activity, spooling statistics, volume mounts, terminal connect time, logons/logoffs, and similar measures. Most job accounting systems have some data base management capability to permit the retention and processing of historical data.

By their very definition, all job accounting systems have some capability for charging usage back to customers, although not all with the same degree of sophistication. In many cases, there is both an on-line and off-line aspect to the system. The on-line capability generally provides users with immediate feedback on the cost of their jobs or sessions and may provide for on-line inquiry into accounting data. The off-line portion produces invoices and other accounting reports. Many systems provide capabilities for user-defined charging algorithms, the input of manual charges and adjustments, comparison to budget data, and cost liquidation for full recovery chargeback situations.

The other major use of job accounting systems is in the reporting of performance data. In addition to serving as a basis for computing charges, the collected data can be processed and summarized to provide a wealth of information on performance and capacity utilization. Data can be sorted and summarized by user, project, shift, department or any other entity which can be identified as the source of work. Since all data is date and time-stamped, reports can be prepared by day, week, month, or any other time period to show workload levels and resource utilization for both a central system and a network. Reports can also be prepared of abnormal terminations and "top 10" or "top 20" lists to identify the largest users.

Although job accounting packages generally don't provide the same level of performance detail as either hardware or software monitors, they have the advantage of not requiring any changes to the operating system or operating environment. For this reason, they often serve as the starting point for users just starting in performance evaluation and capacity planning.

Hardware/Software Monitors

Software monitors differ from job accounting in that they generally have "hooks" into the operating system so that they can collect performance data directly, either from operating system tables and/or "control blocks", or by sampling various internal status conditions directly. Hardware monitors collect data by attaching to "probe points" on the computer system itself, avoiding the CPU and memory overhead that is required by a software monitor.

Monitors of both types provide more accurate measurement data than job accounting information and generally provide a more detailed look at the internal workings of the operating system. They tend to be more system-oriented than job or work unit-oriented, as are job accounting packages, although many of these packages allow the user to see relationships between job class performance and overall system performance.

Hardware monitoring of mainframes seems to be on the decline. In the past few years, hardware monitors have been disappearing from the market, although there are still a number of them to be found in user installations. They have not disappeared altogether, however. There has been a significant growth in the use of hardware monitors for communications networks.

Software monitors may be either sampling-type monitors or event-driven. In either case, they do impose some amount of overhead on the system, requiring a small amount of CPU time, memory space, and a collector device, usually either tape or disk. There is generally an extractor component, which actually does the data collection, and an analyzer component, which produces hard-copy reports from the collected data. Many software monitors also provide for on-line, real-time display of performance data to assist operators in controlling the system. In most cases, operators control the activity of the monitors (sampling intervals, duration of monitor period, areas to be monitored, etc.) through an on-line terminal.

Many different measurements may be taken by monitors, including CPU utilization, I/O and channel activity, paging and swapping, device allocation, disk arm contention, internal system queues, interrupt activity, and storage utilization. Some monitors also provide information about network activities, reporting on such things as response time, TSO activity, transaction rates, and transaction types. They may also provide information about the internal workings of the operating system to aid in decisions regarding page fixing, module assignments. etc.

In addition to raw measurement data, monitors may also detect and report certain kinds of system problems, monitor performance activity against operator-defined performance thresholds, and produce a variety of performance profiles and reports. In many cases reports and displays may be in graphic form, and user-defined reports may be facilitated through a report generation language.

The outputs of monitors are intended to support system optimization activities, and in some cases the monitor itself may take direct optimization actions. In addition, the outputs support capacity planning activities by providing the basic measurement data needed to detect trends in utilization, bottlenecks in configurations, and workload changes. In some cases, the data collected by monitors can be used as direct input to modelling packages.

Operations Management

This category of software packages is really made up of several sub-categories. The common denominator among them all is their support of the operations function in terms of streamlining work flow and optimizing the human/computer interface at the operator control level. There are five sub-categories which are described separately below:

Backup and Recovery - One common problem that all DP installations have is the backup, restoration, and recovery of DASD files and data bases. These packages generally replace mainframe vendor supplied utilities with improved performance and added functionality. The systems provide for the dumping of files to tape, compression of the data, frequency control of backups, automatic JCL creation, and security through encryption and/or passwords. Another type of package facilitates recovery from tape and/or disk errors, and analysis of tape media for quality.

Hardware Management - There are basically two functions performed by this class of package. The first accumulates error statistics from logged peripheral errors, maintaining historical records and providing for reports on potential reliability problems based on threshold error limitations. Potentially bad devices and/or media are identified. The second type of package maintains inventory data on all hardware devices incuding descriptions, leasing/pricing data, dates installed, maintenance contracts and similar information to facilitate management of the inventory of hardware and the preparation of equipment lists and other reports as necessary.

Operator Control - There is considerable diversity among the specific packages in this grouping, but most are directed at an improved operator/system interface. Such packages typically give the operator better control over the running of applications, improved communications with the system, special function keys, new message capabilities, access to and control over spool files, displays of system and job status, shared consoles, and other operational controls. Some of the packages also provide special capabilities for problem or event tracking and reporting.

Scheduling - This is the largest of the five groups and generally these packages are the most sophisticated and complex. Scheduling capabilities provide for the automatic submission of scheduled jobs, taking that task out of the hands of the operations personnel. Such systems include built-in calendars, job history information, priority setting, on-line inquiry into job status, automatic rescheduling, recognition of pre and post run manual activities as well as job dependencies, the prompting of operators for expected events, schedule revisions, and JCL input and maintenance. Most scheduling systems can also be run in a simulation mode to test the effect of new applications. A number of reports are typically provided as well, including daily production schedules, jobs completed and backlogged, performancc against schedule, off-line workstation activities, and job tickets.

Tape Management - This special class of package is intended to optimize and simplify the manual handling involved in tape libraries. Typical capabilities include automatic volume recognition, operator prompts for needed tape mounts, an on-line tape catalog, early device release, security controls, ownership pools, scratch dates, usage history, maintenance of generation data, and identification of tape location (including vault storage). Tape management packages also provide for several types of reports including data set lists, volume serial number lists, scratch lists, daily pull lists, tapes due for cleaning and certification, and volumes out of service.

Communications Management

In the context of performance management and capacity planning, the communications network is often just as important as the mainframe environment. There are several sub-categories of software tools which assist the user in analyzing and optimizing the communications environment.

Configuration Management - There is quite a range of variety among this group of packages, but most are intended to facilitate the management of the physical network configuration. The more elaborate of the packages provide for inventory management of the entire communications network, including problem/change control and tracking. Some packages generate the necessary software tables, parameters, and commands to properly start up the network. Others allow for special configuration capabilities not supported by standard mainframe software, for example automatic speed recognition and code conversions. Various reports may be produced by certain of the products to aid in the management of the network.

Data Manipulation - The few packages in this category generally provide data compression capabilities to reduce transmission times and improve throughput.

Design Aids - This group of products provides assistance to network designers in engineering optimum network layouts. Simulation capabilities provide estimates of service times by priority and throughput rates based on the characteristics of the network, traffic, and applications as specified by the analyst. The more sophisticated of the packages may produce an optimized topological design in hard copy and/or on a display screen. Yet another group of packages provides for an analysis of telephone traffic with recommendations for optimum line usage.

Network Monitors - This class of products includes both hardware monitoring devices as well as software monitors. Like mainframe monitors, they are designed to measure performance characteristics of a network during operation and provide network control personnel with displays and reports of network status, with particular emphasis on the status of lines, response times, outages, and traffic contention. Other types of measurements may include disk I/O activity, message lengths and counts, numbers of transactions by type, buffer use, terminal traffic, error counts, and polling time. Some monitors allow the operator to conduct tests and diagnostics on remote devices and provide alarms when certain performance thresholds are exceeded. Log files and/or a data base of historical network performance data may also be generated.

TP Control Programs - This group of packages have also been called teleprocessing monitors, but should not be confused with the type of monitor discussed above. Control programs provide operating system-like services, specifically improved interfaces between the application programs and the remote devices, including line control and terminal interfacing. They often perform functions which one normally associates with operating systems, including the scheduling and dispatching of TP programs, file handling capabilities, access to data bases, and message switching. These control programs may also collect operating statistics, provide restart capabilities, generate transaction logs, and provide traces of TP activity.

Data Management

With the expanding use of Data Base Management Systems and the growth of data bases, DASD storage has become one of the most significant resources relative to both day-to-day system performance and long term capacity planning. There are a number of tools available to aid the user in designing a data base, tuning and optimizing DASD storage, and handling utility functions such as backup.

Access Methods - There are only a handful of these packages, but they are intended to provide faster processing and access times than standard access methods.

Analysis and Monitoring - This group of tools performs analysis of existing DASD environments, either by examining VTOCs or Directories, or by monitoring DASD activity during program execution (much like a software monitor). The former type report on space usage, free space, track allocation, clustering, etc. The latter provides actual measurements of service time components on disk, CPU times, record counts, etc. Some packages maintain trend information to predict when space will run out and may provide information on such things as pointer problems, defective tracks, workload volumes, and problem areas. Analysis reports may support decisions regarding reorganization of DASD space.

Backup/Recovery - There are a number of products on the market to facilitate the backup and recovery function, most providing faster operation than standard system utilities, plus added functionality. Backup functions may provide for data compression and restructuring of files, compaction of fragmented files, and audit trails. Recovery tools typically produce a log or journal of activities, provide for the back-out of transactions when necessary, and requeue messages after a restart.

Data Base Design - In many cases, the design of a data base has a significant effect on the performance of an application. This group of tools provide the user with information on which to base design decisions. Given various design alternatives and information about the DBMS and the workload, such packages provide estimates of space and time requirements, recommend record design and logical/physical file organization, and may simulate application program logic. Outputs are analytical reports providing information on which users can base design decisions.

Space Management - This group of tools perform an active, rather than a passive, role in terms of DASD space allocation and management. Many of them actually administer direct access storage including such capabilities as archiving and migration of dormant files, sharing of disk areas between partitions, deleting obsolete files and truncating unused space, pooling of unused fragments of space, and dynamically allocating space as requested. Another group of products provide for optimizing the selection of modules for in-core storage to eliminate frequent fetches. In many cases, the products in this category produce reports analyzing the use of storage space, much like the Analysis/Monitoring category.

Utilities - Various DASD utility programs provide specific functions to improve the use of DASD storage including such capabilities as data compression, calculation of optimum blocking factors, conversion of data files from one device type to another, and encryption of data files.

Simulation and Modeling

For the most part, this category consists of queueing-theory-based modeling packages which are used for prediction of future system performance and capacity planning. The models typically allow the user to specify system configurations and workload characteristics and volumes, and produce projections of system response times, throughput, CPU utilization, device utilization, waiting times, and queue lengths. Most packages have interactive capabilities allowing the user to alter the basic inputs to the model and ask "what if" questions regarding future performance and capacity expectations.

Many of the packages accept measured performance data from job accounting or software monitor files and use this as the basis for constructing so-called "baseline" models in order to validate the basic model for the given environment.

In addition to modeling mainframe system operation, there are also several models which can be used to evaluate communications networks, and others specifically designed to predict the performance of applications prior to their development. There are also synthetic workload drivers which allow a user to simulate a real workload on their actual hardware and software configuration and measure the results directly.

A number of years ago, before the advent of queueing-based models, there were several event-based simulation packages which were used primarily for equipment selection decisions. These packages maintained libraries of hardware/software specific data to enable the comparison of different vendors' systems on a given workload. There is only one of those packages, SCERT, which is still being marketed. Otherwise, the queueing-based models are used primarily for capacity planning within a single installation, rather than for comparison of different vendor's equipment.

Integrated Systems

This relatively small group of products generally encompass several of the functional characteristics covered in the other categories, possibly providing capabilities in the areas of job accounting, monitoring, operations management, and modeling or at least an interface to another modeling package. One of the unique characteristics they possess is a performance data base, or a formal and organized approach to the archiving and summarization of historical performance data.

These packages provide capabilities in both performance evaluation and capacity planning, usually with interactive user control over their operation as well as an extensive repertoire of reports.

Summary

Readers might argue that many of the capabilities of software tools discussed above don't really have much to do with capacity management. Technically, this is true; many of them are strictly for tuning and operational enhancement. However, all of the categories should be considered within the context of capacity management, even though some of the specific capabilities may not be applied in that area.

The important point to remember is that any capacity plan must be constructed on a foundation of solid measurement data. All of the various tool categories provide measurement data in one form or another. Furthermore, even optimization and tuning affects capacity planning to the extent that future hardware requirements are reduced as the performance and throughput of existing systems is improved. Certainly, capacity planners must at least know what the possibilities are and when improvement efforts are being applied.

We have not provided any references throughout this paper, not because there aren't any, but because there are too many, few of which really stand out, at least when we restrict the subject matter to tools per se, rather than the larger subject of the tool category itself. In ACR's *EDP Performance Management Handbook*[1], Volume 1, there are bibliographies for most of the areas covered listing numerous references. Similarly, in the Annual Reference Issue of the *EDP Performance Review*[2] a subject index of the literature for the previous calendar year includes coverage of most of the tool categories.

The only book which has been written specifically on the subject of tools in this field is *Computer Performance Evaluation: Tools and Techniques for Effective Analysis*[3], although there is also coverage in the *EDP Performance Management Handbook*[1] of tool usage (Volume 1) as well as detailed descriptions of specific tools in Volume 2 (updated quarterly). The Special Reference Issue of the *EDP Performance Review*[2], mentioned above, provides capsule descriptions of the available tools in ten subject categories.

THE EVOLUTION OF WORKLOAD MANAGEMENT IN DATA PROCESSING INDUSTRY: A SURVEY

T. Leo. Lo

McDonnell Douglas
Aerospace Information Services Company
St. Louis, Missouri 63166

ABSTRACT

Data processing workload management is an essential component of the capacity management (CM) process. Workload management consists of workload characterization, workload forecasting, and workload control. Workload characterization is concerned with the measuring and modeling of production workloads; workload forecasting is a process of projecting future resource usages based on measured or observed statistics; workload control is a procedure to implement and monitor the workloads.

This paper reviews the past ten years (1976-1986) of workload management activities in the data processing industry based on documents and proceedings from the Computer Measurement Group (CMG), the International Conference on Computer Capacity Management (ICCCM), the Computer Performance Evaluation User Group (CPEUG), and the European Computer Measurement Association (ECOMA) conferences. All three areas in workload management are discussed with emphasis on their past and present activities and future direction.

INTRODUCTION

Capacity Management (CM) can be generally described as a process to ensure that the processing capacity can and always will deliver the services to meet DP users productivity goals within their budget requirement. These capacity, service and cost requirements are the integrated mechanism driven by the processing demands (workloads) to provide information for DP management making appropriate decisions. Therefore, capacity planning, service level management, cost management, and workload management, together with the corporate business plans constitute a management decision support system (ALLE83, DITH83, HOWA80, LO84, MULLE85).

Capacity planning is concerned with the management of resources and configuration and the prediction of service impact due to workload changes. Service level management is concerned with the service agreements between service provider and end-users in terms of timeliness, accuracy, reliability, and cost (HOWA80). Cost management deals with the recovery of DP expenses by establishing standard rates for different types of users running in different time zones and applications. Workload management is treated as an external driving force to the capacity-service-cost component due to its vacillating nature. The corporate business plans are also treated as an external factor, but they are more influential than workloads since business plans include many non-DP factors such as business strategy, industry growth potential, competitive pressures, and economic impacts. The conceptual diagram of these relationships is shown in Figure 1.

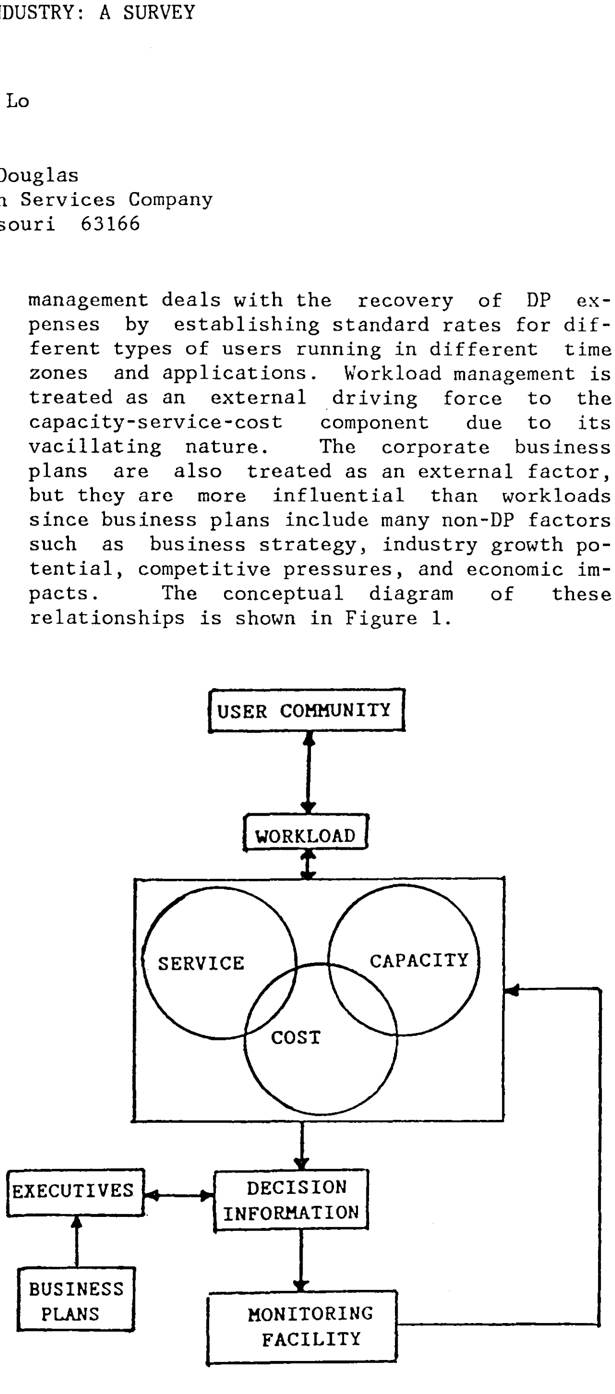

FIGURE 1 - A MDSS STRUCTURAL DIAGRAM

This paper only addresses the workload management portion of the capacity management. It however will conceivably address other areas of CM since they are interrelated. Workload man-

agement consists of three key prospective areas: workload characterization, workload forecasting and workload control. Workload characterization is concerned with the measurement and modeling of the production workloads; workload forecasting is a process of projecting future resource usages based on measured or observed data; workload control is a procedure to incorporate the forecasted requirements into the capacity planning process and continue to monitor the implemented workloads for possible future modifications. It is not the intent of this paper to suggest or recommend methods or techniques for workload management. It merely reviews all three areas in detail with respect to how the DP industry has been dealing with them in the last ten years (1976-1986), and what the future directions are. Some of the problems encountered in managing workload are also presented.

The references used in this paper are based on the Computer Measurement Group (CMG) 1976-1985 conference proceedings, the International Conference on Computer Capacity Management (ICCCM) 1979-1985 proceedings, the Computer Performance Evaluation User Group (CPEUG) 1976-1983 conference proceedings, and the European Computer Measurement Association (ECOMA) 1983-1985 conference proceedings. All references are listed in one of the three areas based on the nature of the material: workload characterization, workload forecasting, and workload control which addresses other areas in CM including the workload management.

WORKLOAD CHARACTERIZATION

Workload characterization, or workload classification as some DP analysts call it, is concerned with the measurement and modeling of the production workloads. The purpose of characterizing the workloads is to understand/determine the resource usages and performance behavior for subsequent system tuning, performance evaluation, and/or capacity planning activities. Most workload characterization performed in DP industry is for workload forecasting which is used as an input to the capacity planning process.

The most publicized workload characterization technique is the Cluster Analysis approach. It is a technique which attempts to identify the natural groupings of jobs (or transactions) based on the similarity of the resource requirements. One way to determine the resource requirements is to use the vector form. There are generally five steps to group jobs or transactions.

* Define a resource vector (CPU seconds, storage bytes, disk I/O etc.) for jobs;

* Identify sets of similar jobs (or jobs steps) based on the description of their resource requirements. A geometric distance between a resource vector and a cluster is the measure of similarity. A job can be assigned to a cluster by finding the minimum of the distances between this job and each of the cluster centroid;

* Scaling the resource vectors; scaling is designed to avoid possible mistakes when comparing the geometric distances of a resource vector (e.g. number of tape drives) with another distinct resource vector (e.g. No. of disk I/Os). Scaling can normally be accomplished by normalizing each resource with its robust mean and standard deviation via a Z statistics;

* Provide the description of all the input data and cluster assignments. When the clusters generated from the sample input are used to classify the entire input data, each resource vector is assigned to the nearest cluster based on the geometric distance calculations; and

* Create a workload mix using a mix vector representing the different time intervals (i.e. prime shift, weekends,etc.) for subsequent benchmark generation.

Artis (ARTIS76) presented a case study using this technique for determining the capacity of a batch computer system at the 12th CPEUG conference in 1976. Agrawala and Mohr (AGRAW76) at the same conference presented the result of applying the cluster analysis technique to predict the workload of a computer system. Agrawala & Mohr (AGRAW77A) again presented the results of applying the clustering approach to workload modeling at 13th CPEUG conference in 1977, and discussed the relationship between pattern recognition problems and workload characterization problems at the 1977 CMG conference. Since then there have been many applications of the cluster analysis on computer workload modeling (AGRWA78B, HUGES78, ARTIS79, HARTR79, ELMS80, MOHR80B, LEVY81, SMITH81, FRIED83, LEE83, VINCE84, DOMAN85).

In addition to the application of cluster analysis, there were several articles discussing characteristics and problems of the technique. Mohr (MOHR80A) presented a survey of available workload characterization techniques at the 1980 CMG conference. There were many articles in ICCCM conferences to discuss workload characterization problems (MERLO83, PRICH81, YEN83). There were also many articles discussing the workload characterization and modeling implications/problems at the CMG conferences (HUGES80, MOHR81, SMITH81, WIGHT81, GILMO82, FRIED84, DOMAN85).

Although benchmarking is a natural continuation of workload characterization, it can be treated as a separate topic in workload management. Benchmarking is one of many ways to determine the dynamic nature of a user workload on a given system configuration. Determining the workload characteristics and the basic benchmark measurements can be accomplished following basic modeling techniques. There were so many fine articles on benchmarking at the ICCCM, CMG, CPEUG and ECOMA conferences (e.g. DUJMO80, KAZLA83, PLICH84), that this paper does not attempt to address the benchmarking issues.

The second workload characterization approach is the use of Software Physics concept first introduced by Kolence (KOLEN76) in 1976. It is a study of the quantitative and measurable properties of executable codes and their operands in relation to configurations and class of processors and storage devices. Kolence (KOLEN77) and Hoffman (HOFFM77) both gave a very good presentation on software physics at the 1977 CMG conference. Software physics focuses on a single measurement: software work. User demands, system performance and future requirements can all be represented and quantified through the application of this measure. The basic measurable properties are work (W), time (T), and storage (S). The basic unit is a quantified unit which can be converted to software work per equipment class by means of some scalar quantity. Workload can then be characterized in a vector form which can be normalized as the unit vector form. For example, for a Mth class job, it could have

$$J(M) = W \begin{vmatrix} W(CPU) \\ W(I/O) \\ W(tape) \end{vmatrix}$$

units of software works, where W is the total work performed over a period of time for Mth class job, and W(x) is the measured work for an equipment class, CPU, I/O or tape.

The application of software physics has been greatly promoted by the Institute for Software Engineering, which was changed to the Institute for Information Management later to broaden its services to the information society. Greenacre (GREEN76) presented a general description of the software physics at the 1976 CMG conference in Atlanta; since then more applications were reported at various DP conferences (HOFFM77, DAVID79, KOLEN79, SENSA79, WILLI80, KOVAC81, MEADA83, CLEME85).

In addition to the cluster analysis and software physics approaches, the traditional way of using some statistical methods still accounts for a significant portion of the workload characterization activities in the DP industry. The common practices are: (i) to identify the resources to be tracked, such as CPU utilization, I/O EXCP counts, (ii) to collect resource usage statistics, and (iii) to group resources either by major application class (e.g. IMS, TSO), time zones (8 to 5, weekend), or both. However, this approach is different from cluster analysis and software physics that it uses collective sum of ALL jobs belong to an application class, thus ignoring individual job's influence.

Anderson (ANDER79) presented a technique using statistical regression to determine the resource consumption overhead for each major class of users at the 1979 CMG conference. Davis and Lo (DAVIS81) reported the evaluation results of several methods in determining resource overhead for proper workload characterization at the 1981 CMG conference, and concluded that even with the production workloads, there is no one method that is always superior than the other methods. The Statistical Analysis System (SAS) is probably the most widely used tool for reducing and grouping workload data on IBM systems (e.g. PEDRI78, PHIPP81, BROCK82, and HINTZ83). Again, the data manipulation is a separate topic in capacity management and is also addressed at this conference. Therefore, most SAS related reports were not included in the reference.

In the last six years, the concept of the Natural Forecast Unit (NFU), introduced by Kolence (KOLEN76), has been gradually applied to both workload characterization and forecasting. The NFU approach is to identify and group resource usage patterns based, not on the traditional DP resources, but on the end-user business oriented terms, such as number of checks printed and number of hospital beds. This approach is different than the traditional approaches, including cluster analysis, that it uses a bottom-up approach as opposed to the top-down approach. The NFU approach will be explored further in the workload forecasting section.

WORKLOAD FORECASTING

Forecasting can generally be described as a process of projecting the past into the future. It is concerned with determining what the future will look like. There are three types of forecasting routines that are frequently referenced by the DP industry:

* Short-range forecast - usually is in monthly/quarterly units and extends out over the next few months/quarters, but seldom goes beyond one year. It is sometimes referred to as an "operating" forecasting since it deals with the immediate future operations.

* Medium-range forecast - usually is made on a quarterly or annual basis, and is used to establish the processing capacity for the next year. It is often referred to as the "budgetary" forecasting. Some organizations extend the range to one to three years.

* Long-range forecast - most companies make some attempts in various degrees of sophistication to determine the long-run course of the future. The business direction and national economy trend are the key elements considered. It usually forecasts over the next five to ten years; thus is referred to as the "strategic" forecasting.

Most DP workload forecasting activities deal with the short and medium range forecasts, and very seldom deal with the long range forecast (MAGER79, SHERK84) since the DP workload forecasting tends to become less accurate the further into the future.

Before any forecast is done, a forecast system needs to be established. Three generally used approaches are:

* Model development - based on objectives, various models can be properly chosen. One analyst may use a regression model whereas the others may wish to use a smoothing technique.

* Eclectic research - is a strategy of comparing one method against the others both objectively and subjectively. Tables, graphs, surveys, and models are commonly used to serve the means of comparison.

* Judgement model - it is generally a subjective process, qualitatively but not quantitatively. It usually consists of information or opinion from people who have direct experience on the subject, historical analogy, and the management's direction.

Most DP installations establish their forecast systems using the first two approaches. This paper does not intend to address how to establish a forecast system.

Once a forecast system is established, certain analysis techniques are required to calibrate and validate the data. There are three general approaches that are used by DP analysts and planners: naive method, time series and natural forecast unit.

The naive method generally does not attempt to explain the cause of an event, but simply examines variations over times. In other words, it only uses data on the variables of interest and simply projects the historical patterns into the future. The "rule-of-the-thumb" sometimes are applied to incorporate expert's experience into the data analysis process. In the early DP days when the system accounting data was not fully implemented, the eclectic research and judgmental approaches were used.

The second type of data analysis approach and probably the most common approach is the use of the time series techniques. A time series is a set of observations taken at specific times, usually at equal intervals. It can be described by thinking a point moving to the passage of time. Analysis of such movement is of great value in many respects, one of which is the problem of forecasting future movements. There are in general four types of movements:

* Trend movement - refers to the general direction in which the point moves over a long period of time.

* Cyclical movement - refers to the long range oscillations about a trend line or curve. The cycle may or may not follow exactly the similar patterns after equal time intervals.

* Seasonal movement - refers to the identical patterns which a time series appears to follow during the corresponding months of successive years.

* Irregular or random movement - refers to the sporadic motions of time series.

A majority of the reported DP workload forecast approaches use the time series analysis techniques (DEAGR84, HOFFM82, KULP80, LUIST83, MACKI78, PERLM79, ARTIS80, LINDE80, NIEDZ83, REED81, SHERK84). Some consider the trend only while others consider both trend and seasonality effects. There were also general descriptions on workload forecasting techniques at the CMG (BIASI85), ICCCM (LO80), and CPEUG (MCNEE79) conferences. Although workload forecasting is commonly used to determine an application's future resource usages, it can be used to estimate other types of DP activities such as software development effort (GODWI85), new applications (INGRA85), resource correlation analysis (YEN85), and service level management (HALBI80). In addition to the application of time series techniques, the potential problems facing workload forecasting were also discussed by Allen (ALLEN83), Applegate (APPLE83), Lo (LO85), and Wandzilak (WANDZ84) at the CMG conferences, and by Lo (LO84) at the 1984 ECOMA conference.

The third approach of the DP workload forecasting is the use of the natural forecast unit (NFU) concept. The NFU concept is also referred to as the Key Volume Indicator (KVI) by Sarna (SARNA79). A NFU is a measurable business oriented unit for which DP resource usages are tracked. For example, in an airplane manufacturing factory, the appropriate NFUs could be the number of engineering drawing hours, number of spare parts ordered, and number of training hours, etc. The underline principle behind the NFU approach is that the DP users, given sufficient information, understand their own needs. They probably can not forecast accurate DP resource usages, but can predict their business related growth with a fair degree of confidence.

When a corporation's business plans are established, they can be translated into the corresponding DP resource units (DPUs). Therefore, the NFU approach attempts to link business plans to DP plans. Figure 2 shows a conceptual process which links corporate plans and DP plans.

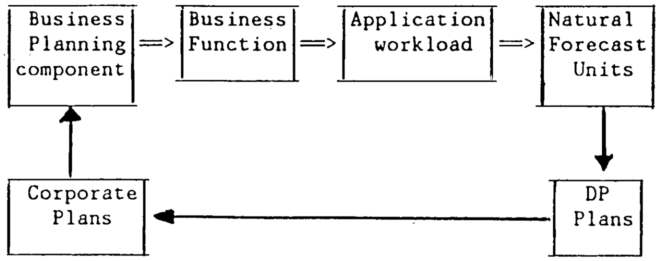

Figure 2 A Conceptual NFU Approach

To Correlate the NFUs to DPUs is not a straightforward process. In addition to the correlation process, the accuracy of the future DPUs is depended on the accuracy of the business forecasts. It is therefore advisable to use multiple forecasted values to represent a range of expectations in order to minimize forecasted errors. The NFU approach requires a computer resource usage measurement package, such as job accounting system, and a statistical method, such as regression models, to correlate business and computer forecasts.

Febish (FEBIS81) discussed the fundamental rules of converting business plans to DP workload forecasts at the 3rd ICCCM in 1981. Waggoner (WAGGO84) emphasized the importance of database design to integrate business and DP plans at the 6th ICCCM in 1984. Liu (LIU85) presented an excellent case study on using NFU dependency analysis for the production CICS workload forecasting at the 7th ICCCM in 1985. Lo and Elias (LO86) discussed the pros and cons of applying the NFU concept in a manufacturing environment (the paper has been submitted to 1986 CMG conference to be held in Las Vegas).

WORKLOAD CONTROL

The workload control is concerned with the implementation and monitoring of the workloads. The implementation involves the data selection, data adjustment, and forecasting technique implementation. Workload monitoring includes data collection and reporting, and data projection analysis.

The essence of workload forecasting is the extrapolation into the future of some structure in the past and present situation, regardless which approach is used. The approach itself, however, can not provide good forecasts unless there are some controls over input data as well as the selection of the forecasting parameters. Therefore, the forecasting parameters must be determined. As indicated before, most DP installations use system accounting data as the forecasting parameters. The length of historical data to be collected is suggested, as a rule of the thumb, at least four times the square root of the number of forecasted periods (LO80); that is, d > 4 * SQRT(f). Others simply use d > f.

There are two major concerns regarding data selection. The first one is the data quality; most DP installations archive a lot of system log data over a period of several years, but may not have the "right" type of data. For example, if the number of sheet metal cut per hour is used as the forecasted NFU, an installation may not have that type of information in its historical database. The second concern is the way data is collected and interpreted. For example, marketing people may forecast their sales revenue based on individual salesman's numbers which generally contain more variances since they always use a % growth over the past year.

To reduce data variances, data need to be adjusted. There are four practical ways for data adjustment. The first one is the adjustment of the time period. Most forecast mechanisms are based on the assumption that data arrive at fixed intervals. An accounting month may not be the same as a calendar month. Therefore, accounting data periods may require adjustment. One way to adjust the differences between a four-week month and a five-week month is to assign weights to make them equal. The second data adjustment is the adjustment for known causes such as holidays, strikes, etc. One example of data adjustment used in DP industry is to determine the peak-to-average resource usages for planning purpose.

The third data adjustment is to adjust the range of the data in order to reduce the variances. For example, the Z statistics is used in cluster analysis (ARTIS76) to reduce the variances between two types of resource vectors with distinct values. The fourth type of data adjustment is also concerned with the reduction of data variances. It transforms the data before carrying out the forecasting process. The common transformations are

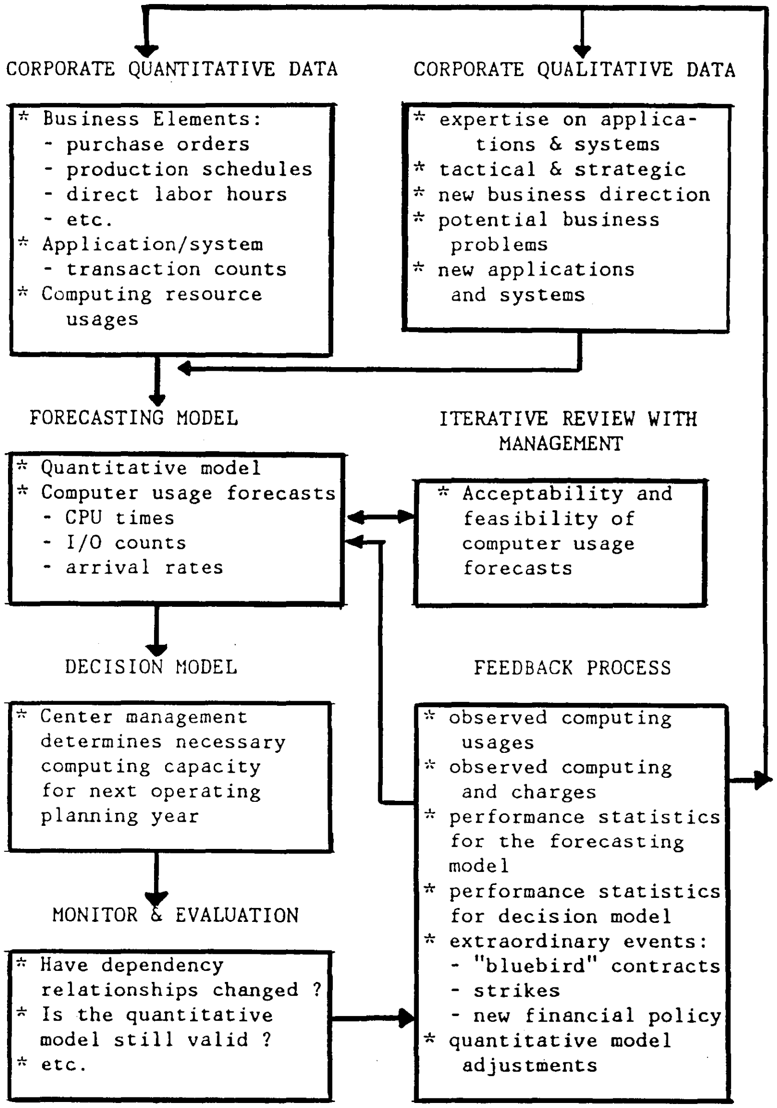
$$Y(t) = LOG\ X(t)$$
$$T = X(t) - X(t - 1).$$

The first one is commonly applied to reduce the percentage changes to absolute changes, to reduce the growth model to a linear model, or to change from a multiplicative to an additive seasonal form. The second transformation is frequently used as a device for removing the effect of a wandering mean.

The workload monitoring process involves data collection and reporting, and projection analysis. Data collection and reporting are generally managed by using either vendor supplied system accounting packages, home-grown data collection tools, or commercial packages. Regardless which method is used, a large amount of storage would be required to to store the historical database. Most DP installations keep the current month/quarter data on on-line storage devices and the past months/quarters on either off-line storage or mass storage system. In order to produce reports, most IBM installations use SAS to manipulate their voluminous data. There are many data collection and reporting packages, such as Morino Associates' MICS, Boole & Babbage's CMF, Boeing Computer Services' SARA, and IBM's RMF and SMF, to just name a few.

One of the major concern, from capacity management viewpoint, is how to link the end-user services (e.g. response time and availability for on-line applications) and the processing capacity (e.g. CPU, memory and I/Os). In a large corporation, it is cost prohibitive to measure the entire workload with respect to linking service and capacity. In other words, what end-users see the response time (service) may be different from what the monitor reports simply because delays occurred at the communications network components can not be accurately and/or completely measured. Consequently, the forecasted resource (capacity) usages can not be correlated with the services delivered.

The projection analysis is actually a review process which tracks forecasting parameter statistics, incorporates the forecasts into the management decision support system, and reviews the feedback process. The center of the review process is the management decision support system; the relationship among various components in capacity management has been extensively discussed at the CMG, ICCCM and ECOMA conferences (ALLEN83, DITHM83, HOWAR80. KOLEN77, LO84, LO85, MULLE85, ORCHA85, POLLA84). The overall concept of the review process can be illustrated by the detailed execution flow of the NFU application discussed by (LO86), as shown in Figure 3.



CORPORATE QUANTITATIVE DATA
* Business Elements:
- purchase orders
- production schedules
- direct labor hours
- etc.
* Application/system
- transaction counts
* Computing resource usages
CORPORATE QUALITATIVE DATA
* expertise on applications & systems
* tactical & strategic
* new business direction
* potential business problems
* new applications and systems
FORECASTING MODEL
* Quantitative model
* Computer usage forecasts
- CPU times
- I/O counts
- arrival rates
ITERATIVE REVIEW WITH MANAGEMENT
* Acceptability and feasibility of computer usage forecasts
DECISION MODEL
* Center management determines necessary computing capacity for next operating planning year
FEEDBACK PROCESS
* observed computing usages
* observed computing and charges
* performance statistics for the forecasting model
* performance statistics for decision model
* extraordinary events:
- "bluebird" contracts
- strikes
- new financial policy
* quantitative model adjustments
MONITOR & EVALUATION
* Have dependency relationships changed ?
* Is the quantitative model still valid ?
* etc.

Figure 3 NFU Application Execution Flow

DISCUSSIONS & CONCLUDING REMARKS

It appears that cluster analysis is more popular than software physics probably because of its statistical nature for easier acceptance. The software physics actually requires no more background skill than cluster analysis technique, but has not gained much acceptance probably due to its symbolic formats that are not natural to most DP analysts. One of the concerns on cluster analysis is that if a cluster contains a mix of applications such as TSO and IMS transactions, and short batch jobs, where and how to properly incorporate end-user's forecasted growth. In other words, a cluster's future direction may represent that particular cluster's growth, but an application's forecasts do not break down by clusters. Hence, it may require another layer of processing and analysis effort to translate user's forecasts into each clusters. The concern on software physics is not on its technicality, but on its formality. Performance analysts may be familiar with the hexadecimal numbers but may not be, psychologically, familiar with the Greek-like symbols and its multidimensional vector relationship.

However, both approaches are no doubt better than the traditional intuitive workload characterization approaches. One of the major factors that will make any method popular is through commercialized packages. Although there have been a lot of reported case studies on workload characterization, they are individual applications. There are several cluster analysis programs such as the ISODATA Points program by Ball & Hall from Stanford Research Institute (ARTIS76). The Institute for Software Engineering (now The Institute for Information Management) had partially incorporated the software physics concepts into their DP educational programs and consulting services. For example, they developed a set of programs to measure the relative power of various types of CPUs and I/O devices. However, as far as workload characterization is concerned, there is still a demand for an automated commercial package to characterize the workloads from immense data.

Workload forecasting is probably the most difficult task in capacity management process. It is a collection of individual forecasts which tend to inherit errors from the algorithm used. Another layer of complexity is that each corporation's business plans actually govern the future business direction. Business plans are made based on previous experiences and external influences rather than internal measurable units; hence they tend to produce higher forecasting errors. One good example is that the sale of the high technology product (i.e personal computers) was forecasted to be doubled every year. We have seen a much slower growth rate after only five years of the introduction of the personal computers.

As far as DP workload forecasting is concerned, the dominant techniques are still statistical methods especially the time series techniques. The NFU/KVI concept is an ideal way to incorporate business activities into DP plans, but its acceptance has not been as expected mainly for two reasons. First, there are lack of standards to select proper NFU parameters to forecast since every business preserves its unique characteristics and requires special skill and understanding to select NFU parameters; and second, there is no available commercial package which can readily link the business plans and the corresponding DP resource requirements. Boole & Babbage company is probably one of the leading developers to incorporate the NFU concept into their CMF product lines. Regardless which approach is used, there is still a demand for a complete commercial package to incorporate proper forecasting techniques into an automated process with satisfactory results. Again, a word of reminder: the skill, experience and knowledge of the analyst still play an important role in the workload forecasting process.

The workload control is actually an instrumental measurement and reporting process. There are many automated data collection and reporting packages that provide excellent data manipulation and management capabilities for a DP installation. The only problem is that there is no one complete package that can link the capacity, service and cost information to produce a timely decision support information so that the management can make right decisions at the right time to provide the best services at the most economic means.

In summary, the three pertinent components of the workload management have been discussed. There have been many individually reported case studies applying various techniques in workload management. But the urgent need is not to develop more techniques but to incorporate available techniques such as cluster analysis and the NFU concept into a complete package which provides sufficient and timely information for the analysts and management to properly manage their workload growth in the years yet to come.

Abstract

This paper surveys the approaches to software performance from the 1960's to the present. It points out the breakthroughs leading to the software performance engineering approach (SPE), a comprehensive methodology for constructing software to meet performance goals. SPE advocates building performance into the software architecture (as opposed to tuning code). The paper summarizes the concepts, methods, models, tools, and use of software performance engineering and suggests future trends in each of the areas.

Introduction

Software performance engineering (SPE) is a method for constructing software systems to meet responsiveness goals. With it, one models software requirements and designs, and evaluates whether predicted performance metrics meet the specified goals. If not, alternatives are proposed and assessed. The process continues through the detailed design, coding, and testing stages to develop more precise models of the software and its predicted performance.

Performance refers to the response time or throughput as seen by the users, that is, its responsiveness. Real-time command and control systems must be responsive to be correct. Shneiderman observed that responsiveness is an important human interface factor in all systems [SHN79]. Since it limits the amount of work that can be processed, it also determines a system's effectiveness.

SPE focuses on software development, but it is also an important part of a capacity management program [BER84]. Accurate planning requires data on new applications and data on the effect on resource requirements of growth in current work; SPE models provide both. Three important factors that capacity management should address are in Figure 1.

A passive capacity planning program anticipates growth and reacts to it. The approach advocated in Figure 1 is an *active* capacity *management* program that controls configuration requirements. Growth in workload demands may be inevitable, but growth due to resource requirements of software can be controlled through SPE.

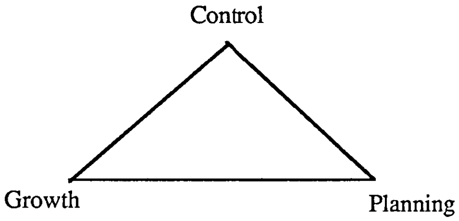

Figure 1. Capacity Management Functions

Many aspects of capacity management are dependent on the execution environment. Other papers in this session are specifically oriented to IBM environments. SPE, though, works in all computer environments. System dependent characteristics are incorporated into the SPE models.

This introduction claims that SPE is a viable methodology. The next section reviews its evolution from the first applications, through the modeling breakthroughs to the tools and methodology that established its viability. Then, recent advances are described, and finally, the future of SPE is predicted.

Early approaches

Performance was typically considered in the early years of computing. The space and time required by programs had to be carefully managed in order to fit them on small machines. The hardware grew but, rather than eliminating performance problems, it made larger, more complex software feasible and programs grew into systems of programs. Some of the software systems had strict performance requirements, such as flight control systems and other embedded systems. Performance modeling and assessment for these systems was expensive and labor-intensive. They used detailed simulation models, consequently creating and solving them was time-consuming. Updating the models to reflect the current state of evolving software systems was also problematic. Thus, the modeling and assessment was cost-effective only for systems with strict performance requirements.

Other systems adopted the "fix it later" methodology. It advocates concentrating on software correctness, deferring performance considerations to the integration testing phase and (if performance problems are detected then) procuring additional hardware or "tuning" the software to correct them. The results have been acceptable until recently. The following figure explains why it no longer works:

Response time was seldom a problem for batch systems. When on-line systems were first introduced, they had modest resource demands, and there were fewer users and other systems competing for the resources. Since then the number of users and on-line systems have grown substantially. The systems now have more ambitious functions, rely on large data bases, and use fourth generation languages; thus, the demand has significantly increased. As Figure 2 shows, an increase in demand on the right end of the curve causes a much higher increase in response time than one on the left. So the likelihood of performance problems was low in the past when demand was low, but they are more likely now.

Unforunately the "fix it later" approach is still used by many system developers. The approach has many disadvantages: it takes time to procure and install hardware and to tune software; testing must be repeated after code changes; and an interim period of poor performance leaves a negative impression with users long after it is corrected [PEAR82]. The rationale for "fix it later" is to save development time, cost and maintenance cost. The

CH2345-7/86/0000/0778$01.00 © 1986 IEEE

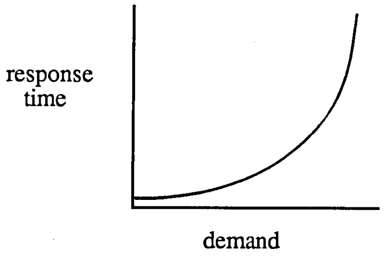

Figure 2. Effect of demand on response time

savings will not be realized, however, if initial performance is unsatisfactory because of the additional time and cost for tuning and maintenance (introduced by efficiency "tricks" for tuning and code entropy resulting from the changes)

Table 1 summarizes the premises that led to "fix it later," the current reality, and the consequences of unacceptable performance. It was a viable approach for batch software, but it is inappropriate for large on-line systems.

Modeling Breakthroughs

In 1971, Buzen proposed modeling systems with queueing network models and published efficient algorithms for solving some important models [BUZ71]. The models are an abstraction of the computer systems they model, so they are easier to create than general purpose simulation models. Since they are solved analytically, they can be used interactively. Since then, many advances have been made in modeling computer systems with queueing networks, faster solution techniques, and accurate approximation techniques [LAZ84, SAU81]. They are commonly used in capacity planning to model large computer systems.

Figure 3 illustrates their use: the model is constructed from information on the computer system configuration and measurements of resource requirements for each of the workloads modeled. The model is solved and the resulting performance metrics (response time, throughput, resource utilization, etc.) are compared to measured performance. The model is calibrated to the computer system. Then, it is used to study the effect of increases in workload and resource demands, and of configuration changes.

The models were used primarily for capacity planning. For SPE they were sometimes used for feasibility analysis: request arrivals and resource requirements were estimated and the results assessed. More precise models were infeasible since the software could not be measured until it was implemented.

The second SPE modeling breakthrough was the introduction of analytical models for software [BOO79, SAN78, SMI79]. With them, software execution is modeled, estimates of resource requirements are made, and performance metrics are calculated. They yield an approximate value for best, worst, or average resource requirements. They can also be used to derive an estimate for response time; they can detect response time problems, but since they do not model resource contention they do not yield precise values for predicted response time.

The third SPE modeling breakthrough was combining the anlaytic software models with the queueing network system models to more precisely model execution characteristics [BGS83,SMI80]. Figure 4 shows

Table 1. "Fix it Later" Approach?

Premises:	**Reality:**	**Consequences (of unacceptable performance):**
Performance problems are rare	The number of on-line software systems, their size, and their complexity have increased; many large systems cannot be used initially due to performance problems	Requires tuning and/or hardware
It's too expensive to build high-performance software	Data on time and cost of building-in performance is out of date; methodologies and tools have dramatically reduced costs	Testing is slower so cost is higher; maintenance costs (for "tuned" code) are higher
Tuning can be done later	Problems are usually due to fundamental architecture or design problems rather than inefficient coding	Code tuning yields modest improvements; large gains require major revisions. Very expensive (often infeasible) to change fundamental design choices
Efficiency implies "tricky" code	Acceptable performance is required; it can be designed-in early	"Tricky" code may be the only option for achieving goals late in life cycle
Hardware is fast and inexpensive	No installations have unlimited hardware budgets. Advanced planning and justification are needed for procurements. Software demands may exceed all hardware capabilities	Lose control of equipment purchase and maintenance budgets

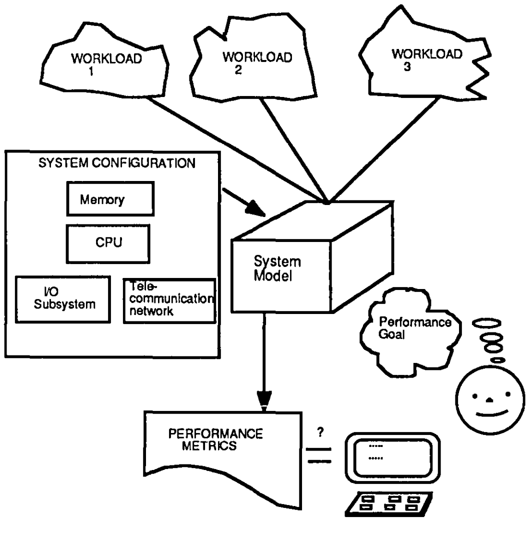

Figure 3. Conventional Performance Modeling

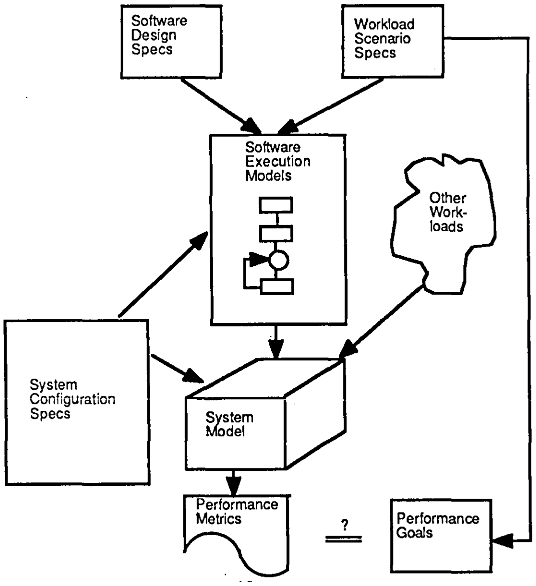

Figure 4. SPE Modeling

the combination of the conventional model used for capacity planning and the software model for systems under development. They not only model more precisely the execution, but also show the effect of new software on existing work and on resource utilization, and identify computer device bottlenecks and the parts of the new software with high use of bottleneck devices.

By 1980, the modeling power was established and many software tools were available [BGS82, BGS83, IRA75, QSP82] (note: the products and publications have been updated since 1980). Thus, it became cost-effective to model large software systems early in their development.

SPE Methodology

Early experience with a large system under development confirmed that sufficient data could be collected early in development to predict performance bottlenecks [SMI82]. Unfortunately, despite the predictions, the system design was not modified to remove them and upon implementation (approximately one year later) performance in those areas was a serious problem, as predicted. The modeling problems were resolved, but that was not enough to prevent problems.

The SPE methodology in Figure 5 was proposed [SMI81] and later updated [SMI84]. Key parts of the methodology are methods for collecting data early in software development, and critical success factors (Figure 6) to ensure SPE success. The methodology also addresses compatibility with software engineering methods, what is done, when, by whom, and other organizational issues. SPE remains an art--the problems are not technical, they require human communication and interaction techniques that can be learned.

SPE Use

Lately, many papers have been written reporting success in applying SPE. A special issue of the *Computer Measurement Group Transactions* on experience with SPE appeared in fall 1985 [CMG85]. It contains an extensive bibliography on SPE reporting experiences, methodologies, modeling techniques, tools, software measurement techniques, and program improvement techniques. The US Army Information Systems Engineering Command developed a performance engineering handbook for their software engineers. Many conferences now include sessions on software performance engineering; and seminars are offered to teach SPE techniques.

Recent Advances

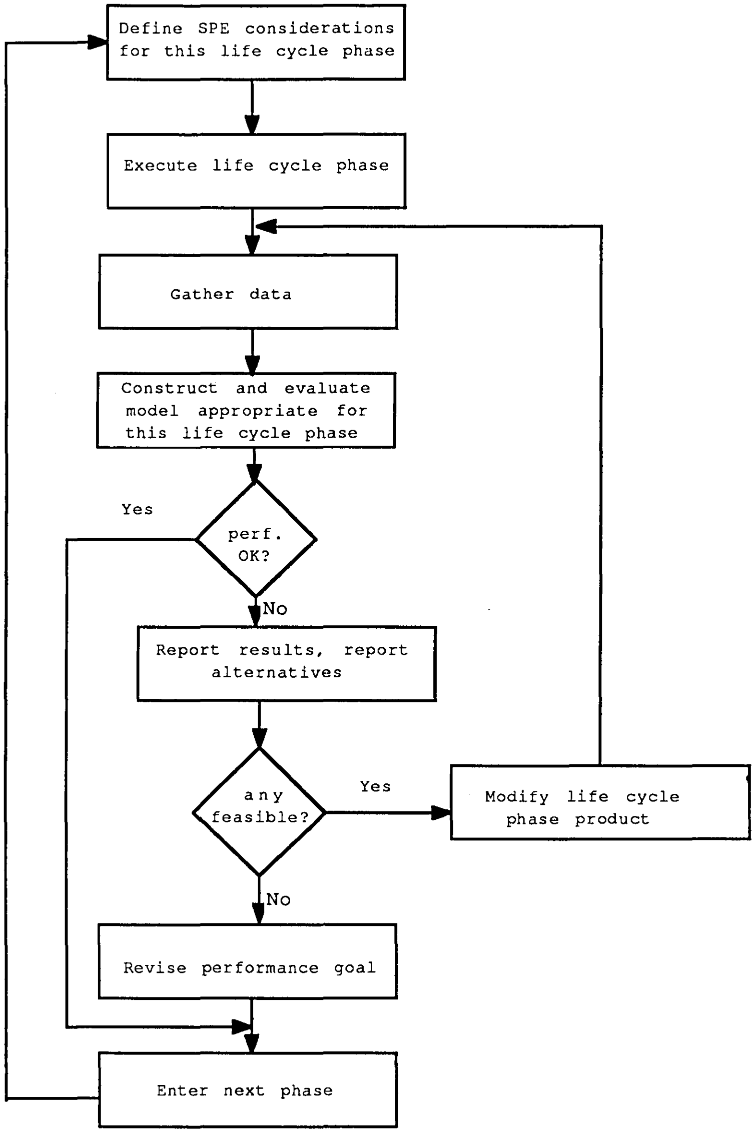
The purpose of SPE is to support the development of software systems that will be responsive to users when they are initially implemented. Performance problems have been detected and corrected early, before implementation. Since ideas and designs must be formulated before they can be modeled, problems still tend to be present in the initial formulation. To prevent this, a set of formal, general principles for performance oriented design was developed [SMI86]. Software architects who are experts in formulating requirements and designs for large, high-performance systems use intuition to develop their systems. The general principles formalize that expert knowledge. They can, thus, transfer the expert's intuition, developed through years of experience, to software architects with less experience in building responsive systems.

With this advance, the evolution of SPE can be depicted with the chart in Figure 7.

Other recent advances offer incremental improvements to the areas in Figure 7.

The models have evolved. Complex execution characteristics (such as memory usage, locking resources, parallel execution, etc.) cannot be solved easily with analytic queueing models. It is easier to use a similar model structure to the queueing network models, but use simulation-based solution algorithms that execute much quicker than the old, detailed simulation models [IRA83]. Petri net models have also been used to model parallel execution of software and hardware [BAL85, SMI85].

The user interfaces of tools have improved; graphics devices provide visual feedback to designers [FRA85, IRA85,LS86]. SPE has been extended to new applications such as point of sale systems [AND84], and software/hardware codesign [FRA85].



Define SPE considerations for this life cycle phase
Execute life cycle phase
Gather data
Construct and evaluate model appropriate for this life cycle phase
perf. OK?
Yes
No
Report results, report alternatives
any feasible?
Yes
Modify life cycle phase product
No
Revise performance goal
Enter next phase

Figure 5. P. E. Methodology

Project management:

commitment -react to significant results

scheduling - include sufficient time for SPE (and
for possible modifications)

control - performance consciousness

credibility of results (analyst training and backing)

Data requirements:

representative workload scenarios

precise estimates of critical resource usage

best and worst case results:
focus attention on problems rather than models
for desirability evaluation

Organizational issues:

outside expert or member of design team?

cooperative effort

ongoing CPE provides better data

Performance analyst responsibilities:

timely results

previous experience (chicken & egg problem?)

quantitative data for alternatives

project visibility

Figure 6. Critical Success Factors for Effective SPE [SMI84]

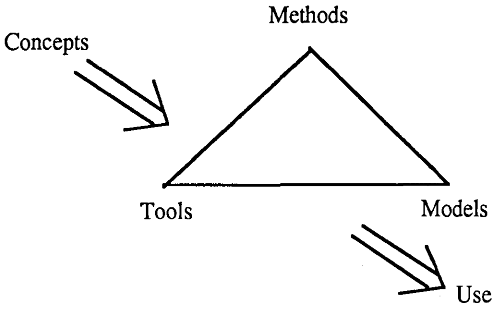


Figure 7. SPE Evolution

The Future of SPE

Advances in SPE are likely to continue at a rapid rate. Table 2 summarizes some predicted advances in each of the five areas identified in Figure 7, and adds a new area: verification and validation of SPE models.

There are many exciting challenges for researchers. Most require skills in multiple areas (e.g., software engineering and performance modeling, computer architecture and software engineering, etc.). For practitioners, many systems under development need SPE. Each will provide new modeling challenges and many learning opportunities. The support tools available in the future will be fun to use and will reduce the amount of time spent "pushing numbers."

Table 2. Future Directions

Area	Improvements
Concepts	General software design principles to incorporate other quality attributes such as reliability, testability, maintainability, etc.
Methods	Formal integration of SPE and software engineering
	Models, tools, and methods for assessing the other quality attributes early in development
	Official organization positions for "performance engineers" with continuing education to improve the human interaction skills
Models	New models to evaluate extensive parallel and distributed processing
	Models for new computer architectures
	Models of transient behavior to study periodic behavior or unusual execution characteristics
Tools	Computer-aided design (CAD) tools to support the designer in automatically performing design assessments while formulating designs, and to integrate the models with the design evolution
	Expert systems to automatically detect and suggest design improvements
	Effective graphical techniques for reporting SPE results
	Software measurement tools to capture, reduce, interpret, and report data at a level of detail appropriate for designers
	A software performance data base to store evolutionary design and model data and support queries against it
Use	Rapid increase in application to new, large systems
	More literature documenting experience with SPE
	New domains, such as predicting performance of VLSI chips early in design
Verification and Validation	Techniques for including instrumentation in software designs
	Techniques for calibrating software models, automatically relating predictions to measurements, and studying discrepancies

PERFORMABILITY ANALYSIS OF OPERATION MODES OF CONFIGURABLE DUPLEX SYSTEMS

Balakrishna R. Iyer, Daniel M. Dias and Philip S. Yu

IBM Thomas J. Watson Research Center, Yorktown Heights, NY 10598

Abstract

Configurable duplex system structures, like the IBM 3084, are capable of operating as one single system (single image mode) or as two independent systems (partitioned mode). The user installation has a choice of operation modes. The single image mode of operation is more tolerant to hardware failures because of component redundancies, but on operating system failure all processors are lost. In the partitioned mode the outage of any hardware component or operating system brings down the affected half of the duplex system. The problem is to select the mode of operation. Since multiple performance levels, derived from a model, are involved a composite performance reliability measure like performability is required. Areas based on the hardware and software failure rates are demarcated, where one of the operation modes is better than the other. The sensitivity of the choice of operation mode to the the goals of the installation (choosing on the basis of average or percentile) is also demonstrated. The use of a steady state performability measure instead of transient performability is shown to distort the choice of operation mode. Hence, simple to compute tight upper and lower bounds for the hard to compute transient performability are derived.

1. Introduction

The demand for higher system availability and greater processing power has been growing rapidly in various installations. A general trend of commercial computer system architectures is towards multiple processor systems with (a) fault tolerance and (b) horizontal growth as major design goals. Both goals can be achieved by replicating functional units and providing proper recovery software. In the IBM 308X processor family, some 3081 models are field upgradable from a two processor system into a four processor 3084 system. Boos (1985) describes an interesting feature of the 3084 system in that it can be configured either as a 4-way tightly coupled multi-processor system or as two separate 2-way tightly coupled multi-processor systems, each of which can be used to service half the total workload.

A simplex system consists of various functional units and operates under a single operating system. A configurable duplex system is obtained by taking two simplex systems and adding interconnections between their functional units. A configurable duplex system may be configured to operate in two different modes - PARTITIONED or SINGLE IMAGE. In the partitioned mode the duplex is configured as two separate (simplex) systems each with a single instance of each functional unit. In the single image mode the duplex runs as one system with dual copies of every functional unit. We consider the problem of selecting the operation mode for a configurable duplex system structure, like the IBM 3084. A study of different configurable duplex system structures can be found in Iyer (1985).

The user installation has a choice of operation modes. The single image mode of operation is more tolerant to hardware failures because of component redundancies, but on operating system failure all processors are lost. In the partitioned mode the outage of any hardware component or operating system brings down the affected half of the duplex system. The problem is to select the mode of operation based not only on the the available statistics about the failure rates of the system and the projected performance levels during periods of degraded operation but also based on the installation requirements. For instance, if system availability is a critical installation requirement, as in online ATM systems, then a 95'th percentile metric related to availability may be appropriate. In throughput oriented installations, like those doing check processing, average system performance may be the preferred metric.

Since multiple performance levels are involved reliability or availability analysis based on a binary valued function is inadequate. The composite performance reliability measure **performability** (Meyer (1980)), which can be used both as a percentile oriented metric and a throughput oriented metric, is required for the problem. Performability may be viewed as the total accumulated reward of a system during its mission time - the interval during which the system is required to give uninterrupted service. Examples of mission times are a) 8 a.m. to 5 p.m. for office systems, and b) the blast-off to earth landing time for a computer system aboard a space vehicle. The normalized capacity of a system is defined as the work per unit time (e.g. transaction rate in a database system) that the system can sustain during the system mission time normalized by the maximum work rate. Clearly the available capacity at any instant depends upon the number of functioning processors at that instant. Normalized capacity is a special case of performability. We refer to the work of Furchgott and Meyer (1984), Kulkarni et. al. (1984) and Goyal and Tantawi (1984) for recent investigations into applications and analysis of performability.

The simplex and duplex system structures and the two duplex system operation modes are described in Section 2. In Section 3, the partitioned mode operation and single image mode operation are compared using performability measures. This comparison is found to be sensitive to the metric chosen (e.g average or tail of the distribution of performability) and also to other system parameters. Usage of steady state performability instead of transient is shown to lead to distortion of choice between single image and partitioned modes. In Section 4, we focus on the difference between transient and steady state performability measures and derive easily computable analytical upper and lower bounds for their difference. An approximation is also provided. The bounds themselves are shown to be the basis of good approximations to compute transient average performability starting from the steady state performability measure. Conclusions are drawn in Section 5.

2. System Structures

2.1. Simplex System Structure

The computer system structure envisioned in this paper is depicted in Figure 2.1(a). The configuration is similar to the configuration of the IBM 3081 processor complex described by Pittler et. al. (1982) and

CH2345-7/86/0000/0785$01.00 © 1986 IEEE

Gustafson and Sparacio (1982). The processor (P) executes instructions that reside in the memory (M). Memory access is coordinated by the memory controller (MC). Both the memory controller and processor are connected through the system controller (SC) which serves the purpose of a switch and may be used as a controller for a processor buffer (cache). The system controller is also attached to the external data controller (X) which contains the intelligence required to address the control units which communicate with the disks, tapes, printers, terminals and other peripheral devices for data. Hardware functional units of the above kind are typically subject to frequent transient failures. Each hardware unit described above is assumed to have comprehensive error detection, correction and fault isolation capabilities similar to those described by Bossen and Hsiao (1980,1982) and Tendolkar and Swann (1982). The processor.controller (PC) coordinates such retry activity and maintains a log of functional unit errors. It interfaces to each functional unit through the interface sensor sets (I) over links that are typically of much lower bandwidth than those used between the other hardware units for data transfer. Reilly et. al. (1982) describe the processor controller for the IBM 3081. Operating system software (SW), running on top of the hardware configuration, is considered as another component. We will use the terms component and functional unit interchangeably.

The simplex system is available only if all the hardware and software components of the system are operational. (Discussion of power and thermal unit failures is beyond the scope of this paper.) Basic system availability is pictured by a coherence diagram in Figure 2.1(b). The system is considered to be available if there is an end-to-end path in the coherence diagram that contains non-faulty components. Memory is assumed to be protected by error correcting circuitry and most memory failures are masked out. Remaining memory failures and memory controller failures are lumped together as memory controller failures. There are two such types of failures considered. The first type consists of failures for which the system may be successfully re-IPL'ed (IPL is used to abbreviate the 'initial program load' function) after bypassing the failed portion of memory or memory controller. The system now operates with less memory than before. It is assumed that such loss of memory is usually small and therefore the impact on performance may be ignored. The second type of failure is more serious and knocks off the entire memory until a hardware repair action is taken on the memory modules or controller. The ratio of failures of the first type to the second is assumed to be $r/(1-r)$. Both types of failures cause system outage. Under the assumption that the system is subject only to single component faults, Figure 2.1(c) gives a transition diagram representation of the system availability process. L_P , L_{SC} , L_X , L_{MC} , L_{PC} and L_I are assumed to be the permanent hardware failure rates of the processor, system controller, external data controller, memory controller, processor controller, and the interface sensor set, respectively. The average repair time for such a functional unit failure is assumed to be $1/M_R$. L_{SW} is the failure rate of the operating system running on the simplex system induced by (a) program logic errors and (b) transient or intermittent hardware failure. These do not include operating system failures attributable to its inadequacy in dealing with permanent functional unit failures - these are accounted for by the coverage probabilities. Operating system failure is recovered by a system re-IPL which takes time $1/M_I$. Link failures are assumed to be negligible and are not modelled. There are two modes of failures of the interface sensor set modelled here. In the first we consider the loss of the sensor link to a single component in the system. The failure is incorporated into the individual component failure rate. The second mode of failure, referred to as the common mode of failure, models the loss of all sensor lines from the sensor set. This is modelled by the failure rate L_I.

2.2. Duplex System Structures

The duplex systems may be run in either partitioned mode or single image mode, described below.

Partitioned Mode Operation:

In the partitioned operation mode, depicted in Figure 2.2.1(a), there is no coupling of the two systems running on the two halves of the duplex. In a transaction processing environment, two separate database systems with disjoint sets of databases can be running on each half of the duplex. The advantage of this mode is that failures on one side do not affect the other side. Such failures include both hardware and operating system failure. The disadvantage, though, is that failure of any hardware component leads automatically to the outage of half the system. In Figure 2.2.1(b) these availability considerations are depicted in a coherence diagram. Recall that the system is considered to be available if there is an end-to-end path in the coherence diagram that contains only non-faulty components. Perfect fault recovery coverage is assumed for parallel pairs in the coherence diagrams. In the next section, the impact of imperfect recovery coverage is considered for parallel pairs. We pick throughput as the reward to signify performance levels in different configurations. Each state is associated with a single throughput value, thus ignoring the transient effects of on throughput immediately after a reconfiguration. For systems where the jobs to be processed take small time compared with the time between reconfigurations (e.g. transaction processing systems), our assumptions are realistic. Assuming a (normalized) reward rate of unity for a fully operational partitioned mode system (both systems running) the reward rate for partitioned mode during component failure (only one system running) becomes 0.5. We do not model occurrence of failures during the repair of another failure. Figure 2.2.1(c) is a transition diagram indicating state transitions on failures with the states labeled with the associated reward rates. The failure rates assumed in Figure 2.2.1(c) reflect the fact that there are two of each component in the duplex system architecture. Each operating system is assumed to have the the same failure rate L_{SW} as the operating system for the simplex system. System loss due to either software failures and partial memory failure may be recovered by a re-IPL. Other hardware failures require a hardware repair action.

Single Image Mode Operation:

In this mode of operation, two simplex systems are assumed to be connected through their system controller's with connectivity further enhanced by having each memory controller connect to both system controllers and by having each processor controller connect to both sets of interface circuits, as illustrated in Figure 2.2.3(a). This interconnect architecture is similar to the IBM 3084 interconnect architecture described by Boos (1985), where two tightly-coupled (i.e. dyadic) processors replace the single processor we have assumed for each P in Figure 2.2.3(a). The impact of component failure on this mode of operation is shown in Table 2.1. The rows in this table indicate the effect of component failure. The columns labelled P, S, M, X, show the number of processors, system controllers, memory systems and external data controllers that remain active for each type of component failure. In the last two columns of this table we indicate the transitions experienced due to covered and uncovered failures for each kind of component failure. For uncovered failures there is an outage. Re-IPL (average time $1/M_I$) restores the failed system to a level of degraded performance. A hardware repair action starts simultaneously. At the end of the repair action the system returns to a state of normal performance. We assume that the time for the repair action to complete after the end of the IPL action is given by $1/M_{R-I} = 1/M_R - 1/M_I$. The failure of memory or memory controller leads to an instantaneous loss of half the memory and is assumed to be catastrophic and causes system outage. For covered failures of memory the resultant outage is recovered by a re-IPL. For other component failures, degraded performance results until the end of the repair action (average repair time $1/M_R$). Markov transition diagrams in Figure 2.2.2(c) illustrates these transitions and changes in rewards, graphically.

We make the following additional observations about this mode of operation. (i) Only one operating system is run on the duplex system and hence system software failure leads to system outage for the duration of an IPL. The exact relationship between the operating system failure rate of the simplex machine and the duplex machine running in single image mode is unknown. On the duplex machine we have one operating system controlling twice the number of resources as in a simplex machine. In the absence of experimental evidence we assume for most of this paper that the software failure rate for single image mode operation is twice that for the operating system of the simplex machine. One parametric study varying the ratios between the software failure rate of the single image mode with that of the partitioned mode is conducted in the next section. (ii) Only one processor controller need be available for normal system operation. Since the processor controller is used mainly for error logging and retry operations, the effect of having two or one processor controllers does not have any effect on system performance. Hence it is not included in Table 2.1. (iii) Jobs are assumed to be picked up by any free processor for execution. It is in this way that the single image mode recovers from processor failure. (iv) We assume that there are dual access paths to all I/O devices - one path through each external data controller. Every I/O request is sent to both system controllers and from there to both external data controllers. The external data controller that can first satisfy the I/O request does so. Thus single image mode operation can continue in the face of an external data controller failure. (v) It is assumed that the software system has no capability to recover from a system controller failure. (vi) Both interface sensor sets are crucial to the operation of the system because failure of any one of them brings down half the coupled system, and since half the memory is lost we assume that there is a system outage. .Furthermore, on processor loss, memory loss or external data controller loss the system may be reconfigured leaving out only the lost component. Software failures of the operating system lead to complete system outage until the system is re-IPL'ed.

3 Performability Analysis

3.1 Methodology

Traditionally reliability and performance analysis of computer systems have been carried out separately. Computer system states have been traditionally classified into 'up' and 'down' states. In a reconfigurable duplex system there are a class of states in which the computer system is operational but not at peak performance, due to loss of some component. It is important to further refine the concept of availability to reflect more clearly the performance of the system in these states.

Meyer (1980) first defined performability in terms of the state of the system X_s (at time s). The state dependent function $f()$ defines the reward rate in state X_s. Y_t, the performability of the system over the mission time $(0,t)$ is defined as the distribution of the accumulated reward

$$Y_t = \int_{s=0}^{t} f(X_s)ds.$$

When the states space is discrete and finite and $X_s \in (0,1,2,..,N)$ then

$$Y_t = \sum_{i=0}^{N} f(i)\tau_i$$

where τ_i is the time spent in state i during the system mission time. We pick $f_{\max}$ to denote the largest reward in the system states and define normalized capacity as $Y_t/(t f_{\max})$, and steady state normalized capacity as $\lim_{t\to\infty} Y_t/(t f_{\max})$. If we let $f(i)$ denote the throughput of the system in state i then normalized capacity is the normalized work output by the system per unit time over the course of the system mission.

Both the mean $E(\frac{Y_t}{t})$ and the distribution $P(\frac{Y_t}{t} < \hat{y})$ metrics are of interest in this paper.

We quote the following result due to Iyer et. al. (1984) that sets forth an analytical method to compute the moments of the performability distribution. They assume that the time to failures and repair times are exponentially distributed. All vectors shall be understood to be column vectors. Let $\mathbf{m}_n(t)$ be the vector with entries $m_{i,n}(t)$ where $m_{i,n}(t) = E(Y_t^n \mid X_0 = i)$ is the n'th moment of performability starting from state i. Note that $m_{i,0}(t) = 1$. The n'th moment of performability is given by

$$\mathbf{m}_n(t) = \sum_{i=0}^{N}\sum_{j=0}^{n} \mathbf{v}_n(i,j) e^{\lambda_i t} t^j,$$

where, the λ_i 's are the eigenvalues of the generator matrix of the Markov process X_s and the vectors $\mathbf{v}_n(i,j)$ are computable by recursions.

Programs were developed to compute all n moments of performability based on the above result and used to generate transient average normalized capacity for the different system configurations described in Section 2. For the Markov models considered in this paper, the steady state normalized capacity is derived through the steady state probabilities derived by using balance equations and the normalization constraint.

No general closed form solution is known for the distribution of performability. Kulkarni et. al. (1985) have recently used a numerical Laplace transform inversion procedure to obtain the distribution of performability for Markovian models. Donatiello and Iyer (1985) have recently shown that even in the case of a simple two state Markov process the distribution of performability is composed of modified Bessel functions. We use simulation to generate the performability distribution. The simulation assumes that the time to failure is exponential and uses both the exponential and deterministic distribution for repair times.

3.2 Comparison of Operation Modes

In this section we investigate the choice of single image or partitioned operation modes. The choice is found to be sensitive to the hardware and software failure rates, and other factors. We compare the use of steady state measures as approximations to transient measures and show that conclusions drawn by using the former may lead to anomalies. This observation motivates the approximation technique for the transient average normalized capacity proposed in the next section.

Instead of differentiating operation modes on the basis of the reward rate during normal operation we focus on the difference in the impact of component failures on different system structures and modes of operation. System operation is quantified by the accumulated reward. The reward rate may signify the throughput of the system under a response time constraint or may reflect other performance related variables as described by Donatiello and Iyer (1984). The choice of the reward rates is a function of the computing system environment. For example, in a high availability environment a severe penalty may be the reward for down states.

The performance level of each operation mode is different for each state and can be derived from some lower level model. For example, in the Appendix a model is presented to evaluate the system throughput for a transaction processing environment. The impact of each type of component failures is captured in the modelling. To evaluate the effect of external data controller or system controller failure, IO paths to storage devices are explicitly modelled. In the partitioned mode, the two halves of the duplex are assumed to run different database systems with disjoint sets of databases. For an equitable comparison with the partitioned mode, the same types of transactions and databases are assumed in the single image mode. The performance level derived for the single image mode of operation for each state is summarized in columns 6 and 7 of Table 2.1.

There are two coverage probabilities involved in this study. One is the probability r that a memory can be reconfigured after either memory or memory controller failure to continue system operation. This coverage probability is usually a characteristic of the memory hardware design. We set $r = 0.75$. Then there is the coverage probability that the system does not suffer an outage on the failure of one component of a parallel pair in the coherence diagram. This coverage probability is determined by the functionality of the software to continue operation in the face of component failure. In an ideal system this probability should be unity. However in practical systems limitations of software (due to which every possible error state is not covered) cause the coverage probability for each type of failure to be smaller than unity. In this study we set coverage probability for all such components to the same value c and vary c in our studies.

Figure 3.2.1 shows the transient average normalized capacity of the single image and partitioned modes of operation as a function of the coverage probability. Software failure rate is assumed to be 0.5 per week. For these parameter values, partitioned mode operation exhibits smaller performability as compared to the single image mode operation. The comparison is sensitive to the software failure rate, as indicated in Figure 3.2.2(a). For higher software failure rates partitioned mode operation exhibits greater performability. This is because while partitioned mode loses one half of its processing capability on software failure, the single image mode loses its entire processing capability. In contrast single image mode has greater performability than partitioned mode for large hardware failure rates, because of the ability of the single image mode to use redundant components to mitigate the degradation in performance during hardware component failure. This is illustrated in Figure 3.2.2(b). In Figure 3.2.3(a) steady state and transient average normalized capacity for the single image and the partitioned mode operation are plotted, assuming that software failure rate is 0. Transient average (curves with labels subscripted with a T) is always greater than the steady state (curves with labels subscripted with an SS) because for smaller mission time the probability of a failure within the mission is smaller and because we always start in the normal system state for transient performability. The single image normalized capacity (curves labelled SI) is better than partitioned (curves labelled P). When the software failure rate is set to 1 per week (Figure 3.2.3(b)) the partitioned system has greater normalized capacity - indicating the sensitivity of the comparison to software failure rate.

As pointed out earlier the exact relationship between the software failure rate in single image mode and in partitioned mode is unknown. An expansion factor of 2 for the software failure rate in single image mode over the simplex software failure rate has been so far assumed. We explore the sensitivity of the comparison between the partitioned and single image modes to the expansion factor in Figure 3.2.4. Each half of the duplex in partitioned mode is assumed to suffer a software failure rate of 1 per week - that for the simplex. We vary the software failure rate expansion factor of the single image mode from 1 to 2. For low software failure rate expansion factors the single image mode has greater performability than partitioned mode because of the ability of the single image mode to partially cover hardware component failure. On the other hand partitioned mode always loses half the system. As the single image mode software failure rate expansion factor increases the relationship between the performabilities in the two modes is reversed exposing the greater impact of a software failure on single image mode of operation.

Since the difference between steady state and transient normalized capacity is of the order of less that 1%, one may be tempted to use steady state normalized capacity itself to approximate the transient normalized capacity as the comparison metric. Unfortunately, such an approximation leads to anomalies shown in Figure 3.2.5, over a wide parameter range. In Figure 3.2.5 we vary both the software failure rate and the coverage probabilities and find that in region A, single image mode operation is superior to the partitioned mode operation when compared on the basis of transient normalized capacity. The relation is reversed in regions B and C. Comparing on the basis of steady state normalized capacity, single image is better in regions A and B and partitioned mode better in region C. In region B the single image is better for the steady state but worse for the transient. The reason is that steady state favors single image because even though uncovered failures cause system outage for the single image, a re-IPL following the outage puts the single image into a state with reward rate greater than 0.5 in some cases and at worst 0.5 in the remaining, as in Figure 2.2.2(c). For short mission times the single image does not derive the full benefit of being in the intermediate stage and the penalty of the 10 minute system outage is amplified. Hence, even though the using steady state instead of transient performability constitutes less than 1% error, conclusions drawn by the use of steady state performability may not be the same as using the results of transient analysis. Therefore, in section 4 we derive a quick way to approximate the transient normalized capacity from the steady state normalized capacity.

In Figures 3.2.6 and 3.2.7 the 99'th percentile of normalized capacity has been plotted for the single image and partitioned modes for software failure rates of 0 and 1 per week, respectively. Both exponential and fixed repair time distributions are considered. The jagged nature of the curves are due to inaccuracies inherent to simulation. We observed from simulations that the fixed repair time distribution has a smaller transient average normalized capacity than the exponential. This is because in the exponential case - long repair times tend to get cut off by the end of the mission; hence the expected outage time in the exponential case is smaller than that in the fixed repair time distribution case. However, there are some missions with large outage times, for the exponentially distributed repair times (as expected), in comparison to the fixed repair time cases. Thus, the tail of the transient normalized capacity is longer for the exponentially distributed repair times cases than for the fixed repair time cases. This phenomenon can affect the higher percentiles. In Figures 3.2.6 and 3.2.7 the effect is seen for the partitioned 99'th percentile capacity, where the exponential case is worse than the fixed. From Figures 3.2.6 and 3.2.7 we find that the single image mode of operation exhibits better 99'th percentile transient normalized capacity for both software failure rates of 0 and 1 per week. In the previous figures we had plotted average normalized capacity and found that the comparison between the two modes was affected by the two failure rates. (This implies that we have to be careful about the choice of metric for comparison of the modes of operation of the two systems - because they give different results.) The choice of average or percentile of the performability distribution is of course determined by the goals of the system installation.

4. Approximations for Transient Performability

The previous section presented results of the transient analysis and simulation of normalized capacity for the two operation modes, and compared these with the steady state results. We note that while the steady state analysis is straightforward, transient analysis is complex. The complexity of transient analysis arises because it requires the solution of an eigenvalue problem as illustrated in Theorem 3.1, and involves evaluating time constants and coefficients of the transient terms. The solution procedure can lead to numerical problems. Although the difference between the transient and steady state average normalized capacity can be small the use of steady state analysis may give rise to anomalies, as discussed in Section 3. Thus, the question arises as to when transient analysis is required. In this section we develop simple upper and lower bounds and an approximation for the difference between the transient and steady state average normalized capacity. These bounds can be used both to determine the deviation of steady state normalized capacity from transient average normalized capacity and as an approximation to the transient solution. We illustrate the use of these bounds by applying it to the operation modes of Section 3, and observe that the bounds are tight. The approximation lies between the bounds, and appears to be a good one.

For ease of presentation, we first consider a simple two state case, with states denoted by 1 and 0, and with rewards 1 and 0 in these states respectively. The high reward state typically represents the "up" state, and the low reward state the "down" state. Thus, the system starts in the 1 state at the start of the mission. Furthermore, failures are rare. That is, on the average, the system spends most of the mission time (t) in the 1 state.

For computing the steady state average normalized capacity, the time axis can be divided into intervals, each of length equal to the mission time t, and averaging over this ensemble. For a Markov failure and recovery process (i.e. an exponentially distributed time in each state), the steady state average normalized capacity $\overline{m}$ can be computed as,

$$\overline{m} = \pi_1 m_{1,1}(t) + \pi_0 m_{0,1}(t) ,$$

where, $m_{x,1}(t)$ is the transient normalized capacity when starting in state x at the beginning of the interval, and π_x is the probability of being in state x at the start of the interval. For the transient normalized capacity, we are typically interested in the performability given that we start in the "up" (1) state. The difference between the steady state normalized capacity and the transient average normalized capacity when starting in the "up" state is

$$m_{1,1}(t) - \overline{m} = (1 - \pi_1) m_{1,1}(t) - \pi_0 m_{0,1}(t) .$$

Since $\pi_0 + \pi_1 = 1$,

$$\begin{aligned} m_{1,1}(t) - \overline{m} &= \pi_0 (m_{1,1}(t) - m_{0,1}(t)) \\ &\leq \frac{\pi_0 t_0}{t} , \end{aligned} \tag{4.1}$$

where t_0 is the mean "down" time. This last inequality is derived as follows. Figure 4.1(a) shows that the average normalized capacity, $m_{1,1}(t)$, starting in the "up" state is monotonically decreasing. Figure 4.1(b) shows the case of starting in the "down" state, and staying in the down state for time $\hat{t}$. Following this down time, the average normalized capacity for the rest of the mission time is $m_{1,1}(t - \hat{t})$. The average reward when starting in the "up" state, is the area marked as A and bounded by **adef** in Figure 4.1(b), while the corresponding average reward starting in the "down" state is marked as **B** and bounded by **bcjf**. The difference $m_{1,1}(t) - m_{0,1}(t)$ is (Area A - Area B)/t. An upper bound on this difference is merely (Area C)/t, where area C is bounded by **ghej**, or $\hat{t}/t$. Now, the mean value of $\hat{t}$ is,

$$\int_0^t \frac{x}{t_0} e^{-x/t_0} dx + \int_t^\infty e^{-x/t_0} dx = t_0 - t e^{-t/t_0} < t_0 \tag{4.2}$$

Thus, $(m_{1,1}(t) - m_{0,1}(t)) < t_0/t$, giving inequality (4.1). The bound can be improved by using equation (4.2).

This bound is easily generalized to a system with more than two states. For a system with (N+1) states denoted by 0,...,N , and state N as the "up" state,

$$\begin{aligned} m_{N,1}(t) - \overline{m} &= m_{N,1}(t) - \pi_N m_{N,1}(t) - \sum_{i=0}^{N-1} \pi_i m_{i,1}(t) \\ &= \sum_{i=0}^{N-1} \pi_i (m_{N,1}(t) - m_{i,1}(t)) \\ &\leq \sum_{i=0}^{N-1} \pi_i \frac{(f_N - f_i) T_i}{t} \end{aligned} \tag{4.3}$$

where, π_i is the probability of being in state i at the start of the interval, f_i is the reward in state i, T_i is the mean time to get from state i to state N , and t is the mission time. The final inequality in equation (4.3) follows by an extension of the argument used in deriving equation (4.1), and assumes that the reward in intermediate states in returning from a down state i to state N is a non-decreasing reward function.

The bound in equation (4.3) can be tightened by considering the rewards and times spent in intermediate states between states i and N. Suppose that the system (given that a transition occurs) goes from a failure state i to state N through intermediate states, with rewards as indicated in Figure 4.2. The concomitant loss in performability is indicated by the area A in this figure, and will be denoted by Δ_i for the loss in state i. Suppose that the system goes from state i to state j, $0 \leq j < N$, with probability p_{ij} when a transition occurs. Then, for exponential failure and repair times,

$$\Delta_i = \sum_{j=0}^{N-1} \Delta_j p_{ij} + (f_N - f_i) t_i , \tag{4.4}$$

where t_i is the mean time spent in state i and $f_N - f_i$ is the loss in reward in state i compared with the "up" state N. Thus,

$$\begin{bmatrix} 1 & . & . & . & . \\ . & 1 & . & -p_{ij} & . \\ . & . & . & . & . \\ . & . & -p_{ij} & 1 & . \\ . & . & . & . & 1 \end{bmatrix} \begin{bmatrix} \Delta_0 \\ \Delta_1 \\ . \\ . \\ \Delta_{N-1} \end{bmatrix} = \begin{bmatrix} (f_N - f_0) t_0 \\ . \\ . \\ . \\ (f_N - f_{N-1}) t_{N-1} \end{bmatrix}$$

Writing this equation as $\mathbf{P} \underline{\Delta} = \mathbf{R}$,

$$\underline{\Delta} = \mathbf{P}^{-1} \mathbf{R}. \tag{4.5}$$

Now, we may rewrite equation (4.3) as,

$$\begin{aligned} m_{N,1}(t) - \overline{m} &= \sum_{i=0}^{N-1} \pi_i (m_{N,1}(t) - m_{i,1}(t)) \\ &\leq \sum_{i=0}^{N-1} \pi_i \frac{\Delta_i}{t} = \frac{\underline{\pi}^T \mathbf{P}^{-1} \mathbf{R}}{t} \end{aligned} \tag{4.6}$$

While equation (4.6) expresses a solution for the general case, for most systems, such as those examined in Section 3, $\underline{\Delta}$ reduces to a simple summation and can be written directly by inspection, as discussed below; this applies to transition diagrams in which all cycles pass through the "up" state, as in the transition diagrams of Figures 2.2.1(c) and 2.2.2(c).

Figure 4.2 illustrates an alternate method of deriving the upper bound of equation (4.6), and an approximation and lower bound. This figure shows the reward as a function of time, starting in a down state i, with reward rate f_i. At time $\hat{t}$ the system is in the "up" state N for the first time, with reward rate f_N. Thus, from time $\hat{t}$ to the end of the mission time t, the system behaves as though it had started in the "up" state N, and had a mission time of $(t - \hat{t})$. That is, the average reward from time $\hat{t}$ to t when starting in the "down" state i, is the same as the average reward from time 0 to $(t - \hat{t})$ when starting in the "up" state N. Notice from equation (4.3), we are interested in the difference $m_{N,1}(t) - m_{i,1}(t)$ representing the difference in rewards when starting in state N, and when starting in state i. From the above observation, it follows that this is the same as the difference in the reward from time t to $(t + \hat{t})$ when starting in the "up" state at time $\hat{t}$ (denoted as Reward1) and the reward from time 0 to $\hat{t}$ when starting in the down state at time 0 (denoted as Reward2). This difference in rewards is shown as area B in Figure 4.2 (where the reward from time 0 to $\hat{t}$ when starting in state i is replicated between times t and $(t + \hat{t})$, so that the difference in rewards can be indicated). The upper bound in equation (4.6) takes Reward1 as $(f_n \times \hat{t})$, with area B upper bounded by area A in Figure 4.2. A closer approximation can be obtained by taking Reward1 as $(\overline{m} \times \hat{t})$, where $\overline{m}$ is the steady state normalized capacity. With this approximation, equation (4.4) is changed to,

$$\Delta'_i = \sum_{j=0}^{N-1} \Delta'_j p_{ij} + (\overline{m} - f_i)\, t_i \ , \qquad (4.4')$$

with Δ'_i as an approximation to the mean lost reward (i.e., mean area B) when starting in state i. The rest of the development is similar to deriving equations (4.5) and (4.6). Again, Δ'_i can be written by inspection for many interesting cases, such as those in Section 3.

A lower bound for the difference between transient and steady state can be derived for cases in which all cycles pass through the "up" state. The error in the upper bound of equation (4.6) is due to two approximations. First, the up-state reward f_N is used for the mean reward during times t and $(\hat{t} + t)$, when starting in the "up" state at time $\hat{t}$. This is an upper bound, while the steady state performability is a lower bound on this mean reward, because the average normalized capacity, when starting in the up-state is a monotonically decreasing function of mission time. Second, the mean time in a down state is overestimated in the upper bound, as expressed in equation (4.2). This is because, the effect of the mission time boundary is not accounted for in the upper bound. As for the two state case, for which the mean down time is derived in equation (4.2), the exact mean down time can be derived in closed form, as discussed in Donatiello and Iyer (1984), and used in place of t_i in equation (4.4′) Combining this with using the steady state performability instead of f_N, as in the above approximation, leads to a lower bound.

First consider the partitioned system structure of Figure 2.2.1(a). The transition diagram of Figure 2.2.1(c) shows the "up" state and two failure states, each with reward 0.5, and mean down times of $1/M_R$ and $1/M_I$ respectively. Denoting these failure states as 0 and 1, and since there are no intermediate states between these failure states and the "up" state, equations (4.3) reduces to,

$$m_{N,1}(t) - \overline{m} \ le \ \frac{0.5\pi_0}{M_R\, t} + \frac{0.5\pi_1}{M_I\, t} \ .$$

The resulting bound on the transient normalized capacity is shown in Figure 4.3 for a software failure rate of 1 per week. The value computed by the exact analysis of Section 3 is shown as a solid line that is barely distinguishable from the bound, shown as the dotted line. The error in the difference between the steady state and transient normalized capacity is about 0.6%. (The percentage error in estimating the transient normalized capacity, rather than the difference between the transient and steady state, is much smaller, or about 0.0002%.)

We now consider the single-image mode. The transition diagram of Figure 2.2.2(c) shows some failure states that return to the "up" state through some intermediate states. However, the solution of equation (4.5) for $\underline{\Delta}$ can be written directly by inspection. For instance, for the failure of the interface sensor sets (I), with rate L_I the system goes to a state with zero reward, say state i, for time $1/M_I$, and then goes to a state with reward 0.5 and stays there for time $(1/M_R - 1/M_I)$. Thus, Δ_i equals $1/M_I + 0.5\,(1/M_R - 1/M_I)$. The other components of the vector $\underline{\Delta}$ can be computed similarly. Figure 4.4 shows the resulting bound on the transient normalized capacity as a function of the coverage probability, for a software failure rate of 1 per week. Again, the bound (dashed line) is seen to be very close to the exact analysis (continuous line).

The bound can also be applied to some non-exponential repair time distributions. No exact solution to the general mean normalized capacity is known for non-exponentially distributed repair times. The only difference in the bound for non-exponential repair times is in estimating T_0 in equation (4.1), or Δ_i in equation (4.4). Considering the simple two state problem for which equation (4.1) was derived, the remaining time in the "down" state given that the (mission time) interval starts in the "down" state, now depends on the repair time distribution. For a fixed down time, the mean remaining "down" time is one half of the (fixed) down time. Thus, the bound predicts that the difference between the transient and steady state normalized capacity for a fixed down time distribution is about one half that for the exponential distribution with the same mean down time. A similar argument can be used to compute Δ_i in equation (4.4) for a general system with fixed repair times. Applying this bound to the partitioned system structure and assuming a fixed repair time distribution, provides a bound on normalized capacity of 0.997865 for a mission time of 21 hours and a zero software failure rate, versus a simulation estimate of 0.997818 and a steady state normalized capacity of 0.997705. Similarly, for a software failure rate of one per week, the bound on normalized capacity is 0.99689 versus a simulation estimate of 0.99693 and a steady state value of 0.99672. The difference of 0.00004 is within simulation accuracy.

The error in the above bound (i.e., the bound versus the actual difference between the steady state and transient normalized capacity) is sensitive to the error rates. For high error rates, the probability of being in a down state increases and so does the accumulated error in equation (4.3). Figure 4.5 shows the effect on the bound of varying the error rates from the nominal values in Section 3 up to ten times the nominal error rates, for the single image mode. The figure indicates that the upper bound is good even at ten times the nominal error rates. Figure 4.6 shows the upper and lower bounds, the approximation for, and the exact difference between steady state and transient normalized capacity with increasing failure rates. The upper bound is reasonably good even at high error rates, while the approximation and lower bound are practically indistinguishable from the exact value.

5. Conclusion

In this paper we used performability analysis to compare configurable duplex system structures. Since they differ in both frequency of outages and in the impact of outages on the system performance normalized capacity is used as a measure for comparison. We found the choice of optimal mode sensitive to the failure rate and to the performance metric - average or percentile. It is precisely for this reason that choice of mode of operation should be left to the installation, that can best determine which mode is suited for a particular environment. Use of steady state analysis instead of transient analysis gave rise to some anomalies. This motivated the upper bound, lower bound and approximation formulae for transient average normalized capacity derived in this paper. Both the bounds and the approximation were found to be very close to the values of transient average normalized capacity. The approximation and bounds are also applicable for computing the difference between steady state and transient average normalized capacity. In summary, we have shown that the combined goals of performance and reliability for reconfigurable duplex systems affect the choice of operation mode. While we have applied this methodology to configurable duplex systems, it can be used in any system with combined performance and reliability requirements.

Acknowledgements

We would like to thank Don Brand for discussing the single image and partitioned mode operations of the IBM 3084 with us, Joshua Kurtzberg and Al Pastro for developing the programs and plotting the curves used in this paper, Brian Bennett for useful comments on I/O modelling, Mickey Tsao for many clarifications and Yann-Hang Lee for reviewing a previous draft of this paper.

Appendix

In this appendix we use an example to illustrate the performance levels that can be obtained by the single image and partitioned modes of operations for different failure scenarios. The performance levels depend on the workload and the configuration. Here we will assume a typical transaction processing environment similar to that reported by Yu et. al. (1985).

Figures A.1 and A.2 show the assumed system configuration for the model. The figures show a typical I/O subsystem consisting of two sets of disks connected to the EXDC's through heads of string and control units, such that each disk has a dual path to the main memory. We will assume an equal load on each disk.

We use an approximate model to estimate the transaction response time versus throughput characteristic for normal operations and different failure scenarios. The average transaction path length, *INST* that includes the overheads for locking, I/O, application and commit processing, is assumed to be 1000 K instructions. Each CPU is modelled as an M/M/1 server. An M/M/1 model is natural for each processor in the partitioned mode. For the single image mode an additional assumption is required to justify the M/M/1 queueing model, i.e., the assumption that transactions are pre-assigned to execute on specific processors. This may be done to eliminate processor cache degradation. I/O's for a disk are queued in the operating system so that only one outstanding I/O can ever exist for a disk. The I/O time is derived by estimating the utilization of each channel path (the communication path between the EXDC and a control unit controlling accesses to disks, communications occur over these paths synchronously to match the rates at which data are accessed on disks during their rotation) and disk, computing the mean time taken by the disk for each I/O and then using an M/M/1 model for the total I/O time, including queueing for I/O requests. The CPU time is added to the total I/O time to give the total transaction response time. Finally, using a binary search procedure, we compute the throughput that can be supported for a given a response time constraint.

For more detail, the I/O time is estimated as follows. The disk service time consists of components, to send the I/O request to the disk (t_d); disk seek and latency ($t_s + t_l$); missed rotation time if no path is available from the disk to the EXDC when the required data on the disk arrives under the disk head (t_m); and the time to transfer the data (t_t). Let the probability that no channel path can be obtained at the time the channel program is started (I/O request is initiated) be β. This is also the probability that channel path is not available when the disk head is over the location of the data to be transmitted for the I/O. If the I/O request is blocked due to the channel busy condition it must wait for the current I/O transmission to end. Thus $t_d = \beta t_t/2$. Similarly the disk must rotate once more if the channel path is not available when the disk is ready for transmission, giving (using a geometric probability distribution for the wait time measured in number of disk rotation times) $t_m = t_r \beta/1 - \beta$, where t_r is the the time for the disk to complete one revolution. Typical values for the other delay components are $t_s = t_l = 8$ msec, $t_t = 1.5$ msec, and $t_r = 16$ msec.

The probability of obtaining a path depends on the number of channel paths to a disk and the probability that a channel path is busy when the request is made. The probability that a path is busy due to transfer of data to or from another disk is

$$\beta' = \left(\frac{n-1}{n}\right)\frac{\lambda I t_t}{P},$$

where n is the number of disks with which the path contention occurs, λ is the transaction rate, I is the number of I/O's per transaction, and P is the number of channel paths to each disk. Then $\beta = (\beta')^P$. For these configurations of Figures A1 and A2 $P = 2$.

The disk utilization is given by

$$\rho_{disk} = \frac{\lambda I}{n}(t_s + t_l + t_m + t_t).$$

Finally, the delay for an I/O seen by the operating system, because of queueing for the device, is estimated as

$$t_{IO} = \frac{t_d + t_s + t_l + t_n + t_t}{1 - \rho_{disk}}.$$

The number of I/O's per transaction depends on the number of memories available. Typical values are used as follows: 16 I/O's per transaction for configurations with 2 (1) memories and 2 (1) processors, 15 I/O's per transaction for the configurations with 1 processor and 2 memories and 19 I/O's for the configurations with 2 processors but 1 memory. Note that these values are sensitive to the workload. If *MIPS* denotes MIPS per CPU then the CPU time is estimated as

$$t_{CPU} = \frac{INST}{MIPS(1 - \rho_{CPU})}.$$

where ρ_{CPU} is the CPU utilization estimated as

$$\rho_{CPU} = \frac{\lambda\, INST}{N_P\, MIPS},$$

where N_P is the number of available CPU's in the complex. For the fully operational system, $N_P = 2$. For either a processor, SC or I failure, $N_P = 1$.

Using the following values for the parameters: total number of disks $n = 32$, $CPUMIPS = 15$ MIPS per processor and a response time bound of 0.5 seconds, the transaction rates that can be supported are shown in Table 2.1 after being normalized with respect to the transaction rate for the fully operational case.

Recognition of Error Symptoms in Large Systems

R.K. Iyer, L.T. Young and V. Sridhar

COMPUTER SYSTEMS GROUP

University of Illinois at Urbana-Champaign, Urbana, IL 61801

ABSTRACT

In this paper, a methodology for automatically detecting symptoms of frequently occurring errors in large computer systems is developed. The proposed symptom recognition methodology and its validation are based on probabilistic techniques. The technique is shown to work on real failure data from two CYBER systems at the University of Illinois. The methodology allows for the resolution between independent and dependent causes and, also quantifies a measure of the strength of relationship among the errors. Comparison made with failure/repair information obtained from field maintenance engineers shows that in 85% of the cases, the error symptoms recognized by our approach correspond to real system problems. Further, the remaining 15% although not directly supported by field data, were confirmed as valid problems. Some of these were shown to be persistent problems which otherwise would have been considered as minor transients and hence ignored.

Keywords: Error records, persistent errors, failure symptoms, probabilistic techniques, automatic recognition.

1. INTRODUCTION

The diagnosis of the causes of persisting errors in computer systems is difficult because the underlying faults are complex and may affect different parts of the system. The system usually detects the effects of the faults as many isolated errors. An incorrect diagnosis leads to improper recovery management which ultimately affects the integrity of the system. For the diagnosis to be effective, it is imperative that the system be able to relate errors occurring in different parts or different times.

When a service engineer tries to rectify a fault, he or she studies the error log for the period during which the fault occurred. Though the system may record the effect of a fault as many isolated incidents, the service engineer recognizes the different error entries as symptoms of the same error. This recognition of related error records is based on the service engineer's observance of some similarity, e.g., a recurring pattern among the error records.

This paper proposes a methodology for recognizing symptoms of severe errors in large systems. The goal of the methodology is to automate and formalize a process to relate errors occurring in different parts of a system. The method was developed after several years of study of system error logs and through close consultations with maintenance and field engineers from several manufacturers. The approach uses the system error rate to identify error records among which relationships can exist. Probabilistic techniques are then used to validate and quantify the strength of relationships among error records. The approach takes as input the raw error logs containing an entry for each error detected as an isolated event by a computer system, and produces as output symptoms which characterize persistent errors.

The methodology for automatically recognizing the error symptoms involves three steps:

(1) The recognition of error records among which relationships can exist,

(2) The determination of the existence and validity of relationships among these records and

(3) The quantification of the strength of a relationship if one is found.

The method is illustrated on error data collected from two large Cyber systems used on campus at the University of Illinois at Urbana-Champaign. The approach is simple in concept and hence easy to apply and simple to use. Since it is not based on any specialized characteristics of the Cyber systems or the error logs, it is expected to be applicable to other systems as well. Analysis of error data from two IBM systems is now in progress. Comparison made with failure/repair information obtained from field maintenance engineers shows that in 85% of the cases, the error symptoms recognized by our approach correspond to real system problems. Further, the remaining 15% although not directly supported by field data, were confirmed as valid problems by the engineers. Indeed, some of these were shown to be persistent problems which otherwise would have been considered as minor transients and hence ignored.

1.1 Related Research

Two studies which offer insight into the characterization of errors by their associated symptoms are [Velardi 84] and [Iyer 86]. Software errors in a production environment are analyzed in [Velardi 84], and permanent CPU errors and their relationship to workload are discussed in [Iyer 86].

CH2345-7/86/0000/0797$01.00 © 1986 IEEE

Research closely related to that described in this paper (symptom-based recognition) is that of [Tsao 83a] and [Sanders 85]. Tsao's work is motivated by the fact that a module exhibits a period of (potentially increasing) unreliability before final failure. The approach attempts to analyze trends in errors by first grouping errors occurring within a short period into Tuples. Heuristics, specific to DEC system error logs, are then used to determine if one tuple is similar to another [Tsao 83b]. As the author points out, two Tuples may be found to be identical by one algorithm, not identical by another. The result of the analysis is a small set of tuple types, each of which are expected to contain error records pointing to the same cause. The approach assumes that all error records in a Tuple are related.

In [Sanders 85], a technique which uses both complete and partial recurrences is proposed. The technique is similar in concept to that proposed by Tsao. Instead of using matching algorithms, a software table is used to quantify system organization. The software table is also used to capture both partial and complete recurrences as well as similarities among error groups. It was found that nearly 15% of the groups (similar to Tuples) contained a collection of unrelated error records, i.e., random groups.

An alternative approach to the above is called "structure-based" diagnosis. The development of a scheme based on the description of the structure and function of a system is described in [Davis 82]. Similar diagnostic schemes have also been proposed in [Shubin 82] and [Genesereth 82]. Another approach called "violated expectation" ([deKleer 76] and [Brown 81]) has also been proposed for troubleshooting. This approach looks for mismatches between the values expected from correct operation and those actually obtained. Whenever possible, the approach identifies a specific component that may be faulty. All these diagnostic systems have been shown to work on modules within a computer system. It is not clear how they will work when a whole computer system is taken into account.

In [Iyer 85], the analysis shows that the system is most vulnerable to errors in the hardware/software interface. It is not clear that a structure-based diagnosis can be fully successful under such circumstances. A structure-based diagnostic system may diagnose the hardware fault in a limited domain, but the chances are that complex faults (e.g. hardware-related-software errors) may be detected as more than one error. In this context, it becomes important to study the relationship among errors that occur within a short time.

In our opinion, both the symptom-based and structure-based approaches are still in their infancy. Hence, further research in both areas, particularly practical studies, needs to be done before either of them can generally be implemented.

The approach proposed in this paper is geared toward determining the symptoms of persistent errors in large systems by probabilistically relating the different manifestations of the same problem. The approach is naturally geared toward differentiating between transient and intermittent errors. To the authors' knowledge, there is no methodology that is able to do this at present. Further, the approach can also evaluate a diagnosis by analyzing the diagnoses made in the past, i.e., the goodness of system diagnostics. A methodology that quantifies the symptoms associated with related errors by determining the relationship among detected errors is essential for this purpose. The development of such an approach is discussed in the following sections.

2. SYSTEM CONFIGURATION AND ERROR MEASUREMENT

2.1 System Configuration

The system studied consisted of two Control Data CYBER 170 systems maintained by the Computer Services Office at the University of Illinois at Urbana-Champaign. The two machines, a model 174 and a model 175, are coupled by their disk system. The two machines run independently but share resources such as tape drives, etc. An interlock table is maintained for use by both machines to prevent deadlock arising from conflicts over shared resources. Details of the system configuration and the error detection are given in the Appendix.

2.2 Recognition of Error Groups

A cursory analysis of the data showed duplicate entries within a short time period describing the same error condition. It was decided to coalesce error records that report the same conditions (i.e., same type of error and same machine state) to avoid multiple records referring to the same error. This process is referred to as *error clustering*. Details of the clustering on the Cyber systems are given in [Sridhar 85]. A visual examination of the clustered data showed the existence of sets of clusters occurring within a short time interval. The close time proximity among some clusters means a substantial increase in the system error rate during that period. The high error rate introduces a suspicion that the errors occurring during the high error rate period may be related, i.e., different errors may be due to a single cause, to multiple but related causes, or to multiple and independent causes.

The high error rate periods referred to above are called error groups, and are formed by grouping all error clusters occurring within a small time interval of each other. (This interval was chosen to be fifteen minutes.) Analysis showed that the results were largely insensitive to variation in this time interval between 5 minutes and 1 hour. It will be seen in section 4 that relationships among error records not captured by this choice of time interval will be captured during subsequent analysis.[1] The primary difference between a cluster and a group is that clusters contain only occurrences of the same error (same error type and machine state), whereas groups contain occurrences of different errors (different error type or machine state).

[1] The choice of the interval is analogous to choosing a starting point in numerical optimization. A poor starting point will mean that the analysis will take a longer time.

As an illustration of the value of grouping, consider the series of observations in Figure 1. Looked upon singly, these would appear to be separate occurrences of different single bit memory errors. Yet, when the errors are combined into an error group, apparently all of them occur within bank 4. Also, the syndrome, or the problem bit, is the same for all the observations. This points to a problem within bank 4, and not to three isolated problems occurring within three different memory locations. Specifically, it refers to a problem that affects one particular bit of the word -- which means the problem is even further isolated to the module. The probable causes now are confined to those that affect only one module -- such as a faulty driver or path. In general, of course, the relationships will not be so obvious, hence the need for a probabilistic methodology proposed in the next section.

In summary, we start with the error log file and at the end of preprocessing we have reduced isolated errors to sets of clearly demarcated, periods of high error rate. These sets of error records are called error groups. Error groups identify periods of high unreliability in the system. The frequency of error groups demonstrates the need to relate errors occurring in different parts or times, i.e., global diagnosis. The tbf of the system increases considerably when groups are treated as single events. Thus, clearly, if the system were able to relate the errors in these groups it would be much more reliable. The determination of the existence and strength of relationships among error records in a group is described in the next section.

3. RECOGNITION OF ERROR PATTERNS

Errors in computer systems occur at various times and in many different locations. Often, the most severe errors are hard to diagnose because of the varied and seemingly unrelated symptoms associated with them as they occur in different locations and at different times. A successful diagnostic technique should be able to relate these errors in much the same way as a service engineer, through past experience, identifies a set of error records as the symptoms associated with a particular problem. The goal of this research was to automate and formalize a process to relate errors occurring in different parts of a system.

This section describes the key aspects of such a methodology, and the succeeding section gives examples illustrating the use of this approach. The objectives of the symptom recognition strategy are to start with the error log file, consisting of entries for all the errors detected as *isolated* errors by the system, and to produce as output symptoms associated with related errors that are being diagnosed as isolated and unrelated errors.

The symptom recognition methodology involves three steps:

(1) recognizing candidates among which relationships can exist,

(2) checking to see if a relationship actually exists among these candidates, and

(3) then estimating a measure of strength of the evaluated relationship (if a relationship does exist).

The first step, i.e., recognition of potential candidates for further analysis, is the time-based grouping described in the section 2.2. The second and third steps which are now discussed are recursively used at three levels of validation. At the first level, the relationship among the error records within an error group is evaluated; i.e., we determine whether there is a valid probabilistic relationship among the records in a group or whether they are simply a collection of unrelated records. The second level looks for inter-group relationships because the same cause(s) can give rise to multiple error groups within a short period. The third level looks for overall relationships in the entire data. Each level of analysis increases the resolution of the data and adds more certainty to the results. At each level, a measure of strength of the evaluated relationship is quantified.

The next subsection discusses the probabilistic validation procedure; the subsequent sections discuss the use of this procedure at different levels of analysis.

3.1 Probabilistic Validation Criterion

In this subsection, the technique used recursively to validate and measure the strength of relationships among the error records at various levels is described.

This technique examines the different records between which a relationship may exist and determines whether a valid relationship is possible among them on a probabilistic basis, based on the past data. In formal terms consider the probability space of n error records $A_1, A_2, \cdots, A_n$. Let $P(A_1), P(A_2), \cdots, P(A_n)$ be their respective individual probabilities calculated from the data, i.e.,

GRPNO	TIME	NPTS	REC- TYPE	ERR	SYN	QUAD	CSU	BANK	CHIP	ERR- TYPE
129	23SEP:14:38:18	3	0003	PARITY	52	1	0	4	2	MEM
129	23SEP:14:38:18	1	0003	PARITY	52	1	0	4	3	MEM
129	23SEP:14:38:18	1	0003	PARITY	52	1	0	4	0	MEM
129	23SEP:14:38:18	2	0003	PARITY	52	1	0	4	3	MEM
129	23SEP:14:38:18	2	0003	PARITY	52	1	0	4	2	MEM
129	23SEP:14:38:18	1	0003	PARITY	52	1	0	4	0	MEM

Figure 1: Sample of Grouped Data

(template)	(time)	(error description)			(associated device)	(exact location)			
Record Type	Timestamp	Error Type	Error Code	Syndrome	channel	disk	chassis	quadrant	bank

Figure 2: Error Log Entry for Memory Error

$$P(A_k) = \frac{\#\ of\ occur.\ of\ A_k}{\sum_{i=1}^{i=n} \#\ of\ occur.\ of\ A_i}$$

Then, $P(A_1) * P(A_2) * \cdots * P(A_n)$ is the probability that $A_1, A_2, \cdots, A_n$ will occur together, assuming they are independent. Further, let $P(A_1, A_2, \cdots, A_n)$ be the joint probability of occurrence computed from all the joint occurrences of $A_1, A_2, \cdots, A_n$ in the error log, i.e.,

$$P(A_1, \cdots, A_n) = \frac{\#\ of\ joint\ occur.\ of\ (A_1, \cdots, A_n)}{\sum_{i=1}^{i=n} \#\ of\ occur.\ of\ A_i}$$

If

$$P(A_1) * \cdots * P(A_n) < P(A_1, \cdots, A_n) \qquad (3.1)$$

then it is reasonable to assume that the joint occurrence of $A_1, \cdots, A_n$ is not random. A measure of the strength (S) of the evaluated relationship is given by the ratio

$$S = \frac{P(A_1, \cdots, A_n)}{P(A_1) * \cdots * P(A_n)}$$

What $A_1, A_2, \cdots, A_n$ stand for depends on the level of analysis:

(1) When we are attempting to validate the relationship among the error records in an error group, $A_1, \cdots, A_n$ stand for the individual error records within the error group

(2) When we are studying the relationship among the error groups in an event, $A_1, \cdots, A_n$ stand for each individual error group. Since the existence and strength of relationships are evaluated probabilistically, the approach is not constrained to specific architectures or system configurations.

3.2 Validation at Group level : Inter-Record Relationships

Recall that error groups represent high error rate periods during the operation of the system. The high error rate introduces a suspicion that the error records within an error group may be related. It is, of course, possible that the rise in error rate is just a random incident. To distinguish between these two possibilities, error records in an error group are analyzed in three different ways to determine if the records in an error group have a valid relationship.

Complete Analysis

The first is referred to as a *complete analysis*. The probabilistic validation procedure discussed in the previous subsection is applied to all the records in an error group, i.e., the individual and the joint probabilities of all the error records in a group are computed from the data. If all the error records in an error group are found to be statistically related, no further analysis is done on that error group.

Subset-Based Analysis

If error records in a group are found not to be related through a complete analysis described above, then it may be that subsets of the original error group have valid relationships. Different combinations of error records in a group are then analyzed to determine the existence of valid statistical relationships among them. For example, if there are three records (A, B, C) in an error group, the subsets (A, B), (A, C) and (B, C) are analyzed and Equation (3.1) is used to determine the relationship among the error records in these subsets. This approach is referred to as a *subset-based* analysis.

Truncated Analysis

If no relationship is found with complete or subset-based analysis, a third analysis based on truncated records is carried out. In this step, a few fields of the error records are masked from the analysis. This is best illustrated using the format in Figure 2, which refers to the log of a memory error.

The fields chassis, quadrant, bank and chip describe the location of error. It may be that a statistically valid relationship exists at the bank level (say among a few banks) and that the chip identity of the error records may thwart the recognition of the valid bank level relationship.[2] Thus, when the chip identity is dropped, we are attempting to determine the existence of statistically valid relationships at the bank level. Note that when the analysis is carried out with truncated records, more records can enter the probability space. Thus, the final result can be substantially different from the original result.

[2] When the chip identity is also taken into account, we are essentially trying to determine if errors occurring in different chips within a short period are statistically related or not.

[3] The same masking analysis may be carried out by starting from the highest level of resolution, i.e., the last field of the record. The chip identity is masked and the analysis is carried out; then the bank identity is masked and so on until a relationship is found or until all the fields are masked. This algorithm will require more run time. The higher resolution offered by this analysis is achieved by subsequent analysis.

The fields to be masked are determined as follows: starting from the lowest level of resolution, i.e., the beginning of error records, the records in a group are scanned until the first field wherein they are dissimilar is found. All the fields beyond this field are masked from the analysis. For example, two records with the format shown in Figure 2 may have identical fields up to the chassis. The quadrant is the first field with non-identical values. Then the fields bank and chip are masked from the analysis.[3]

This three-tier analysis eliminates error groups consisting of records with no relationships, i.e., random errors, from further analysis. The importance of this analysis is underscored by the fact that in our analysis (shown in section 4) over 25% of the groups were rejected as random groups. The validation of subsets eliminates stray records present among related error records in an error group, and the validation of truncated records captures non-obvious relationships among error records. Thus, the original error groups consisting of records among which relationships *can* exist is refined to error groups consisting of records among which relationships *do* exist.

In some cases, the stray record does not invalidate a group. It merely reduces the strength of the evaluated relationship. Consider three records in a group, say A, B and C. A and B may be related and C may be the stray record. The strength of the relationship computed by analyzing A and B may be much higher than that obtained by analyzing A, B and C. It is possible to perform the three-tier analysis in all the cases and accept only the relationship with the highest strength. Such an analysis is, however, very computer-intensive and, therefore, was not performed here. Stray records are ultimately eliminated in subsequent analysis.

Relationships can exist across error groups; i.e., a single cause can give rise to a persistent error and thus foster multiple error groups within a short time. Therefore, it becomes necessary to examine the validated groups for inter-group relationships. The methodology to recognize inter-group relationships is described in the following subsections.

3.3 Validation at Event Level : Inter-Group Relationships

The persistence of a single cause(s) and the possibility of stray error records among related error records in an error group motivate the second level of analysis, i.e., recognition of related error groups and the elimination of stray error records from error groups.[4]

To analyze the relationship among error groups, it becomes necessary to introduce the concepts of events and symptoms, and symptom sets. An event is defined as the collection of error groups occurring within twenty-four hours and having at least two error records in common. A symptom is defined as a collection of statistically related, non-redundant error records that are common to most of the groups in an event. A symptom set associated with an event is defined as a collection of symptoms that best describe the event. Symptom sets are recognized by analyzing the error groups in an event.

When an event has just one error group, the statistically related error records within that error group form the symptom set associated with that event. When there is more than one error group in an event, the symptom set is formed by intersecting the error groups within the event. The error groups are taken N groups at a time, N-1 groups at a time, and so on down to (N/2), or to the next higher integer number of groups. The intersection of such different combinations of error groups yields different symptoms that are found in these groups. It also eliminates any stray records that occur in a few of the error groups in an event.

Once the symptom set associated with an event is derived, Equation (3.1) is used to check for the relationship among the different symptoms. If only one symptoms is extracted from an event, the event is probably due to a single cause. When more than one symptom is extracted from an event, the probabilistic validation procedure is used to determine if the different symptoms are caused by related or independent causes. For example, if two symptoms, say A and B, are extracted from an event, and if the symptoms satisfy Equation (3.1), i.e.,

$P(A) * P(B) < P(A,B)$

then the event is due to multiple but related causes, and the ratio

$P(A,B) / (P(A) * P(B))$

quantifies the strength of the relationship between A and B. If

$P(A) * P(B) > P(A,B)$,

the event is caused by multiple and independent causes.

If two independent causes exist and persist simultaneously,[5] the extracted symptoms will consist of confusing sets of error records. This is because all or most of the groups in the event contain records referring to both causes. When such groups are intersected, symptoms associated with both are extracted as though they were related causes. The records due to one cause are strays with respect to the other cause, and some technique is necessary to discriminate between the two. A higher level of analysis, necessary to deal with such occurrences, is described in the following section.

3.4 Validation at Super-Event Level : Inter-Event Relationships

The possibility of the presence of stray records in all of the error groups in an event, and the need to capture relationships missed by the choice of twenty-four hours as the time interval while forming events, motivate the next and the last level of analysis, i.e., determination of inter-event relationships. Further, when the events resulting from the same cause(s) across the entire data are analyzed, the stray records occurring in one particular event become visible. This allows for the resolution between independent and dependent (related) failures.

Three simple rules are used to recognize related events and to form *super events*. Two events are grouped into a super event if they satisfy any one of the following

[4] Noise is a representative term for stray error records.

[5] Such conditions occur rarely, but they do occur.

criteria:

(1) They have at least one symptom in common

(2) A symptom of one event is a sub or super set of at least one symptom of another event

(3) If they are single-group events, then they have at least two records in common.

Importantly, there is no time restriction when forming super events.

Next, a set of super symptoms, which are collections of symptoms found in common among two or more events in a super event, is generated. The procedure is exactly the same as for events except that instead of taking groups, we take events described by the symptom sets. The intersection operation among the events yields symptoms found in common among these events. The non-null result of each intersection operation forms a super symptom for the associated super event.

Some super events have just one super symptom associated with them, while others have more than one associated with them. To determine whether the different super symptoms associated with a super event are related, (i.e., whether the super event has a single cause) we use the probabilistic validation procedure described in Section 3.1. If the different super symptoms are not related, then the super event is due to multiple and independent causes.

When a super event is due to multiple and independent causes, the number of such distinct independent causes may be determined as follows: the super symptoms are considered in different combinations, taken N-1 super symptoms at a time, and so on down to 2 super symptoms. The probabilistic validation procedure is applied to each such combination. This analysis determines the relationship within a particular subset of super symptoms associated with a super event. If the subset is found related, it is counted as one cause. The analysis is continued until all independent causes associated with a super event are found.

Recall that the goal of this paper is to automate the process by which a service engineer relates errors occurring in different parts of a computer system. The super symptoms derived from the error log file not only consist of sets of related error records but also quantify the strength of their relationships. Whereas the service engineer usually scans the error log pertaining to the short period during which the error occurred, recognizes related error records and makes a local judgement, the methodology scans all the errors that occur in a system and is capable of making a global judgement. The application of this technique to real data is discussed in the next section.

3.5 Summary

The methodology described in this section establishes that it is possible to build a system that will relate errors occurring in different parts/times in a computer system or when two unrelated causes occur simultaneously in a system. It has been shown that the proposed methodology allows for resolution between them. Some causes persist for days or even months. While such causes persist, other independent errors can also occur in a system.

Three levels of validation are used in a recursive fashion. In the first, all groups (high error rate periods) are examined to determine if they contain related records. Next, the validated groups are examined for inter-group relations (events). Finally, the events across the entire date are examined for inter-event relationship.[6]

The symptom sets obtained using this methodology imply that if one error within a symptom set occurs, other related errors within the symptom set can be expected to occur. The strength of the relationship says how likely it is that related errors will follow.

The number of levels of analysis can be varied for higher resolution. That is, if a system is highly error-prone and a grouping of errors occurring within fifteen minutes leads to coalescing of unrelated errors, then this grouping time interval may be reduced to, say, five minutes or less. The next section illustrates various facets of this approach by applying it to determine the error symptoms in the CYBER system.

4. EXAMPLES OF ERROR SYMPTOMS

This section illustrates the various stages of the analysis involved in the automatic recognition of error symptoms from error log data. A summary of the analysis is given first. Then three examples are provided, illustrating the three levels of analysis, namely, the group, event and super event levels. Some features of the proposed methodology not illustrated by the first example are illustrated in the last two examples.

4.1 Summary of the Analysis

Table 1 sums up the number of groups, events and super events derived from the error logs of Cyber 174 and Cyber 175 machines. Note that 67.1% of the Cyber-174 groups and 27.5% of the Cyber-175 groups were rejected as random groups. Most of the super events in both the machines were due to single or related causes. In all, there are fifteen distinct causes that result in severe errors on the Cyber-174 and thirty-three causes on the Cyber-175.

TABLE 1:
FREQUENCY OF GROUPS, EVENTS AND SUPER EVENTS.

	Cyber 174	Cyber 175
# of groups	85	142
# of groups rejected	57	39
# of events		
due to single cause	19	53
due to multiple causes	0	2
# of super events		
due to single cause	15	33
due to multiple causes	0	2

[6] Note that each level of analysis adds to the information gathered at previous levels, i.e. a group validated at the group level cannot be rejected in subsequent analysis but can find other related groups.

There are 85 error groups in the Cyber-174 data and 142 groups in the Cyber-175 data. These numbers quantify the periods of highly unreliable operation during the operation of the computer system. During these high error rate periods, many of the system resources may have been utilized in recovery measures.

4.2 Cyber-174 Super Event with Multiple Super Symptoms

This section illustrates the various facets of the proposed methodology. This particular example is chosen because it illustrates all the important steps and the major problems involved in the automatic recognition of symptoms.

Figure 3 shows a super event consisting of four events. Here all events are single group events. As an example of analysis at the group level, we consider the group of error records in the second event, marked EVT 2. In this group, we find four types of records, i.e., those records with ERRTYPE/locations corresponding to E/..., S/0-0-7-1, S/1-0-1-2, and S/1-0-5-0. Using the method of Section 3.1, the strength of this group was 76.50. Since this strength is greater than 1.0, the records exhibit a valid relationship within this group, so subset-based and truncated record analyses are unnecessary. The strengths of the groups respective of the order that they appear in Figure 3 are 1.56, 76.50, 1.56, and 4.00. Analysis of symptoms at the event level is trivial in Figure 3, since each event has only one type of error symptom. An example which better illustrates event level analysis is discussed in the next section.

Figure 3:
Example of Multiple Symptom Super Event on CYBER-174

Analysis at the super event level is performed by applying the probabilistic validation procedure to the set of super symptoms extracted from a super event. In Figure 3, the union of event symptoms yields the following super symptom set:

$$(1)\ (\ E/\cdots\ .\ S/0\text{–}0\text{–}7\text{–}1\ .\ S/1\text{–}0\text{–}1\text{–}2\ .\ S/1\text{–}0\text{–}5\text{–}0\ )$$

$$(2)\ (\ E/\cdots\ .\ S/0\text{–}0\text{–}7\text{–}1\ .\ S/0\text{–}1\text{–}5\text{–}3\ ) \qquad (4.1)$$

By definition of a super event, these super symptoms can occur within only this super event. The strength of the entire super event by Equation (3.1) is 2.0, which indicates that the events are strongly related. Thus, this super event may be considered the result of a single cause. Had these super symptoms failed to satisfy Equation (3.1), we would have inferred that the super event was due to multiple causes.

It should be noted that the error records in this super event span a period of seventeen days. The cause appears to be an intermittent error which recurs, apparently affecting different components. That they are due to a single cause would not be immediately obvious from looking through the entire error log. This example clearly demonstrates the power of the proposed methodology to extract good quality symptoms associated with severe errors in computer systems.

4.3 Cyber-175 Super Event with Multiple Super Symptoms

Figure 4 shows part of a super event. This super event consists of ten events persisting over a period of the ten weeks from July 8 to September 18 of 1985. Three of these events are shown in Figure 4. The second event, marked EVT 2, consists of three groups, spanning a period of less than seven minutes each. In addition to occurring less than an hour apart and having at least two records in common with another group, these three groups had to be validated at the group level to be included in the same event. Using the measure of strength of relationship between records as described in Section 3.1, the value for the first group's locations (1-1-1-0 , 1-1-2-2 , 1-1-0-1 , 1-0-0-1) is 8.444. For the second group, the value for locations (1-1-1-0 , 1-1-2-2 , 0-1-7-2 , 1-1-3-3) is 12.901. And for the third group, the value for locations (1-1-1-0 , 1-0-0-1 , 0-1-7-2 , 1-1-3-3) is 10.411. These strengths clearly indicate the validity of the record relationships within the three groups.

Event Level Analysis

As an example of analysis at the event level, we consider the set of symptoms generated by the groups in EVT 2. Four symptoms are generated:

$$(1)\ (\ 1\text{–}1\text{–}1\text{–}0\ )$$

$$(2)\ (\ 1\text{–}1\text{–}1\text{–}0\ .\ 1\text{–}0\text{–}0\text{–}1\ )$$

$$(3)\ (\ 1\text{–}1\text{–}1\text{–}0\ .\ 1\text{–}1\text{–}2\text{–}2\ )$$

$$(4)\ (\ 1\text{–}1\text{–}1\text{–}0\ .\ 1\text{–}1\text{–}3\text{–}3\ .\ 0\text{–}1\text{–}7\text{–}2\ ) \qquad (4.2)$$

By Equation (3.1) the strength of event EVT 2 is 32.16. This indicates a valid relationship between the three error groups in event EVT 2, i.e., they were all caused by the same problem. But this inference is only a local view. To get a global view, we look for related events across the entire data.

Super Event Level Analysis

For the super-event level analysis, other events with at least one symptom set in common are extracted from the data. Here we illustrate the procedure for the events shown in Figure 4. Events EVT 1 and EVT 3 are single-group events. Their symptom sets are simply the groups themselves. The super symptoms obtained are:

$$(1)\ (\ 1\text{–}0\text{–}2\text{–}0\ ,\ 1\text{–}0\text{–}2\text{–}2\ ,\ 1\text{–}1\text{–}3\text{–}3\ )$$

$$(2)\ (\ 1\text{–}1\text{–}1\text{–}0\ ,\ 1\text{–}1\text{–}3\text{–}3\ ,\ 0\text{–}1\text{–}7\text{–}2\ )$$

$$(3)\ (\ 1\text{–}1\text{–}1\text{–}0\ ,\ 1\text{–}1\text{–}2\text{–}2\ ,\ 1\text{–}0\text{–}0\text{–}1\ ) \qquad (4.3)$$

Note that the first three symptoms of Equation (4.2) have been absorbed into the third super symptom of Equation (4.3). This provides global support of the inference made at a local level that errors occurring in locations 1-1-1-0, 1-1-2-2, and 1-0-0-1 are due to the same cause.

The physical interpretation of these three super symptoms is that the occurrence of one error implies that another error is likely to follow. The strength of the relationship among the errors in a symptom set tells us how likely it is that the related error will follow. The probabilistic validation procedure quantifies a measure of the strength of the relationship among error records based on their joint and individual occurrences.

For example, the values of the measure of relationship strength between error records pertaining to the three super symptoms of Equation (4.3), respectively, are 5.37, 5.26, and 2.17. Thus, when an error occurs in location 1-1-1-0, errors are likely to occur in locations 0-1-7-2, 1-0-0-1, 1-1-2-2 and 1-1-3-3. Given that an error has occurred in location 1-1-1-0, the chances are that an error is more likely to occur in location 1-1-3-3 or 0-1-7-2 than in location 1-1-2-2 or 1-0-0-1. Thus, the symptom sets tell us about the other parts or other errors that are likely to occur, and the measure of strength of the relationship among the records in a symptom set tells us which parts are more likely to be affected from among all the parts that can be affected.

A practical benefit of the proposed methodology is that it makes service/maintenance engineers aware of all the severe or persisting errors in a system. Although most causes of error took the form of single, transient groups of errors, there were quite a few that resulted in numerous recurring groups of errors, spanning months of time. For example, 26.7% of the CYBER-174's super events were composed of multiple groups of errors, as were 36.4% of the CYBER-175's super events. In this context, it is interesting to note that the maintenance engineers were unaware of the persisting errors discussed in this section until we brought it to their attention. This was not withstanding the fact that the same maintenance engineers went through the error log on alternate days of the week during the six-month period when these errors persisted. They, however, failed to notice them.

Figure 4:
Example of Multiple Symptom Super Event on CYBER-175

4.4 Super Event with Unrelated Super Symptoms

This section illustrates an example of a super event whose records appear to be strongly related at both the group and event levels but fail to show significant relationships at the super event level.

Figure 5 shows a super event constructed from CYBER-175 error records and consisting of two events. In the first event, marked EVT 1, there are two groups. Analysis of the records in each group yields strengths of

1.42 and 19.27 for the smaller and larger, respectively. In the second event, marked EVT 2, there are three groups. Their strengths, in chronological order, are 19.27, 5.23, and 1.42. Clearly, the records in all five groups are strongly related.

This strong relationship is preserved at the event level as well. The groups of EVT 1 are represented by a single symptom: (1-1-1-0, 1-0-2-0). EVT 2 had three symptoms and an event strength of 4.54:

$$(1)\ (\ 1\text{–}0\text{–}2\text{–}0\ ,\ 0\text{–}0\text{–}2\text{–}1\ ,\ 1\text{–}1\text{–}7\text{–}2\ )$$

$$(2)\ (\ 1\text{–}0\text{–}2\text{–}0\ ,\ 1\text{–}1\text{–}1\text{–}0\ )$$

$$(3)\ (\ 1\text{–}0\text{–}2\text{–}0\ ) \qquad (4.4)$$

This strength again indicates that the error records in EVT 2 are related to a single cause.

When analyzed at the super event level, however, we find that there is no longer enough statistical support to indicate that the super event of Figure 5 was due to a single cause. The super symptom set is found by taking the union of the symptoms generated by EVT 1 and EVT 2 and is simply the first two symptoms of Equation (4.4). The first super symptom appears independently four different times among all the events generated from the CYBER-175 data. The second super symptom appears eight times independently. By Equation (3.1), the strength of this super event is only 0.38. This low strength indicates that the super event consists of errors due to unrelated causes. The super symptoms occur independently so frequently that their joint appearance in the super event of Figure 5 cannot be considered significant.

Two specific procedure of the proposed methodology, namely, the subset based and truncated analyses, have not been illustrated in the examples discussed so far. Examples of these procedures can be found in a related technical report [Sridhar 85].

Figure 5:
Example of Super Event Due to Unrelated Causes

5. PERFORMANCE OF THE METHODOLOGY

As a final check on the performance of the methodology, we obtained independent corroboration of our results from the log of failures and repair maintained by the field engineers. Although this recording was not always complete, it did allow us to perform an independent check on our evaluation. The results of this check are summarized below.

In nearly 85% of the cases the engineers were directly able to confirm that our validated superevents corresponded to real system problems. The evaluation was made both on the basis of their experience and from their field maintenance logs. The confirmed cases corresponded to single event superevents.

For the remaining 15% of the cases, although the engineers could not confirm "noticing" a valid problem, they agreed that (with the benefit of hindsight) that a problem had existed. However, the manifestation (an event) was not severe enough to be noticed by their analysis. One important case was the superevent consisting of ten events, discussed in section 4.2. This superevent spans ten weeks. Although, each event by itself was not severe enough to show up, when taken as a whole it was clear that a persistent problem had existed. It appears that as a result of our information corrective action was taken because this particular superevent does not exist in the data which has been gathered since then. In summary, we find that not only do our results agree with field findings but also we are able to relate problems over a long period of time which would otherwise go undetected.

The proposed methodology, thus, can be used to evaluate the goodness of any diagnostic system, whether primitive or sophisticated. This can be done by analyzing the relationship among the errors the diagnostic system detects as isolated. A very simple measure for the goodness of diagnosis of a system could be given by

$$1 - \frac{\textit{number of error entries coalescing into related errors}}{\textit{total number of error entries in the error}\ \text{log}}$$

6. CONCLUSION

This paper has developed a methodology for automatically detecting symptoms associated with persistent errors in computer systems. The methodology was shown to work on two large computer systems in a multisystem configuration. The recognition process is based on probabilistic techniques and is implemented in three levels. Each level adds confidence to the results. The power of the methodology to allow for the resolution between single and multiple but independent causes was also demonstrated. With multiple but overlapping symptoms, the methodology determines the number of distinct independent symptoms. The methodology quantifies the strength of the relationship among related errors. Research is now in progress to develop a suitable diagnostic system that will use the extracted error symptoms and automatically carry out diagnosis and recovery. This would not only facilitate better diagnosis and recovery management, but will also improve the overall reliability and performance of a system.

ACKNOWLEDGEMENTS

The authors thank George Badger, Director CSO, Warner Brigham, Sandy Moy and Milt Cloud at CSO for providing insight into the measured systems and access to the data. This work was supported in part by the Joint Services Electronics Program (U.S. Army, U.S. Navy, and U.S. Air Force) under contract number N00014-84-C-0149 and in part by IBM corporation.

APPENDIX
SYSTEM DESCRIPTION

This analysis uses detailed error data automatically collected over a six-month period by the operating system. As with other large systems, the CYBER machines maintain a log of a variety of normal and abnormal events -- called the "system dayfile." The abnormal events are errors automatically detected by the system. Errors can originate in the peripheral processors, the central processor, main memory, or the disk subsystem. The errors are captured by hardware that checks the integrity of information being transmitted between physical elements in the system. When an error is detected, a system routine collects pertinent information from the hardware concerning the state of the machine at the time of the error and stores it in the dayfile. A decoded sample of the information logged is shown Figure A.1.

The fields of information include:

(1) record type: specifies the format of the rest of the record (RECTYPE)

(2) error code: specifies the nature of the error (ERR)

(3) time and date of error

(4) channel in use at the time of error (CHAN)

(5) equipment number of the device involved (EST)

The three major record types are:

(1) deadstarts (RECTYPE = 0001): these are logged for all scheduled and unscheduled system restarts. The two common deadstart levels are (a) deadstart level zero which denotes a complete halt of the machine with no job recovery possible, and (b) deadstart level three which implies that the integrity of the machine state is maintained and recovery is possible for most jobs.

(2) disk subsystem errors (RECTYPE = 0024): these included disk checkword errors, channel parity errors, and device contention errors.

(3) parity-related errors (RECTYPE = 0003): these include memory errors (single error correction, double error detection), peripheral processor errors, channel errors, extended core parity and central memory controller errors.

Abstract

This paper describes a software package that assists the construction and solution of performability models based on stochastic activity networks. Stochastic activity networks, a generalization of stochastic Petri nets, permit the representation of concurrency, timeliness, fault tolerance and degradable performance in a single model. Their structure allows for direct construction of analytically tractable stochastic base models under certain well defined conditions, as well as simulation under very general conditions. For a given system, the input to METASAN consists of two parts: a description of the structure of the net, and a description of the desired performance variables and solution method. Each part is specified in a flexible input language. This language allows the analyst to define very general performance variables in terms of the behavior of the net. The user interface and solution methods employed are reviewed, and an example is given illustrating use of the package.

1. Introduction

Extensions to Petri nets have proved to be valuable tools for both the verification and evaluation of concurrent systems. Many of these extensions have included the addition of an explicit representation of time. In particular, one approach has been to add timing of a probabilistic nature to transitions in the net. This permits the representation of timeliness as well as concurrency in a stochastic setting. As models for performability evaluation [1], they also permit the representation of fault tolerance and degradable performance. Stochastic activity networks (SANs) [2, 3, 4] were developed to facilitate the performability evaluation of systems which exhibit any or all of these four characteristics. Through the introduction of several new primitives, they allow the model to be specified in a convenient way, while providing the formal structure necessary for analytic solutions. When model characteristics preclude analytical evaluation, performability can be evaluated via simulation.

Others have likewise examined the use of stochastic extensions of Petri nets for performance and/or reliability evaluation. Solutions via analysis, and to a lesser extent, simulation have been considered. Notable in the area of analysis is the work of Natkin ([5]; Timed Petri Nets), Molloy ([6]; Timed Petri Nets), Marsan et al. ([7]; Generalized Stochastic Petri Nets), Chiola ([8]; Generalized Stochastic Petri Nets), Cumani ([9]; Stochastic Petri nets with phase type distributions), and Dugan et al. ([10]; Extended Stochastic Petri Nets). Examples of solution via simulation include work by Behr et al. ([11]; Evaluation Nets), Dugan ([12]; Extended Stochastic Petri Nets), Chiola ([8]; Generalized Stochastic Petri Nets), Godbersen and Meyer ([13]; Function Nets), and Törn ([14]; Simulation Nets).

In what follows, we assume familiarity with the basic structure and execution of SANs [2, 3]. For a brief review of basic concepts and terminology, consider the stochastic activity network of Figure 1. Activities ("transitions" in Petri net terminology) are of two types, timed and instantaneous. Elongated ovals represent *timed activities* (e.g., compute1) and solid bars represent *instantaneous activities* (e.g., disk1). Timed activities are used to represent activities of the modeled system whose durations impact the system's ability to perform. Instantaneous activities represent system activities which, relative to the performance variable in question, complete in a negligible amount of time. Places are depicted as circles (e.g., A-J) and, as with Petri nets, each place can hold a nonnegative number of *tokens*. The distribution of tokens in the places of the network at a given time constitutes the *marking* of the network at that time.

Cases can be associated with both timed and instantaneous activities and are represented by small circles (e.g., as in compute1). Cases permit the realization of two types of spatial uncertainty. Uncertainty about which activities are enabled in a given marking is realized by cases associated with intervening instantaneous activities. Uncertainty about the next marking assumed upon completion of a timed activity is realized by cases associated with that activity. The two remaining net primitives are input gates and output gates. Input gates (e.g., computein1) contain both an enabling predicate and input function (on the marking of the places). The enabling predicate must be true for the activity associated with that gate to be enabled. Upon completion of the associated activity, the input function is executed, possibly changing the marking of the net. Output gates (e.g., diskout1) have a single output function (on the marking of the places) associated with them, which is executed upon completion of the associated activity.

The stochastic nature of the nets is realized by associating an activity time distribution function with each of the timed activities and a probability distribution with each set of cases. A *reactivation function* [3] is also associated with each timed activity. This function specifies, for each marking, a set of *reactivation markings*. Informally, given that an activity is activated in a specific marking, the activity is *reactivated* whenever any marking in the set of reactivation markings is reached. This provides a mechanism for restarting activities that have been activated, either with the same or different distribution. Note that this decision is made on a per activity basis (based on the reactivation function), and is not a net-wide execution policy.

As stochastic activity network models grow in size and complexity, analysis by hand quickly becomes intractable. Both the growth in possible markings and complexity of activity time distributions contributes to this difficulty. Such considerations have resulted

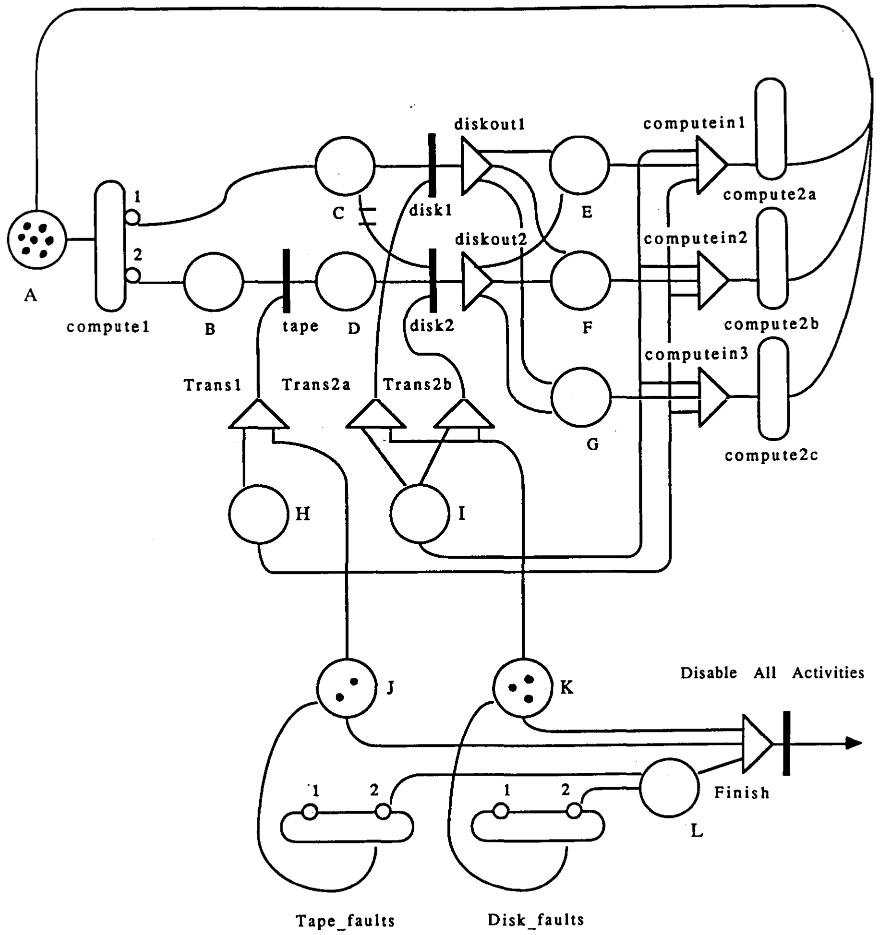

Figure 1. Example Stochastic Activity Network

in the development of METASAN (Michigan Evaluation Tool for the Analysis of Stochastic Activity Networks). METASAN contains routines for both model construction and model solution, and contains both simulation and analytical solvers.

In the discussion that follows, Section 2 describes the high level organization of METASAN. Section 3 discusses model construction and Section 4 describes model solution. Use of the package is illustrated in Section 5 via its application to a specific evaluation problem. Finally, suggestions for further work are discussed in the concluding section.

2. METASAN Organization

METASAN was designed in a modular manner to allow for the addition of new solution methods as these become available. It is written using UNIX tools (C, Yacc, Lex, and Csh) and currently contains some 30,000 lines of source code. Steady-state and transient evaluation, via both analysis and simulation, are supported by the tool.

At the highest level, the analyst interacts with METASAN through a menu structure. This menu (Figure 2) permits access to the two basic files that make up a METASAN model: a structure file and an experiment file. The menu also permits access to the compilers for each of the description files and the solution modules. The structure file is a direct translation of the SAN into a textual form that can be accepted by the package. Specification of desired performance variables and solution algorithm is done via the experiment file. Each of these files will be described in more detail in Section 3. Model construction consists of describing the structure of the system to be modeled using the editor (option vs), compiling the description (option s), describing the experiment file (option ve) and compiling the experiment file (option e). The result of these actions is a machine understandable description (a collection of C data structures and procedures) of the system to be modeled and the desired performance variables. By then selecting model solution (option r) this machine readable description is bound to the correct solution module and is executed. A flowchart of this process is given in Figure 3. Output from the solver depends on the solver chosen, but contains either estimates or exact values of the chosen performance variables.

Items in the pictured menu that are identified by a capital letter designate lower level menus. "Set Files" allows the user to specify each of the files associated with a particular model. "Set Runtime Options" offers a variety of options which, depending on the solution module selected, allow the user to set various trace and debug options, run the model in the background or on remote machines, and direct the output to several locations. "System Commands" consists of a collection of commands to aid the user in creating new model directories, removing or copying description files, etc.

3. Model Construction

In the context of METASAN, model construction consists of describing both the stochastic activity network and chosen performance variables in a manner understandable to the package and translating these descriptions into a form that is understandable to the solution modules. This is accomplished in METASAN via two input languages and their corresponding compilers.

3.1. Sanscript and the SAN Compiler

The SAN description language, *Sanscript*, allows the analyst to specify the SAN in a textual form understandable to the (SAN) compiler. Sanscript permits easy specification of complex enabling predicates, activity time functions, reactivations functions and gate functions. To give the reader a feel for Sanscript, we describe the language via the example presented earlier. Figure 4 is the Sanscript representation of the portion of the stochastic activity network that represents variations in the internal state and environment of the system; activities representing fault occurrences are not represented. At a high-level, a Sanscript description consists of four parts: a header, local variable declarations, definition of all the primitives used, and a specification of all functions, values, and interconnections associated with each primitive.

In our example, the header specifies that the name associated with this SAN is multi1. The local variable declaration section is not used. Next comes the declaration of primitives. Note that the initial marking for each place is specified directly after the place name. The specification section follows. In any function, the current marking of the place can be referenced by using the notation *MARK*(*place*), where "place" is the name of the desired place. For an example specification, refer to the definition of compute1. As can be seen in the graphical representation, timed activity "compute1" has two cases, one connected to place C, and one to place B, and a single input place A. The activity time distribution is specified to be exponential with parameter 1.0 * *MARK*(*A*) and the case distribution is specified such that there is a 30% chance of choosing case 1 and 70% chance of choosing case 2 upon completion of the activity. The reactivation function is specified so that for every marking (denoted by the 1 in the first set of brackets after "react") the set of reactivation markings is all markings (denoted by the second 1 in brackets). In other words, the activity is reactivated at every state change. The reason for this will be discussed in the example section. Note that any expression that evaluates to the correct type (real for prob and exp, boolean for react) may be given between the curly brackets; complex interactions, activity time descriptions, reactivation functions, and case distributions can be represented easily via a few C statements.

A host of activity time distribution types are available, representing all service distributions normally used in evaluation. An activity time distribution function of "inst" is used to denote an instantaneous activity. Of course, the choice of distribution affects the nature of the underlying stochastic process and the solution methods that may be used. Complex reactivation functions can be represented by specifying several pairs of predicates, the interpretation being that the activity is reactivated if, a) the activity was activated in the subset of the reachable markings specified by the first predicate, and b) a marking in the subset specified by the corresponding second predicate is reached. Again, if the activity is enabled in this second marking it is immediately restarted.

Gates are specified in a similar manner. For example, see the description of the input gate "computein1" in both the graphical and textual representation. The input places associated with the gate are specified as an indexed list. This abbreviated notation allows place names to be abbreviated in the predicate and function descriptions according to the following rule: "Xi" denotes the i-th place specified in the associated input or output (in output gates) place specification.

                  func { X1 = X1 + 1; } ]
Trans2a         [ inputs 1: I; 2: K;
                  pred { X2 > X1 }
                  func { X1 = X1 + 1; } ]
Trans2b         [ inputs 1: I; 2: K;
                  pred { X2 > X1 }
                  func { X1 = X1 + 1; } ]

end.
```

Figure 4. Example Description File

An example of this can be seen in both the predicate and input function description of computein1. Note again that any legal C statements may be placed within the brackets, as well as the abbreviated notation described above and the *MARK* function notation. Output gates are specified in an identical manner except that the keyword "outputs" is used in place of "inputs" and there is no associated enabling predicate.

Many stochastic activity networks contain numerous similar subnetworks (e.g., nodes in a computer network) that are replicated many times. Construction of these subnetworks directly in Sanscript would be tedious. To make this easy, we have recently completed development of a macro-preprocessor for METASAN. This preprocessor allows one to define subnetworks once in a parameterized manner, and then construct a specific subnetwork via a single macro call.

After the specification of the SAN in Sanscript is complete, it is passed to the SAN compiler to be translated into an internal form understandable by the solution modules. The SAN compiler is written in Yacc (yet another compiler compiler), Lex and C.

3.2. Performance Variables

In order to understand the available performance variables, it is necessary to characterize the execution of a stochastic activity network in a more formal manner than is found in [2]. This is done by introducing the notion of a configuration and a step. A ***configuration*** is a triple $<\mu, a, c>$ where μ is a marking, a is an activity, and c is a case of that activity. A SAN is said to be in configuration $<\mu, a, c>$ if μ is the current marking of the network, activity a will complete next, and case c will be chosen. A ***step*** is a triple $(<\mu, a, c>, t, s)$ where $<\mu, a, c>$ is a configuration, t is the time of activation of activity a, and s is the activity time of activity a. Furthermore, an ***execution of a stochastic activity network*** is a sequence of sets of steps $S_1, S_2, \cdots, S_n, \cdots$.

Except for markings in which more than one instantaneous activity is enabled, each set in the sequence of steps is a singleton and corresponds to the state of the network at the specified time. Multiply enabled instantaneous activities lead to sets of cardinality greater than one. A detailed understanding of the execution of the network in this situation is not necessary to understand what follows. A more precise definition of execution is found in [15].

In order to specify general performance variables in terms of the execution of the net, it is helpful to introduce the notion of a path. A ***path*** is a finite sequence of configurations $C_1, C_2, C_3, \cdots, C_n$ such that for each pair of configurations $<\mu_i, a_i, c_i><\mu_{i+1}, a_{i+1}, c_{i+1}>$ the completion of a_i and choice of c_i in μ_i results in μ_{i+1}. During an execution a path may be traversed. The following discussion makes this more precise. A ***completion of a configuration*** $<\mu, a, c>$ occurs at time $t+s$ when during an execution of a SAN the configuration is found in a step $(<\mu, a, c>, t, s)$ in some set of steps. An ***initiation of a path*** occurs when the SAN reaches the marking associated with the first configuration in the path. A ***completion of a path*** occurs when the SAN completes the final configuration in the path after completing each configuration in the path in the order specified without reaching any intermediate configurations other than those specified in the path. A ***traversal of a path*** is the act of first initiating the path and then completing the path.

These definitions allow us to introduce a set of performance variables to study the behavior of the SAN. These variables are listed below. Note that they are indexed either by time or number of occurrence so that, if they converge in distribution, their limit can be studied.

$N_T(f,t)$

a measure of the value of the function f at time t+. f can be any real-valued function on the marking of the net. Examples include the marking of a single place and the sum of the markings of several places.

$T_b(S,n)$

the time between n-1*th* and *nth* completion of any path in a set of paths S.

$T_w(S,n)$

the time to traverse the *nth* path to complete in a set of paths S.

$I(T,t)$

an indicator random variable denoting the event of being in any configuration in a set of configurations T at time t+.

$N_{TR}(S,t_1,t_2)$

the sum of the number of traversals of any path in a set of paths S during $[t_1,t_1+t_2]$.

$T_I(S,t_1,t_2)$

the sum of the time spent traversing all paths in a set of paths S during $[t_1,t_1+t_2]$.

Note that there is a chance, depending on the definition of the sets of paths, that two paths may complete at the same time. Since some of the random variables defined above are indexed by the order of completion of the paths, a rule must be given to resolve any ambiguity as to which path is which. To do this we use the convention that if two paths complete at the same time, the path which took the longest time to traverse will be counted as completing first.

By varying the index of any of the first four variables above, one can construct a sequence of random variables. Under certain conditions, the distributions of the random variables in this sequence may converge to a single (steady-state) distribution. More precisely, following the terminology in [16] , for a sequence of random variables V_n, $n=1,2,3, \cdots$, we define

$$F_V(x) = \lim_{n\to\infty} P\{V_n \le x\}.$$

In terms of the random variables defined above, we have

$F_{N_T(f)}(x) = \lim_{t\to\infty} P\{N_T(f,t) \le x\}$

The distribution of the value of function f in steady-state.

$F_{T_b(S)}(x) = \lim_{n\to\infty} P\{T_b(S,n) \le x\}$

The distribution of the time between completions of any path in a set of paths S in steady-state.

$F_{T_w(S)}(x) = \lim_{n\to\infty} P\{T_w(S,n) \le x\}$

The distribution of the time between initiations and completions of any path in a set of paths S in steady-state.

$F_{I(T)}(x) = \lim_{t\to\infty} P\{I(T,t) \le x\}$

The distribution of the event of being in any configuration in a set of configurations T in steady-state.

Not all solution methods will yield results for all of the performance variables listed above. Currently, all can be obtained using an appropriate simulation (i.e. terminating or steady-state), but analytical methods are limited to those that can be determined from the stochastic process representing the changes in marking of the SAN as a function of time. Work is currently underway to extend analytical methods to capture activity related behavior.

3.3. Experiment File and Perf Complier

Instances of the above performance variables, along with their corresponding path sets, are specified in an experiment file. The exact form of this file varies from solver to solver. In general, the experiment file specifies the paths sets, variables defined on those paths, definitions of any variables derived from previous variables, and characteristics of the defined variables desired (e.g., mean, PDF, variance). For the simulation solvers, these characteristics take the form of mean, variance, interval, and percentile estimators with confidence intervals; for analytic solution they are exact.

For example, consider an experiment file (Figure 5) for the example of the SAN of Figure 1. Here the goal is to obtain the mean, variance, an interval, and several percentile estimates of the the time between firings of activity "compute1". Because the activity time distributions of activities compute2a, compute2b, and compute2c are uniform, the steady-state simulation solver is used. The experiment file requires definitions of configurations, path sets, performance variables, and estimators for the defined variables. Configurations are specified in a compact notation and path sets are built up from sets of configurations. The meta-character "*" can be used to denote any marking, activity, or case, depending on its position. In the example, (MARK(A) == 0, (*,*)) specifies all configurations such that the marking of A is 0, any activity completes (denoted by the first *), and any case is chosen (denoted by the second *). "==TIMED" and "==INST" can also be used in the activity specification to denote any timed or instantaneous activity, respectively. Path sets are then constructed from these configuration sets. The syntax "||" can be used to "or" configuration sets together at either the CONFIGURATION or PATHSET level in the experiment file. Although all of the path sets in our example consist of a single configuration set, longer paths can be specified by naming a sequence of configuration sets separated by commas. The interpretation of this notation (in the context of our earlier theory) is that the set of paths included is all paths constructed by selecting a configuration from each of the configuration sets in order. Two additional operators aid in the definition of path sets. "*( )" denotes that the sequence of configurations within the parenthesis must be repeated 0 or more times. "+( )" denotes that the sequence of configurations within the parenthesis must be repeated 1 or more times.

The user then specifies the desired performance variables in terms of the previously defined path sets. Each of these variable definitions is itself implemented in a low-level language that makes it easy to create new variables. Experiment file section ESTIMATIONS allows for specification of the estimator to be defined on the variables. Currently, mean, variance, interval, and percentile estimators are supported, all with confidence interval estimation. Examples of the syntax for each of these estimators can be found in Figure 5. In each case the user specifies first the relative confidence interval width (.01 in the example) and confidence level (95%). For the interval estimator the user also specifies the bounds for the interval to be considered. In the example, the bounds indicate that the probability that the time is between .5 and 1.5 is to be estimated. For the percentile estimator the user specifies the percentile for which the estimate is desired (.05, .35, .70, and 1.0 in the example).

Similar experiment files are used in conjunction with the analytic and terminating simulation solvers. In each case, the file specifies to the package the performance variables and the characteristics of those variables that are to be determined. The experiment file is then passed to the perf compiler, where the specification is translated into a second collection of C data structures and procedures that are understandable to the appropriate solver.

4. Model Solution

After the Sanscript and experiment files are converted to their internal machine form, they are bound to the chosen solver. Depending on the characteristics of the model to be solved, the solver can be one of several analytic or simulation solvers. Each solver will be discussed in some detail below.

4.1. Analytic Solvers

Model solution, in the context of analytical solution methods, refers to the solution of a base stochastic process for the desired performance variables [17]. In light of this, generation of the stochastic process realized by a specific stochastic activity network is properly part of model construction. However, because generation is specific to analytic solutions, it is incorporated as part of each analytic solver and hence discussed under model solution. In our framework, this consists of generating a ***stochastic activity system (SAS)*** [3] realized by the stochastic activity network. Stochastic activity systems can be regarded as probabilistic extensions of Keller's "named transition systems" [18, 19]. The most detailed description of an activity system's behavior are its ***state-activity*** sequences, i.e., for a given state, the possible sequences of alternating states and activities that can result from a finite number of applications of the transition relation. In the solution techniques implemented to date, we have not exploited the activity related behavior, just state related behavior. The state behavior of a stochastic activity system is a stochastic process that can serve as the base model of a performability model [1].

As can be seen in Figure 6, all analytic solution methods require generation of the stochastic activity system realized by the SAN model. Informally, this is done as follows. First, the set of activities which are enabled in the initial marking is found, by examining the enabling predicate of each input gate. If the enabling predicates for all input gates connected to an activity are true, then the activity is enabled. If any instantaneous activities are enabled in this initial marking, then this is not a valid SAN. Given that the initial marking is stable, the next step is to generate the next marking(s) of the SAN supposing that each activity enabled in the initial marking completes. A possible next marking is generated for each case of each activity. Then, for each of these new markings which is not already in the reachability set, the possible next marking(s) are computed (i.e. the set of enabled activities in each of these new markings is computed, as well as the resulting new marking(s) upon completion of each of these activities) except that now any enabled instantaneous activities must also be dealt with. When all next possible markings which are generated are already in the reachability set, all reachable stable markings have been found. These markings correspond to the states in the realized SAS. The activity time distributions and transition distribution for each labeled transition is then constructed as in definition 3.7 of [3], and the generation of the SAS realized by the structure submodel is complete.

Instantaneous activities complete whenever they are enabled, while timed activities complete only if they are enabled in stable markings. Therefore, whenever an unstable marking (a marking in which at least one instantaneous activity is enabled) is reached, the marking does not correspond to a state in the realized SAS. To find the next stable state, one must examine all possible next markings reached upon completion of this instantaneous activity as well as any other instantaneous activities which become enabled, generating new markings until the set of possible next markings consists of only stable markings. Because we do not know whether the SAN is well-behaved [2] (at the time it is constructed), we must keep track of all reachable unstable markings, until the set of next stable markings is found. The resulting realization procedure is, therefore, somewhat complicated and is omitted in the interest of brevity. It should be noted that the procedure requires human intervention to decide when a particular marking space is judged infinite, and hence the procedure stopped. The result of this procedure is a machine representation of the stochastic activity system; after the nature of this process is determined, one of several techniques may be used to obtain the desired performance variables.

After the stochastic activity system corresponding to the SAN model is generated, a check must be made to determine the nature of the underlying stochastic process. The nature can be determined directly from the structure of the SAS. This check and the desired performance variables determine which analytic solver is to be used.

Solutions for many traditional performance variables can be formulated in terms of the steady-state state occupancy probabilities of the resulting stochastic process. When this process is Markovian, solution for these occupancy probabilities is done either by Gaussian

elimination using a full matrix technique, or by iterative methods using sparse matrix techniques, depending on the size of the state space. The Gaussian elimination technique employed makes use of an algorithm [20] that operates on blocks of columns of the transition matrix individually, in order to reduce paging by the virtual memory management system. This makes solution possible for quite large systems without resorting to iterative solution methods. When this technique becomes impractical, an iterative method based on the Gauss-Seidel technique [21] is used.

Reward model [22] techniques have been used successfully to solve many performance-reliability evaluation problems (for example, see [23, 24, 25, 26, 27]). In the context of performability evaluation, one typically constructs a reward model by associating a set of reward rates with the stochastic activity system realized by the structure submodel [3] (a SAN representing the structure related activities). Each reward rate represents the performance rate of the system in the respective structure state. This reward model then serves as the base model of a performability model. Reward model solution techniques for both Markov and non-Markov systems are implemented as solvers in METASAN.

Once again, applicable solution techniques depend on the nature of the base model and the performance variables. In the case of Markov reward models, a variation on a technique proposed by Goyal and Tantawi [26] is used. Our implementation computes a conditional performability distribution for each trajectory type using the technique described in [26]. Performability is then obtained via knowledge of the probabilities of trajectory types [24]. When the reward model is not Markov, a technique developed by Furchtgott and Meyer [24] is used. This solution technique, while it requires the underlying stochastic process to be acyclic and non-recoverable (i.e. reward rates non-increasing with time), it allows for solutions when the base model is not even semi-Markov. Selection of the appropriate algorithm is based on the Markov check described earlier.

Solution for the state occupancy probabilities at a specific time for Markov stochastic activity systems is accomplished using a randomization technique proposed by Gross and Miller [28, 29]. This technique provides for computationally efficient computation of approximate transient state occupancy probabilities by conditioning on the number of state transitions that may occur during the bounded interval under consideration. The approach is based on the known technique of subordinating a Markov chain to a Poisson process (see[30], for example).

4.2. Simulation Solver

Conditions exist when solution of the base model via analytic means becomes intractable. This can occur, for example, when complex reactivation functions are specified, activity time distributions are general, the desired performance variables are sufficiently complex, or the state space of the underlying stochastic process is extremely large or infinite. To fill this need, METASAN provides facilities for both terminating (transient) and steady-state simulation.

To do this we provide a discrete-event next-event time advance simulator core. Currently, two methods for confidence interval estimation are supported. The first is an iterative method based on the replication approach, and is used for terminating simulations. Using this method, one specifies the relative precision and level of confidence desired as part of the experiment file input. Confidence intervals for steady-state simulation are currently determined using an iterative batching procedure, where the user must specify the length of initial transient, batch size, relative precision desired, and level of confidence desired. Work is currently underway to permit estimation of confidence intervals using the regenerative and spectral techniques.

5. Example

5.1. System Description

Consider, for example, a distributed system where all resources needed are available locally except tape and disk drives. Whenever a disk or tape drive is needed, the processor requests one from a common pool. Time to process such requests is negligible, and the requests are either immediately granted, or the process is blocked. As resources become available, they are allocated to blocked processers in a FIFO manner. Each processor is running an identical application program, whose goal is to process blocks of data. Each block requires processing consisting of the following steps (see Figure 7): 1) computation for an exponentially (with parameter β) distributed amount of CPU time, 2) allocation of either a disk and tape, or just a disk, with fixed probabilities p and 1-p respectively, 3) computation for a deterministic amount of CPU time equal to (α * the number of resources requested), and 4) release of all resources allocated. The disk and tape drive are used only for temporary storage, and hence, are not specific to any processor. Upon completion of the processing of a block of data, the processor immediately begins processing another block.

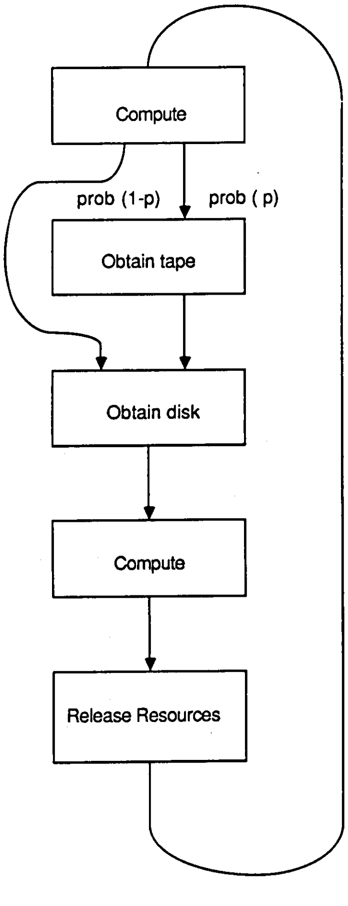

Figure 7. Processing Algorithm

Faults can occur due to the failure of a disk or failure of a tape drive. In each case, the fault may be covered (i.e. the system degrades successfully to a less productive structure state) or it may result in a total loss of processing capability (i.e. total system failure). We assume further that faults in a tape drive and a disk occur as a Poisson process with rates λ and γ respectively. The performance variable considered is the number of blocks that are processed during a finite utilization period of t hours.

5.2. Construction of SAN model of system

Performability evaluation requires the construction of a SAN that corresponds to the system being modeled and meets the characteristics required by the particular solution algorithm. A seven processor case is examined. A SAN that meets these requirements is found in Figure 1. Here tokens represent the jobs executing on the processors and resources (tape and disk drives). Tokens in places A,B,C,D,E,F, and G represent the state of jobs executing on the processors. The marking on the diagram is the initial marking and corresponds to the state where all processors are executing the first compute in the sequence of events. Since the length of this compute time is exponentially distributed with parameter β for each processor, all first compute times can be represented via a single activity. The activity time distribution function for compute1 is, thus, exponential with parameter $\beta * MARK(A)$. Since the rate at which compute1 completes is determined by the number of tokens in place A, it should be reactivated at each state change to insure that the correct rate is always used. Each completion of compute1 corresponds to a processor completing the first compute. When this occurs, the process either requests both a tape and disk or a disk only. This choice is represented by the cases associated with compute1, where case 1 is chosen with probability (1-p) and represents an request for a disk only; case 2 is chosen with probability p and represents a request for a tape and disk.

These requests are processed by instantaneous activities disk1, disk2, tape, and places H and I. Place H represents the number of allocated tape drives. Place J represents the number of functioning tape drives. Input gate Trans1 determines whether there is an available tape drive. Completion of activity tape results in the allocation of a tape drive to the requesting process and the addition of a single token to place H. The number of tokens in place I represents the number of allocated disk drives and the tokens in place K represent functioning disk drives. Input gates Trans2a and Trans2b determine if there is an available disk. Similarly, completion of disk1 or disk2 represents the allocation of a disk drive to the requesting process. The function of gates diskout1 and diskout2 is to keep track of the resources that each process possesses during the second compute phase. Two tokens are placed in an output place if the process has both a tape and disk drive; one token signifies the process possesses only a disk. Activities compute2a, compute2b, and compute2c represent the second compute in the algorithm and have deterministically distributed activity times. The compute times cannot be represented by a single activity since the deterministic distribution is not memoryless. An activity is needed for each process in this phase. Since the maximum number of functioning disk drives in this example is three, only three processes can be in the second compute phase concurrently. Hence, only three activities are needed to represent this phase. Completion of each of these three activities represents the completion of the second compute for a process. The action of the input gate for the activity is to subtract the appropriate tokens from H and I to signify the release of the allocated resources. In addition, a token is added to the output place of the activity (place A) to indicate that the process is again beginning the first compute in the algorithm.

The arrival of faults and (possible) recovery of the distributed system is represented by the remaining places, input gates, and activities. Here places J and K represent the number of fault-free tape and disk drives respectively. Faults arrive to the system upon completion of activities Tapes_faults and Disk_faults. The activity time distributions of these activities are exponential with rates $\lambda * MARK(J)$ and $\gamma * MARK(K)$ respectively. Selection of case 1 of either activity represents successful recovery. In this case, one token is subtracted from the appropriate place to indicate the failure of the corresponding resource. Probabilities c_t and c_b are associated with case one of activities tape_faults and disk_faults, respectively. Selection of case 2 represents unsuccessful recovery. If this occurs, a token is placed in L. Completion of the instantaneous activity Disable signifies total system failure. This occurs when either recovery from a fault is unsuccessful (signified by a token in L) or when the pool of functioning resources is exhausted (zero tokens in J or K). When either of these events occur, instantaneous activity Disable completes and removes all tokens in the network. No blocks are processed in this state.

Figure 8. Example METASAN Output

5.3. Model Construction and Solution

In order to solve for the specified performance variable, we use the performability solution method described in [3]. Using this method, the analyst decomposes the SAN into two submodels, a ***performance submodel*** and a ***structure submodel***. Informally, the performance submodel contains all activities that represent variations in the internal state and environment of the system; the structure submodel contains all activities which represent variations in the system due to a change in system structure. In Figure 1, the places, activities, and gates above and including J and K comprise the performance submodel. The places, activities, and gates below and including J and K comprise the structure submodel. Places J and K are ***common*** places, and represent the structural configuration of the system.

As described in [3] the evaluation consists of determining a reward rate corresponding to each structure state, and solving the resulting reward model. In our example, the reward rate is determined by noting that each completion of compute1 corresponds to a completion of processing on a block of data. Hence, the rate of completion of block processing is just the inverse of the expected time between completions of compute1. In terms of METASAN variables, this corresponds to $1 \,/\, E[T_b(S)]$, where (the path set) S is defined to be $\{< *, compute\ 1, * >\}$. Note that $E[T_b(S)]$ is an estimator defined in the experiment file in Figure 5. Estimates of this measure were then obtained using the Sanscript and experiment files presented together with the steady-state simulation solver. The initial marking of J and K was varied to correspond to each possible structure state. Figure 8 is the resulting METASAN output for the case $MARK(J) = 2$, $MARK(K) = 1$. The results for the mean time between completions of "compute1" for each run are as follows:

MARK(J)	MARK(K)	$E[T_b(S)]$	Half Width	$1/E[T_b(S)]$
2	3	0.710	.003	1.409
1	3	1.403	.004	0.713
2	2	0.850	.001	1.177
1	2	1.408	.004	0.710
1	1	1.701	.002	0.588
2	1	1.699	.001	0.589

"Half Width" refers to the half width of a 95% confidence interval constructed about the estimate. The interpretation of each

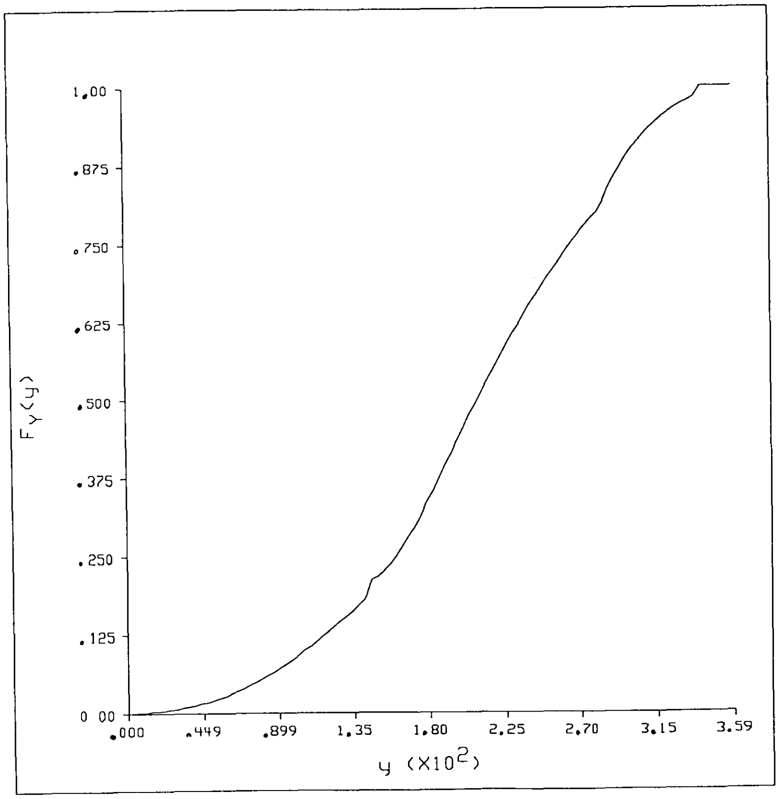

Figure 9. PDF of Number of Jobs Processed during [0,240]

entry in the last column is the rate at which blocks are processed in that structure state. These rates serve as the reward rates in the subsequent reward model solution. This model was then solved using the Markov reward model solver for the following model parameters: $\lambda = .001$, $\gamma = .005$, $c_t = .98$, $c_d = .99$, and performance submodel parameters as in Figure 4. This results in the probability distribution function (PDF) of the number of blocks processed during a specified utilization period [0,t]. Choosing t=240 produces the PDF in Figure 9.

6. Future Extensions

We have described METASAN, a comprehensive package that facilitates performability evaluation via both analysis and simulation. It permits detailed evaluations of systems such as complex computer networks, distributed computing systems, and flexible manufacturing systems. For example, in a recent evaluation study of a CSMA/CD network, a model containing over 500 places, gates, and activities was solved. Although the package has proved to be extremely useful in its current version, extensions would enhance this usefulness. Regarding model construction, a graphical input interface may help entry and debugging of large models. Regarding model solution, several extensions are possible. First, the available methods of confidence interval estimation for steady-state simulation should be extended to include the regenerative and spectral methods. During analytic model construction, an explosion in the number of states with increase in model size should also be dealt with. Methods of decomposition and state aggregation need to be studied and incorporated into future versions. Finally, work should be done to extend analytical solution methods to capture the activity related behavior of the networks.

ACKNOWLEDGEMENT

The authors would like to thank Steve Sparks and Paul Daugherty for their assistance during the design and implementation of this package. Their support has proved invaluable in making the tool a reality.

ABSTRACT

Combinatorial models such as fault-trees and reliability block diagrams are efficient in both specification and evaluation of system models. But it is difficult if not impossible to allow for various types of dependency (such as repair dependency and near-coincident-fault type dependency), transient and intermittent faults, standby systems with warm spares, and so forth. Markov models can capture such interesting system behavior. However, the size of a Markov model for the evaluation of such a system may grow exponentially with the number of components in the system.

This paper presents a modeling tool called SHARPE (Symbolic Hierarchical Automated Reliability and Performance Evaluator), which is a general hierarchical modeling tool for analyzing complex reliability models. SHARPE allows its user complete freedom to choose the number of levels of models and the type of model (combinatorial or Markov) at each level. Thus it allows the flexibility of Markov models where necessary and retains the efficiency of combinatorial solution where possible. The analysis of each model produces a probability function that is symbolic in the time variable *t*.

INTRODUCTION

Combinatorial models (fault trees and reliability block diagrams) and Markov or semi-Markov models are two of the approaches available for analytically predicting the reliability or availability of fault-tolerant systems. The advantages of using combinatorial models are the parsimony in specification and efficiency of evaluation they provide. If components are independent, reliability block diagrams with series-parallel ("well-nested") structure and fault trees without repeated nodes can be analyzed using linear time algorithms.

One method for analyzing structures with dependent components and non-series-parallel structures is the use of conditioning (the theorem of total probability) [16]. With this method, it is necessary to enumerate all of the sequences of events that lead to system failure. The number of such sequences can grow exponentially with the number of components, so this method is quite expensive.

Another alternative for analyzing these structures is to use Markov models. Again, the method is expensive; if there are n components in a block diagram (or n basic events in a fault tree), the corresponding Markov chain may have up to 2^n states. This severely limits the size of problems that can be handled. Since most practical problems do not satisfy the assumptions of independence and series-parallel structure, it is important to investigate ways of dealing with potentially very large state spaces.

There are two separate, but related, aspects to the large state space problem: constructing the Markov chain and analyzing it. The problem of construction can be alleviated by an automatic generation of the Markov chain from a more parsimonious description of system behavior. Examples of programs that do this are SAVE (System AVailability Estimator) [8] and DEEP (Duke Evaluator for Extended stochastic Petri nets) [5,6]. A system can be specified for DEEP by means of a stochastic Petri net, which is automatically transformed into a Markov chain that is solved numerically [6].

The problem of analyzing a Markov chain with a large state space can be handled by one of two methods: either tolerating the large state space or avoiding it. By "tolerating" the large state space, we mean that special solution methods are used that work for very large matrices. Examples are matrix-level decomposition [2] and various numerical methods for solving large, sparse, possibly stiff systems of algebraic equations [8] or ordinary differential equations [12].

One way of avoiding the large state space is by using a stochastic Petri net model and simulation to analyze the system [5,6]. Another way is to use model-level decomposition. This is the method used in HARP [7,17,18], where the reliability model is decomposed behaviorally along temporal lines. The fault-occurrence behavior (a slow submodel) and the fault/error-handling behavior (a fast submodel) are analyzed separately.

We have developed a hierarchical modeling technique that makes it possible to use mixtures of different kinds of models at different levels in order to avoid a state space explosion. Our technique differs from models such as HARP and CARE III [15] in several ways. HARP and CARE III assume a specific fixed hierarchy of models geared toward modeling a chosen class of systems. Our technique allows complete freedom in the number of levels in the hierarchy, which kinds of models to use at each level, and how to combine the models. The previous efforts have used numerical methods to obtain the reliability for a specified mission time. The results are therefore approximate (due to numerical integration), and have to be computed repeatedly for each value of the mission time. Our technique provides a result that is symbolic in the mission time variable.

This work was supported in part by the Air Force Office of Scientific Research under grant AFOSR-84-0132, by the Army Research Office under contract DAAG29-84-0045 and by the National Science Foundation under grant MCS-830200.

In the next section, we provide some details of our approach to hierarchical modeling. In section 3, we show how to use our method to solve non-series-parallel block diagrams. In section 4, we discuss ways to model various kinds of dependencies and give several examples of system models that contain dependency.

THE SHARPE FRAMEWORK

We have developed a hybrid, hierarchical modeling framework that we call SHARPE (Symbolic Hierarchical Automated Reliability and Performance Evaluator). The framework was developed with automation in mind, and it has been implemented as a software tool, which we also call SHARPE. The SHARPE framework provides five model types:

- series-parallel reliability block diagrams
- fault trees without repeated nodes
- cyclic or acyclic Markov chains
- acyclic semi-Markov chains
- series-parallel directed (acyclic) graphs

Block diagram and fault tree models are specialized for modeling reliability and availability. Each component is assigned a cumulative distribution function (CDF) for the time-to-failure of the component. The system is analyzed to obtain the CDF of the time-to-failure of the system as a whole.

The other model types can be used to model performance as well as reliability. This paper focuses on reliability modeling; for examples of the use of SHARPE for performance modeling, see [14].

Markov and semi-Markov chains that have absorbing states are analyzed for the CDF of the time to absorption. If such a chain is acyclic, the analysis also produces the probability of ever visiting each state. Irreducible cyclic Markov chains are analyzed for the steady-state probabilities of being in each state.

The series-parallel graph submodel is the most general model. In this model, the nodes represent activities and the arcs represent precedence constraints placed on the activities. Each node in the graph is assigned a CDF, and the graph submodel is analyzed for the CDF of the time-to-completion of all required events in the graph. Once the CDF of the time-to-completion is obtained, it is easy to compute the mean and variance.

This model type is similar to series-parallel stochastic PERT (Program Evaluation Review Technique) networks [4] but is more general in several respects. (Note that PERT networks have activities on the edges whereas SHARPE associates activities with nodes.) We allow parallel graphs to be executed either concurrently or probabilistically. When a node has more than one predecessor and the predecessors are executing concurrently, most graph models (including PERT) require that the node wait for all of its n predecessors to finish before it begins execution. We include this case as a special case in our graph model; in general, the number of predecessors that must finish before the node starts is part of the graph model specification, and may be any number between (and including) 1 and n.

The different types of submodels can be combined hierarchically by using all or part of the solution to one submodel as part of the specification of another submodel. The solution for each model includes various scalar quantities. SHARPE makes available the mean and variance of each CDF produced by the analysis of a system, and the value of each CDF at specified values of t (including $t=0$ and $t=\infty$). SHARPE also makes available the probability of visiting a state in a Markov or semi-Markov chain. These scalars can be used in another model as elements in the expressions that specify probability values, transition rates, and the parameters of distribution functions. This mechanism allows for the expression of aggregation/approximation within the SHARPE framework. Examples of the use of this mechanism are given in section 4.

A second way to combine models hierarchically is to assign the solution CDF from a submodel as the CDF for a basic event in some other model. This method of combining submodels allows us to efficiently analyze large systems whose "badness" (non-series-parallel structure) is contained in a subsystem or a set of subsystems, with the remaining portions of the system being "well-behaved". We can extract the non-series-parallel portions of the overall structure and pay the price of 2^n states to analyze them exactly. Then we use the results from those portions as the CDFs of basic components in the remaining graph, and use a combinatorial solution method to analyze the system exactly. Section 3 presents an example of this method.

Because we allow the solution CDF from one submodel to be assigned as the CDF of a basic event in another submodel, the CDFs for individual events and the solution CDF for each model type must have the same form. If we are to work with symbolic expressions for the CDFs, we need a class of functions that is closed under the operations we need to perform during the analysis of the different kinds of models. The computational operations involved in the analysis of the models are convolution, order statistics [3] of independent (not necessarily identically distributed) random variables, and mixing of distributions (weighted averages). Therefore, we need a class of functions that is closed under addition, multiplication, differentiation and integration, and includes the exponential distribution.

The class of functions we have chosen is the class of exponential polynomials that are valid distribution functions. An exponential polynomial is a function with the following form:

$$\sum_{j=1}^{n} a_j t^{k_j} e^{b_j t} \qquad (1)$$

where k_j is a nonnegative integer and a_j and b_j are real or complex numbers.

Of course, a distribution function must be real-valued, even if it contains complex coefficients or complex powers of e. Allowing a distribution to contain complex numbers is equivalent to allowing it to contain sine and cosine functions. Such distributions arise naturally in the analysis of processes that have cyclic behavior. In particular, a cyclic Markov chain with absorbing states may have complex numbers in the CDF for its time-to-absorption.

We allow the distributions to have a mass at zero and/or a mass at infinity. A distribution has a mass at infinity if it does not reach 1 in the limit, and in that case, we call it a "defective" distribution. Defective distributions are useful for modeling the performance of programs that might fail to complete because of either software or hardware faults. It is also possible to use distributions that have mass only at zero and infinity. Assigning such a distribution to a component is equivalent to assigning to the component a probability value rather than a distribution function.

The SHARPE program consists of about 4400 lines of code in C [10] and about 260 lines of Fortran and runs under UNIX^{TM} [9] or VMS^{TM}. It is a full implementation of the modeling technique and has been tested extensively. The SHARPE program may be used either interactively or in batch mode. The specification format is the same in either mode. In interactive mode, SHARPE will prompt the user for all the information it needs and indicate the proper format for the information. Experience has shown that this mode is easier for beginning users. There is also an option that allows for interactive input to be stored in a file, thus allowing for a relatively painless way to obtain data files for large systems. The specification language is simple enough that many users will find it easy and convenient to prepare data files using a text editor.

ANALYZING A NON-SERIES-PARALLEL STRUCTURE

When a system has series-parallel structure, its failure-time CDF can be obtained (in linear time) by multiplying together the failure-time CDFs of parallel subsystems, and by subtracting from one the product of the reliability functions of series subsystems. This method works because the series-parallel nature of the system means that it can be broken down into substructures whose failure times are statistically independent of one another. When a system is not series-parallel, such a breakdown is not possible and so the standard block diagram method described above is not applicable.

Consider the system in Figure 1. The system is operative if there is a path from source to sink. We want to compute the CDF of the time to failure of the system. The system has two non-series-parallel subsystems having the same structure, often called a "bridge" structure. Such a structure can be analyzed using conditioning on the cross-over component (*8* in the upper bridge subsystem). Alternatively, if all of the components failure-time distributions are exponential, it is possible to expand each bridge system into a Markov chain.

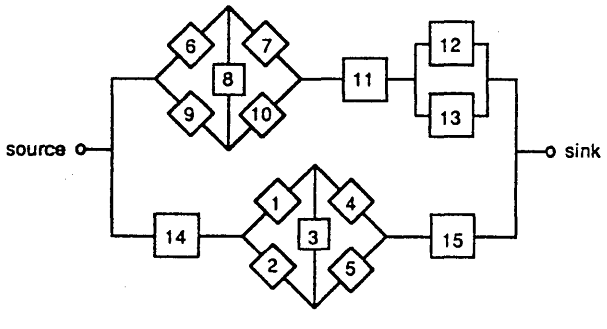

Figure 1. A Non-Series-Parallel Reliability Diagram

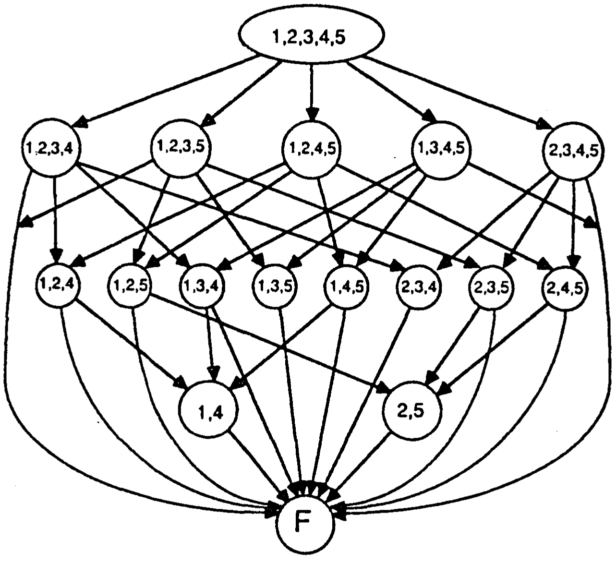

Figure 2. Markov Chain for the Bridge System

We have chosen the second approach, to illustrate the hierarchical nature of SHARPE and its ability to combine results of different model types. The 5-node bridge system expands to a Markov chain with 17 states, shown in Figure 2. Rates are not shown, for the sake of readability. The SHARPE framework allows us to use the time-to-absorption of each Markov chain as the failure-time CDF of a basic component in an upper-level reliability block diagram model. This decomposition and aggregation will give us exact results.

Figure 3 shows a batch input file for the two-level, hybrid system. For the sake of this exposition, the lines in Figure 3 are numbered; an actual SHARPE input file would not have its lines numbered. The SHARPE input language is described in detail in [13]. First, on lines 1 through 66, we define the lower level: a Markov chain called *bridge*, with five parameters. The chain is specified by giving each state transition and its associated rate, one transition per line. The rates are allowed to be any valid arithmetic expression. No initial state probabilities are given; the SHARPE program will assume that the initial state probability is one for the only state (*12345*) with no predecessors.

Next, as an illustration of the distribution specification mechanism of SHARPE, we show (lines 68 through 71) how to define the 2-stage Erlang distribution Erlang2(μ) $= 1-e^{-\mu t}-\mu te^{-\mu t}$. Then, on lines 73 through 85, we define a reliability block diagram for the upper level. We first define the basic components, assigning each one a CDF. Nodes 11, 12 and 14 are assigned the exponential distribution function, which is built in. Nodes 13 and 15 are assigned 2-stage Erlang distributions. Node B represents the upper bridge system of Figure 1 and node A represents the

Figure 3. Input for Non-Series-Parallel System

lower bridge system. Nodes A and B are each assigned the CDF of the time to absorption in the chain *bridge* with appropriate arguments. After the basic components have been defined, we build the block diagram using series and parallel combinations.

Before we can analyze the systems, we must bind the variables used to particular values. This is done on lines 87 through 98. Then we ask SHARPE for the probability that each non-series-parallel subsystem has failed by time t=10,000 (lines 100 and 101) and the probability that the overall system has failed by that time (line 102). Finally (line 103), we ask to have the CDF of the overall system evaluated between t=0 and t=100,000, at intervals of 10,000. Because SHARPE computes the system CDF symbolically, the only work it needs to do after the initial analysis is to evaluate the system CDF for the specified values of t. The results produced by SHARPE are shown in Figure 4. It took SHARPE 4.5 seconds on a lightly loaded DEC VAX 11/750 to produce these results.

Figure 4. Results for Non-Series-Parallel System

MODELING DEPENDENCE

Fault trees and reliability block diagram models generally assume that the component lifetimes are stochastically independent. In real systems, there are several kinds of dependencies. Some of these are:

- **repair dependence**. Two or more components or subsystems may share a repair person.
- **state-dependent failure rates**. It is possible that the failure rate of a component may depend on the past history of the system. For example, it is possible that the repair of a component does not restore it to its original state. In that case, the component may have a larger failure rate after it has been repaired.
- **near-coincident fault dependence**. The design of a system may be such that near-coincident faults cause a system failure, while faults that are separated in time can be handled individually without overall system failure [7,17,18].

The common approach to modeling systems that possess any one of these kinds of dependence is to use a global Markov (or semi-Markov) model. Using the SHARPE framework, we can avoid a state space explosion by isolating the dependencies to portions (subsystems) of the overall system, using decomposition/aggregation, or by a combination of these two methods. The examples in the next three sections show how the SHARPE framework can be used in this way to model the kinds of dependence discussed above.

Repair Dependence

Consider a system consisting of 2 processors and 3 memories connected to a bus [8]. Let us assume that the mean time to failure of a processor is a month (720 hours), that of a memory unit is 2 months, and that of the bus is 3 months. The system as whole is considered to be up if the bus is up, at least one of the two processors is up, and at least 2 out of the three memory units are up. The condition under which the system is down can be expressed by the fault tree in Figure 5. If the system is non-repairable, we can easily evaluate the fault-tree directly by one of many tools available, including SHARPE. Using SHARPE, we can attach either a probability of failure or a distribution of time-to-failure to each basic event.

If the units are repairable and each individual unit has its own repair person, we can model the steady-state unavailability of the system using the same fault tree, by assigning to each component its steady-state unavailability. Using SHARPE, we can also use this fault tree to find the instantaneous unavailability of the system, by assigning the instantaneous unavailability expression as the "distribution" for each basic event. The instantaneous unavailability for a component, labelled i, that is initially operational and has failure rate λ_i and repair rate μ_i is [16, p. 301]

$$U_i(t) = \frac{\lambda_i}{\lambda_i + \mu_i} - \frac{\lambda_i}{\lambda_i + \mu_i} e^{-(\lambda_i + \mu_i)t} \qquad (2)$$

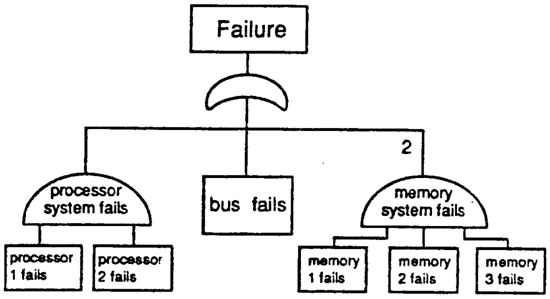

Figure 5. Fault Tree

For a system consisting of parallel components, the unavailability of the system is the product of the component unavailabilities (the system is unavailable only when all components are unavailable). This is the "and" gate computation in a fault tree. For a series of components, the availability is the product of the component availabilities (the system is available only when all subsystems are available). Thus the unavailability of the system is exactly the "or" combination of the components. When the components are combined in this way, the solution "distribution" for the system will be the system unavailability.

The limit of $U_i(t)$ as t approaches infinity is the steady-state unavailability. $U_i(t)$ does not reach one in the limit; it is possible to use this expression as if it were a distribution because the SHARPE framework permits defective distributions.

If we set $\mu_i = 0$ in Equation 2, we have the CDF for the time-to-failure of the component. Thus the same model can be used for both reliability and availability. Furthermore, we may allow some components to have a repair facility and other components to be non-repairable by letting μ_i be zero for some components and nonzero for others.

Now suppose that an independent repair facility is available for each subsystem (not for each unit). Because of the hierarchical capability of SHARPE, we can model each subsystem as an independent Markov chain and still model the overall system by a fault tree. This is shown in Figure 6. In the Markov chain for each system, the state gives the number of failed components in the system. In the fault tree, each component is assigned the steady-state unavailability of a subsystem. For the memory subsystem, the steady-state unavailability is the sum of the steady-state probabilities for states 2 and 3 in the corresponding Markov chain.

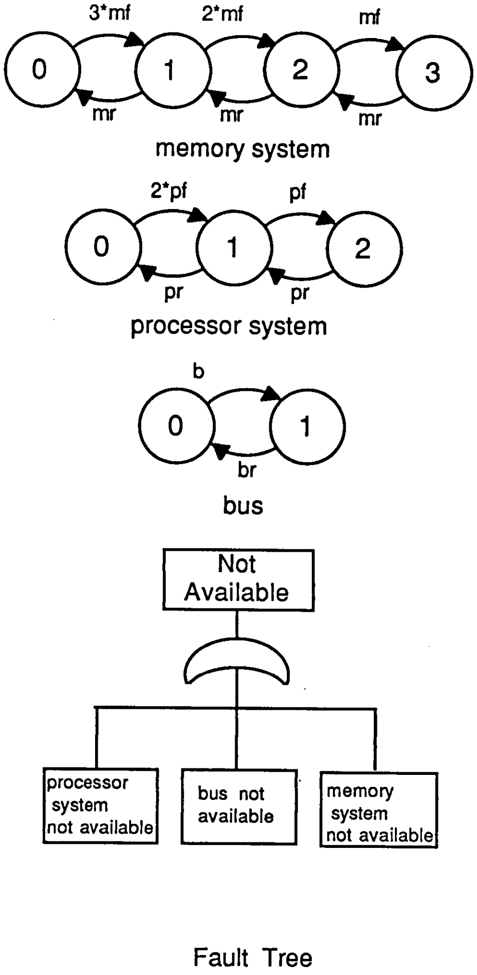

Figure 6. Three Markov Chains Within a Fault Tree

If repair is shared across all subsystems, we must model the entire system by a Markov chain. We assume that the repair priorities are bus first, then processor, then memory. Figure 7 shows the steady-state availability of the system when there is a single repair facility for the system, a repair facility for each subsystem, and a repair facility for each component. The figure shows that the effect of sharing repair persons is relatively minor.

State-Dependent Failure Rates

In this section, we consider a model for a system where the fault-occurrence behavior depends on the history of failures and repairs in the system. Suppose we have a repair strategy that involves two kinds of repair procedures. When a component fails, we first apply a quick, simple repair procedure. This procedure fixes the component so that it is as good as new with probability r, and with probability 1-r the procedure introduces another flaw that alters the failure behavior of the component, causing it to fail more quickly and with a different kind of failure. If the component exhibits the second kind of failure, we use a more complex repair procedure that either restores the system to its original state (with probability c) or fails to repair the system at all (with probability 1-c). A Markov model for the failure of a single component is shown in Figure 8. It is assumed that $\lambda_2 > \lambda_1$ and $\mu_2 < \mu_1$. SHARPE can analyze this cyclic chain for the CDF of the time to reach state F.

type of repair	steady state availability
per component	.998822
per subsystem	.998802
one for system	.998801

Figure 7. Effect of Sharing Repair Facilities

Now assume that we have a system that uses parallel redundancy with three components, using the repair strategy discussed above for each component, and that the system is operational as long as any one of the components is functioning. We can model this system as a reliability block diagram where each component is assigned the CDF of the time to absorption in the Markov chain of Figure 8.

It is possible to give another interpretation to the Markov chain of Figure 8. If μ_1 is very large, then state *fail1* can represent a transient failure, μ_1 the rate of a transient recovery procedure, and r the probability that the transient recovery procedure was successful. If the procedure was not successful, the fault has become permanent, and λ_2 is the repair rate of a procedure for repairing permanent faults, with c being the permanent-fault coverage.

Near-Coincident Fault Dependency

A system design may be such that faults that are separated in time can be handled individually without overall system failure, but near-coincident faults cause a system failure. If this is so, the system components are not independent. In this example, we show how near-coincident faults can be modeled, and also illustrate the flexibility of our hierarchical combination mechanism. We will start with a single-level model and add levels as we show how the model can be refined and how aggregation can be expressed in the SHARPE framework.

We consider problem 7 in appendix G of [1]. This problem models an aircraft flight control system. The system contains three inertial reference sensors (IRS) and three pitch rate sensors (PRS), that monitor the status of the aircraft. All of the sensors are connected to each of four computer systems (CS). The computer systems independently collect information from the sensors and process the information. The computers are connected to each other and to three secondary actuators (SA). At least two of each type of component must be operational in order for the overall system to function correctly. In this system, the computers are most susceptible to failure (the failure rate for a computer is an order of magnitude greater than the failure rates for any of the other components). That is why there are four computers and only three of each of the other component types.

A Single-Level Model: Fault Tree

If we assume that all components operate (and fail) independently, and that system reconfiguration after a failure is perfect, we can model the system using a fault tree, as shown in Figure 9. The SHARPE program calculates that the probability of failure during an interval of 10 hours is 1.02381 × 10^{-6}. This agrees with the result produced by the CARE III package.

A Two-Level Model: Markov Chain within Fault Tree

The fault tree model assumes that system reconfiguration upon failure is a perfect operation. Now assume that the probability of failure in the computer subsystem is high enough that imperfect system reconfiguration may cause the unreliability of the overall system to be unacceptable. Therefore, we would like to model that part of the system more closely to incorporate some of the details of the fault/error-handling procedure. We assume for now that a second (near-coincident) fault does not occur while a first fault is being resolved.

The handling of a single fault can be modeled by the Markov chain in Figure 10. This is a model of the sequence

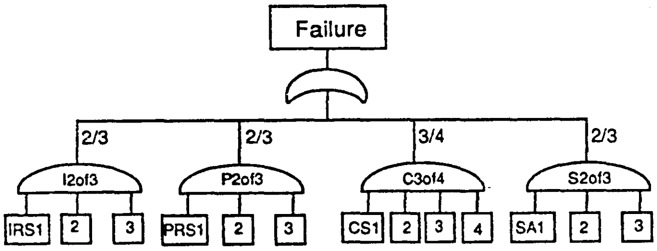

Figure 9. Aircraft Control System: Fault Tree

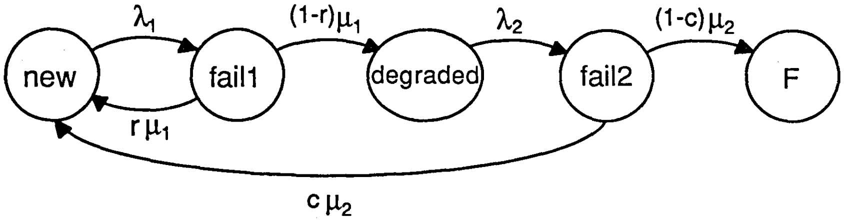

Figure 8. A Component with State-Dependent Failure Rates

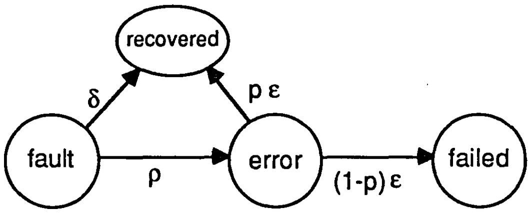

Figure 10. Fault/Error Handling Model

of events that follows the occurrence of a fault in a system that monitors itself periodically. A distinction is made between a "fault" and an "error" [11]. A fault may occur at any time, but it need not cause an error right away. For example, the failure of a pitch rate sensor is a fault, but an error does not occur until one of the computers tries to use results gathered by the sensor.

In state *fault*, a fault has occurred. At this point, one of two things might happen. The first is that the system may detect the fault itself through the self-monitoring process and recover from the fault. This happens with rate δ. The second way of leaving state *fault* is for an error (owing to the fault) to occur, causing the system to go to state *error*. The error rate is ρ. Once an error occurs, some time may elapse before it is detected. The error detection rate is ϵ. It is assumed that the system may not be able to recover from an error. If it can, then the error is "covered", and the system goes to state *recovered*; if not, the system fails and goes to state *failed*. A detected error is covered with probability p.

We now introduce a lower-level Markov model that incorporates the possibility of lack of coverage. The model, shown in Figure 11, is based on the single-fault/error-handling model of Figure 10. The states *4*, *3*, and *2* represent the system when *4*, *3*, and *2* of the computers are operational. Each time a fault occurs, we enter the fault/error-handling model and eventually leave it to enter either the failure state F or a state having one fewer operating computer.

To incorporate this lower-level model into the fault tree, we replace the gate *C3of4* and its four inputs by a basic event having the CDF of the time to reach node F in the Markov chain. (Figure 14 shows how all of the models discussed in the example are specified for the SHARPE program). When this two-level model is analyzed with $p = .999$, the probability of failure during an interval of 10 hours is computed to be 7.40614×10^{-6}. Again, this agrees with the result computed by the CARE III package. There is a noticeable increase in the likelihood of a failure, even though the error detection coverage value is .999.

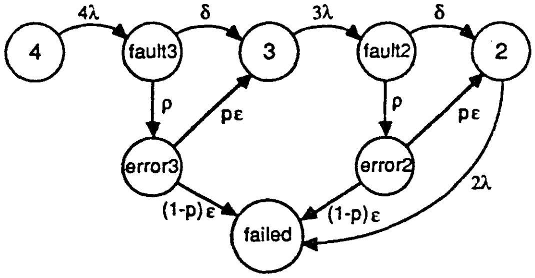

Figure 11. Markov Chain for Computer Subsysteנ

We note that in analyzing this model, CARE III obtains its solution numerically for the specified mission time. The SHARPE program computes the CDF for the system lifetime symbolically in t, and then evaluates that CDF for the specified value of t. Using SHARPE, we could find the probability of failure for other mission times without having to reanalyze the system.

A Three-Level Model: Markov Chain within Markov Chain within Fault Tree

Now suppose that the reliability requirements of the system are so stringent that the possibility of near-coincident faults cannot be ignored. Furthermore, suppose we assume that the occurrence of a second fault during the period between the occurrence of a fault and the completion of system reconfiguration causes the system to fail.

We could model this with a two-level system by refining the model of Figure 11 to include the possibility of the occurrence of a fault while in states *f3*, *f2*, *e3*, and *e2*. Instead, we would like to show how the SHARPE hierarchy of models can be used to express behavioral decomposition [7,17,18].

Behavioral decomposition is based on the premise that a long time passes between faults, but that once a fault occurs, the resolution of the fault happens quickly. Based on this assumption, we model separately the fault/error-handling behavior of the system. In Figure 12 (a) we show the fault/error-handling model, which is the lowest-level model. This is a Markov chain that models the sequence of events that follows the occurrence of a fault. The difference between this model and the model shown in Figure 10 is that here we incorporate an additional way for failure to occur; failure occurs if a second fault occurs while the chain is in state *fault* or state *error*. The rate at which the second

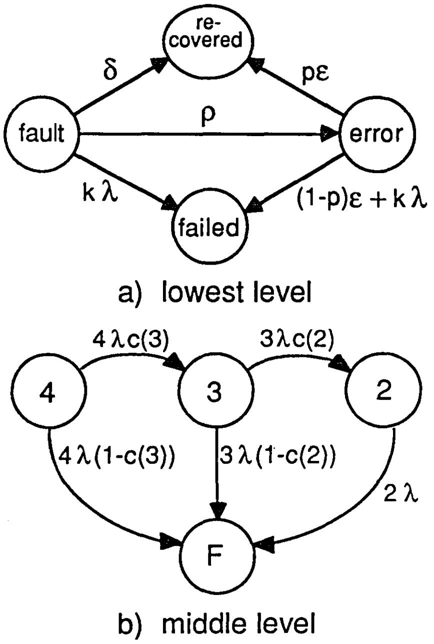

Figure 12. Markov Chains for 3-level Model

failure occurs is $k^* \lambda$, where k is the number of components that remain operational after the occurrence of the first fault.

Figure 12 (b) shows the middle-level model for this system. At this level, we have a Markov chain where state k represents the system having k operational computers. A state change occurs whenever there is a fault in one of the computers. >From state k, we go to state k-1 if there is a covered failure and the number of operational computers has not fallen below 2. We go to state F if there is an uncovered failure or the number of operational computers falls below 2. The coverage values (which are state-dependent) will be computed by solving the lower-level model of Figure 12 (a). The middle-level model is incorporated into the fault tree of Figure 9 by replacing the gate *C3of4* and its four inputs by a basic event having the CDF of the time to reach node F in the Markov chain of Figure 12 (b).

When SHARPE analyzes this three-level system, the results show that the probability of failure during an interval of 10 hours is 7.46150×10^{-6}. As expected, this is a little higher than in the previous two-level model. It is also slightly larger than the exact failure probability, which is computed by SHARPE to be 7.45961×10^{-6}.

We have noted that because the rate of occurrence of the second fault depends on k, the coverage values are state-dependent. This means that SHARPE will have to reanalyze the lowest-level (coverage) model of Figure 12 (a) for each value of k. With a model of this size, the expense of doing that is negligible, but it is interesting to see in the next section how we can extend the model one further level to avoid some of that extra computation.

A Four-Level Model: Markov Chain within Semi-Markov Chain within Markov Chain within Fault Tree

Let the bottom-most level of our model consist of the single-fault/error-handling model of Figure 10. At the next level up, we use the semi-Markov model shown in Figure 13. The initial state is *fault*. When a fault has occurred, two processes compete. The first process is the fault/error-handling process of Figure 10. If this process finishes first, we go to state *resolved*. The second process is the occurrence of a second fault, happening at a rate of $k^* \lambda$ (a state-dependent rate).

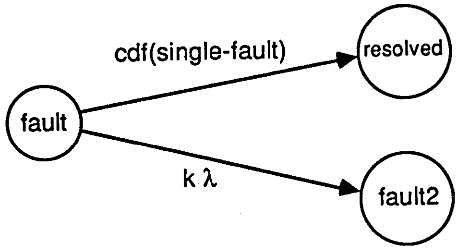

Figure 13. Semi-Markov Chain in 4-level Model

The fault is covered if the fault/error-handling process finishes first and if, within that process, the state *recovered* is reached rather than *failed*. Thus the coverage value is the probability of reaching state *resolved* in the semi-Markov chain of Figure 13, multiplied by the probability of reaching state *recovered* in the Markov chain of Figure 10. We still have to solve the model of Figure 13 for each value of k, but we only have to analyze the single-fault system one time. When we have SHARPE analyze this four-level system, the results are, as we expect, the same as for the three-level system.

In Figure 14, we show the complete SHARPE input file for all of the models we have discussed. They are defined in the input file in the same order as presented here.

CONCLUSION

We have developed a hierarchical modeling technique that provides a very flexible mechanism for using decomposition and aggregation to model large systems. The technique allows for both combinatorial and Markov or semi-Markov submodels, and can analyze each model to produce a distribution function. The choice of the number of levels of models and the model types at each level is left up to the modeler. Component distribution functions can be any exponential polynomial whose range is between zero and one.

Work is currently underway to improve and extend the SHARPE technique. Possibilities for future work include adding one or more queueing network models to the list of allowed model types, adding some kind of looping capability to the SHARPE input language, and allowing fault trees to have repeated nodes.

DESIGN OF SYSTEMS WITH CONCURRENT ERROR DETECTION USING SOFTWARE REDUNDANCY

Kien A. Hua and *Jacob A. Abraham*

University of Illinois
Urbana, IL 61801

ABSTRACT

This paper describes a methodology for the design of systems with concurrent error detection through the use of software redundancy. We present a technique for the development of self-checking programs in which assertions are generated systematically from the design of the program. Software that is developed using this technique is guaranteed to be self-checking with respect to all software faults and can be shown in practice to detect most errors due to hardware faults. A less rigorous technique using data encoding is also described. The self-checking capabilities are evaluated using a fault simulation method that allows us to study the coverage of errors due to hardware and software faults. We also propose a dual processor technique that can improve the performance, reliability and availability of the self-checking system.

1. INTRODUCTION

Off-line circuit testing is one of the widely used techniques to detect physical failures and to ensure that a system is defect-free. Unfortunately, the decrease in geometries has increased the possibility of transient errors. Since these errors are usually nonrecurring and not reproducible, off-line testing (useful for permanent faults) will not reliably detect transients. Consequently, it is important that we incorporate concurrent error detection (CED) capability into the design of digital systems in order to detect errors concurrently with normal operations.

Depending on the level in a system at which we apply the checking mechanisms, concurrent error detection can be subdivided into three categories (Figure 1):

- gate-level checking
- functional level checking
- system level checking.

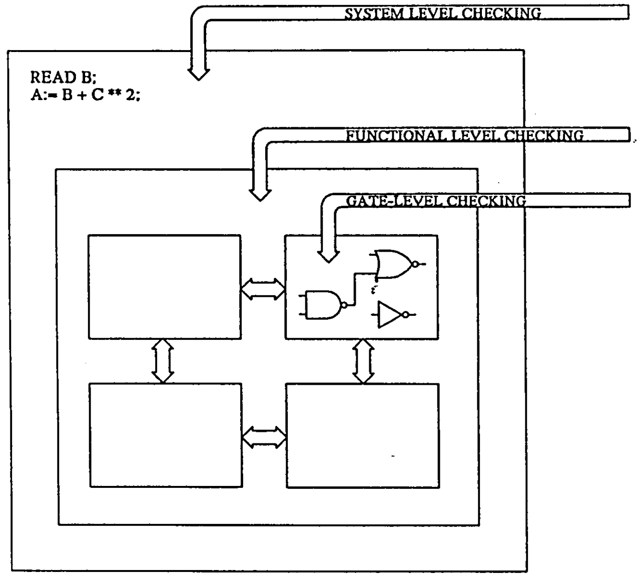

Figure 1. Three categories of concurrent error detection.

Gate-level techniques such as those using error detecting coding [1] usually assume the single or double stuck-at fault model. As the geometric features of integrated circuits become smaller, physical defects can affect a local area of a circuit, and stuck-at fault models are therefore not satisfactory. Functional-level techniques such as those used in algorithm-based fault tolerance [2, 3, 4] assume a more general model which allows any single module in the system to be faulty. These techniques can hence detect errors due to a block of faulty logic that is local to any single module. The third category of concurrent error detection assumes an even more general fault model that includes both design faults in software and physical failures in hardware. These techniques introduce software redundancy in the form of executable assertions into the program to check for the correct operation of the system during its execution. Since the checking mechanism is placed at programming level, both software and hardware faults that affect the dynamic behavior of the program can be detected. Such computer programs that check their own dynamic behavior automatically during their execution are called *self-checking programs* (SCPs).

In recent years, there have been several reports on self-checking programming. Depending on the aspects of the process which the assertions are checking, SCPs can be classified into three major categories:

(a) **Control flow checking** [5, 6, 7]: These techniques assume that malfunctions, such as processor failures, bus faults, or faults in the code being executed will cause errors in the control flow of the program. These techniques insert redundant code into the program so that the actual path traversed at run time can be recorded and checked against the precomputed path information.

(b) **Data structure checking** [8, 9]: These techniques use redundancy in data structures, such as additional pointers, identifier fields, or counters to detect any failures that change the data structure into a structurally incorrect one. The central idea in these

Acknowledgment: This research was supported in part by a contract from IBM Corporation and in part by the Semiconductor Research Corporation under Contract SRC RSCH 84-06-049-4.

techniques is that if a data structure is designed such that at least (n+1) changes are needed to update the data structure, then any faults that cause n or fewer changes in the data structure can be detected.

(c) **Data value checking** [10, 11, 12, 13]: These techniques assume that hardware or software faults will eventually corrupt the data and produce wrong results. They detect such faults by inserting into the programs assertions about the validity of the data values.

Control flow checking is a powerful technique for detecting hardware faults that changes the control sequence of the programs. However, it does not perform well in case of data manipulation errors. For instance, control flow checking will not be able to detect the use of an incorrect algorithm. Data structure checking is suitable for the implementation of reliable data base systems [14]. For general programs, data value checking is the more powerful technique. Since the assertions used in this technique are based on the semantics of the program, control sequence faults or data manipulation errors will change the intended semantics of the program and therefore will be detected by the assertions at run time. Unfortunately, there has not been a systematic technique for generating the assertions for data value checking. A structured technique for the design of SCPs was presented in [13]. This technique derives the assertions from the functional specifications of the program by performing stepwise refinement. Nonetheless, the process of stepwise refinement relies on intuition and is therefore still very much ad-hoc. In this paper, we will present in Section 2 a methodology for the design of SCPs, in which the assertions for data value checking are systematically derived from the design of the program. Software developed using this methodology is guaranteed to be self checking with respect to all software faults.

For some programming problems, checking the correctness of the outputs requires an additional copy of the input. This could be very inefficient if the number of inputs is large. A less rigorous self-checking programming technique for solving this class of problems will be discussed in Section 3.

Although the distinguishing feature of SCPs is the ability to detect both software and hardware faults, hardware fault coverage of SCPs has not been thoroughly studied hitherto. We propose in Section 4 a fault simulation technique that can be used to evaluate the affectiveness of SCPs against both hardware and software faults. This technique was used to study the coverage of errors, due to faults, of some popular programs. The empirical results of the experiments will be discussed

One weakness of SCPs is that the addition of software redundancy will degrade system performance. We propose a dual redundancy architecture to be used for SCPs. The proposed technique can improve both performance and reliability. A comparison of this technique with the conventional dual redundancy approach for CED will be discussed in Section 5.

2. DESIGN OF SELF-CHECKING PROGRAMS

Depending on their scope, assertions can be global or local. A single assertion for a program is an example of a global assertion. Global assertions have the advantage of being checked only once for each execution of the program. Unfortunately for some programs, their global assertions are as complex as the code of the programs. Using global assertions for this class of programs is therefore very inefficient. For such programs, one should replace the global assertion by a set of appropriate assertions inserted at appropriate locations throughout the program.

In this section, we present a methodology for the design of SCPs. First, we discuss the generation of global and local assertions. We then describe a procedure for the design of large scale SCPs. Since assertions are simple, they can be easily verified for correctness. In this paper, we assume that the executable assertions are free of software bugs.

2.1 Global Assertion Techniques

Global assertions are derived from the input/output specifications of the program. Since global assertions check the correctness of the final outputs, SCPs that use global assertions are always self-checking. The following are some examples of global assertions:

Problem:	Find the roots of a polynomial
Inputs:	A polynomial
Outputs:	Roots
Assertion:	The roots must satisfy the polynomial

Problem:	Find the solution of N simultaneous linear equations
Inputs:	A system of linear equations
Outputs:	Solution of the equations
Assertion:	The solution must satisfy all the equations

Problem:	Searching
Inputs:	A key and a list of items
Outputs:	Matched item
Assertion:	The search field of the matched item must match the key

Although global assertions can be easily derived from the functional specifications for many programs, some of the global assertions are very inefficient in terms of memory requirements, time requirements or complexity. This is discussed in [13]. As seen in the preceding examples, programs that are candidates for the global assertion technique are those which do not modify their inputs. Other good candidates are programs which have only a small set of inputs.

2.2 Local Assertion Technique

If the detailed design of a program is available, local assertions can be systematically generated from the semantics of the program design by symbolically "executing" [15] the design in the virtual machine environment (machine that supports the program design language). Since these assertions are derived directly from the design text, they reflect what is actually happening during the execution. These assertions therefore can be used to prove the correctness of the design with respect to the program specifications.

Once the correctness has been verified, the design can be transformed into executable form by translating the statements in the design into statements written in the target language. Even though this translation process may introduce coding errors, they will be detected during run time because the design has already been proved to be correct and the assertions are derived from the design, not the program code. Programs developed using this methodology are therefore guaranteed to be self-checking with respect to software faults: free of design bugs, while coding errors are guaranteed to be detected during the execution.

Conventional software verification techniques are not commonly used in practice due to the large size of software systems. The design of a program, however, is much smaller. The process of generating assertions and proving correctness is therefore much simpler in the proposed technique than in conventional program verification methods. Nevertheless many mechanical techniques for assertion generation intended for conventional program verification [16, 17, 18, 19] can be used in the proposed method as well.

We have given an overview of the assertion generation technique. The proposed technique, however, is best explained by examples. For the remainder of this subsection, we will illustrate the application of the technique to two popular programs:

- sorting (non-numeric)
- finding the Eigenvalues and Eigenvectors of a real symmetric matrix (numeric)

Example 1: This example illustrates our technique that systematically generates assertions from the design of a sorting program. For clarity, we choose a simple single-loop sorting program for the demonstration. The resulting assertions turn out to also be the global assertions for the program. In general, programs are more complex and we usually have multiple sets of assertions located throughout a program.

```
Procedure SORT(A,n)
    k:= 1
    Dowhile k<n
        Find $A_t = min(A_{k+1}, . . . , A_n)$,
              where k+1 $\leqslant$ t $\leqslant$ n
        If $A_k > A_t$ Then exchange($A_k, A_t$)
        increment k
    enddo
end;  (* SORT *)
```

The flow chart for the design is shown in Figure 2. The loop has two paths. Let us call the path with path condition $A_k > A_t$ the right path, and the path with path condition $A_k \leqslant A_t$ the left path. Also we denote by y/m/ the value of y the (m+1)-st time the cutpoint N (Figure 2) is reached since the most recent entrance to the block. We then have the following:

left path:

$$[k/m\text{-}1/ < n \wedge A_{k/m-1/}/m\text{-}1/ \leqslant A_t/m/] \supset [A_t/m/ = \min(A_{k/m-1/+1}/m-1/, \dots, A_n/m-1/) \wedge k/m/ = k/m\text{-}1/ + 1] \quad (1)$$

right path:

$$[k/m\text{-}1/ < n \wedge A_{k/m-1/}/m\text{-}1/ > A_t/m/] \supset [A_t/m/ = \min(A_{k/m-1/+1}/m-1/, \dots, A_n/m-1/) \wedge (A_{k/m-1/}/m/, A_t/m/) \leftarrow (A_t/m/, A_{k/m-1/}/m-1/) \wedge k/m/ = k/m\text{-}1/ + 1] \quad (2)$$

Since the assignments to k and A_t are not affected by which path is used, the following equations are always true at cutpoint N:

$$k/m/ = k/m\text{-}1/ + 1 \quad (3)$$

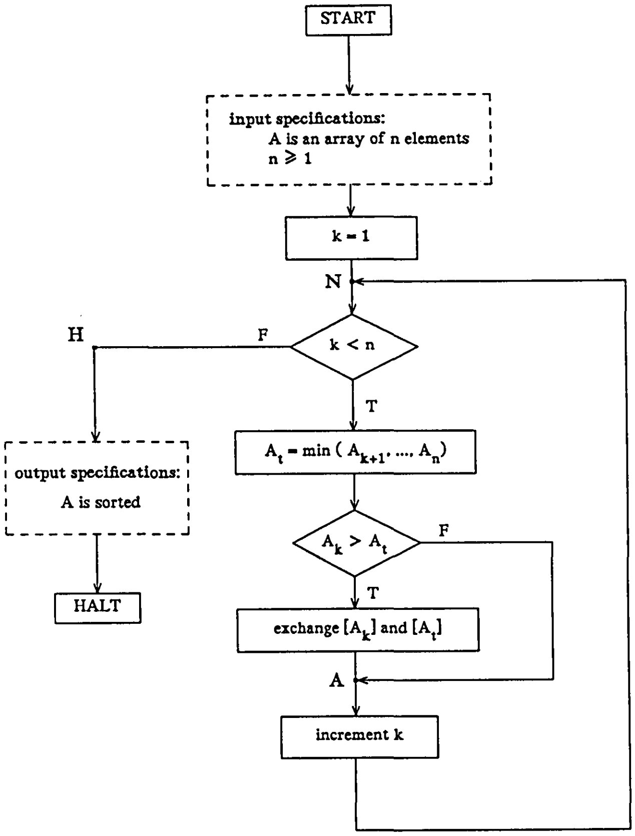

Figure 2. Flowchart for the sort program.

$$A_t/m/ = min\,(A_{k/m-1/+1}/m-1/, \dots, A_n/m-1/) \quad (4)$$

$$(3) \rightarrow k/m/ = k/0/ + m = m + 1 \quad (5)$$

$$(4)\ \&\ (5) \rightarrow A_t/m/ = min\,(A_{m+1}/m-1/, \dots, A_n/m-1/) \quad (6)$$

Ignoring the exit test k<n, and the assignments to k and A_t, combining (1) and (2) gives the following:

If $A_m/m-1/ > A_t/m/$
  then $(A_m/m/, A_t/m/) \leftarrow (A_t/m/, A_m/m-1/)$ (7)

From (6) and (7) we have the following:

m=1:
$A_t/1/ = min\,(A_2/0/, \dots, A_n/0/)$
If $A_1/0/ > A_t/1/$
  then $(A_1/1/, A_t/1/) \leftarrow (A_t/1/, A_1/0/)$
m=2:
$A_t/2/ = min\,(A_3/1/, \dots, A_n/1/)$
If $A_2/1/ > A_t/2/$
  then $(A_2/2/, A_t/2/) \leftarrow (A_t/2/, A_2/1/)$

.
.
.

m=n-1:
$A_t/n-1/ = min\,(A_n/n-2/, \dots, A_n/n-2/)$
If $A_{n-1}/n-2/ > A_t/n-1/$
  then $(A_{n-1}/n-1/, A_t/n-1/) \leftarrow (A_t/n-1/, A_{n-1}/n-2/)$

By induction, we therefore have the following loop invariants:

A1: $(A_1, ..., A_{k-1})$ is monotone
A2: $A_{k-1} \leqslant \min(A_k, ..., A_n)$
A3: A/k-1/ = PERMUTATION(A/0/)

The assertions at H therefore are:

A4: A/n-1/ is monotone
A5: A/n-1/ = PERMUTATION(A/0/)

Since A4 and A5 imply the output specifications, the design of the program is correct with respect to the specifications.

We can also prove the termination based on the classic Floyd's well-found set technique [20, 21]. We choose point A as the cutpoint which cuts both paths around the loop (Figure 2). Let us take the set N of all natural numbers, with regular < ordering, as the well-found set. Since $u_A = n-k$ is strictly monotonic, and are bounded (i.e., $u_A \geqslant 0$), the resultant sequence is therefore well founded. Thus clearly no loop or combination of loops could be executed indefinitely because the no-infinitely-descending-chain condition would be violated.

We see that the sets $\{A_1, A_2, A_3\}$ and $\{A_4, A_5\}$ are equivalent. Thus all five assertions are not required for self-checking. Since the set $\{A_4, A_5\}$ is more time-efficient, we choose it for the program. We might also want to add another assertion, A0: n>0, to check whether the input meets the input specifications.

Although we have proved the termination of the program design, the self-checking program will fail if the program code causes the loop to execute indefinitely. To overcome this problem, we can have a convention that the program designers reserve the right to design the control structures and their termination conditions, and programmers may not alter these constructs. If the designers always prove the termination of the designs and if assertions are added to dynamically check the well founded properties, then this convention guarantees the termination of the final product. There are two kinds of loops: DO loop and WHILE loop. For a DO loop, if the designer proved the termination properties of the loop based on the loop index, then clearly the DO loop must eventually terminate if the programmers do not modify the loop construct and the loop index designed by the designer in any way. In the case of a WHILE loop, the function for proving the termination of the loop (i.e., the function that maps elements of the program's data domain into a well-found set, e.g., u_A in Example 1) can be used as an executable assertion to dynamically check the termination condition. Since this function is monotone and is bounded, if the programmers do not modify this termination-checking function, then the WHILE loop must eventually terminate if the assertion is true for each iteration of the loop.

The design of the sorting program with assertions A0, A1 and A4 added is given in the following. Programmers now can take over and transform it into the target language.

```
Procedure SORT_SCP(A,n)
   If not A0 then ERROR
   k:= 1
   Dowhile  k<n
      Find $A_t = min(A_{i+1}, . . . , A_n)$,
            where i+1 $\leqslant$ t $\leqslant$ n
      If $A_k > A_t$ Then exchange($A_i, A_t$)
      increment k
   enddo
      If not A4 then ERROR
      If not A5 then ERROR
   end;  (* SORT *)
```

Example 2: The following is the design of a SCP that finds the Eigenvalues and Eigenvectors of a real symmetric matrix. The program is based on the Jacobi method. The fundamental approach of this technique is to annihilate, in turn, selected off-diagonal elements of the symmetric matrix by "elementary" orthogonal transformations. For more details on this method, interested readers are referred to [22].

```
Procedure EIGEN_SCP(A,S,N);
   AI= A;  (* Save the input *)
   Generate an identity matrix S;

   Eigenvalues= diagonal elements $A_{ii}$'s;
   Eigenvectors= columns of S;
end;  (* EIGEN_SCP *)
```

As we did in Example 1, we can derive the following loop invariants by symbolic execution:

$$A/m/ = R/m/^T \cdot A/m-1/ \cdot R/m/$$
$$S/m/ = S/m-1/ \cdot R/m/$$

Upon the completion of the repeat loops, we therefore have the following assertion:

$$A/f/ = S/f/^T \cdot A/i/ \cdot S/f/ \qquad (8)$$

where A/f/ is the final matrix A
A/i/ is the initial matrix A
S/f/ is the final matrix S.

Equating the elements of the matrices in (8), we obtain

$$\sum_{k=1}^{N} A/i/_{mk} \cdot S/f/_{ki} = \sum_{k=1}^{N} S/f/_{mk} \cdot A/f/_{ki}$$

Let us denote by $X^{(i)}$ the ith column of a matrix X, we then have:

$$A/i/\cdot S/f/^{(i)} = S/f/\cdot A/f/^{(i)}$$

Since the design of the control structure ensures that A/f/ is a diagonal matrix , the above equation can be written as:

$$A/i/\cdot S/f/^{(i)} = A/f/_{ii}\cdot S/f/^{(i)}$$

The diagonal elements of the matrix A/f/ therefore must be the Eigenvalues, and the columns of the matrix S/f/ then must be the corresponding Eigenvectors. Since the assertion (equation (8)) generated implies the output specification of the program, it guarantees the self-checking properties of the program.

2.3 Design of Large Self-Checking Programs

In this subsection, we describe the procedure for the design of large SCPs. This is a three-phase process. Given a programming problem, we first do the system design using some hierarchical modular design technique: top-down, bottom-up or more often a mixture of the two. This process converts the functional requirements of the program into a hierarchy of program modules. For each module, we then do the detailed design using a procedural design language. The design language used should be precise and contain enough detail so that symbolic execution of the design is possible. In Example 1, we used a program design language similar to that presented in [20].

To make the program self-checking, we then apply the global assertion or local assertion techniques presented in Section 2.1 and Section 2.2 respectively to each module. During this process, a procedure call is considered as an abstract executable instruction of a virtual machine implemented by the program modules in the lower levels of the hierarchy. Since the called modules (procedures) are themselves self-checking, the calling modules can assume that the results returned from the called modules are correct.

Since the assertions for each module are derived independently, the set of assertions generated thus far could be excessive. A final inspection is therefore needed to remove the redundant assertions.

Definition 1: An assertion AI is said to *dominate* another assertion AJ if all the properties checked by AJ are also checked by AI.

Definition 2: If an assertion AI dominates another assertion AJ, then AI is called the *dominating assertion* and AJ is called the *dominated assertion*.

In a SCP, some of the assertions may be redundant and should be removed for better system performance. As an example, if a module that computes solutions of linear equations calls a different module to do the Gaussian elimination and it computes the solutions by back substitutions, then the assertion, in the calling module, that checks whether the solution satisfies all the equations dominates all the assertions in the called modules. The dominated assertions therefore can be removed without impairing the self-checking properties of the software system. Usually, we prefer to save the dominated assertions since they can help to identify faulty modules, and system malfunctions can be detected early. Nevertheless, in some cases the dominating assertions are preferred for the sake of better system performance.

We summarize the three phases of the proposed self-checking programming methodology in the following:

PHASE 1: Design
- Use hierarchical modular design techniques to design a hierarchy of program modules.
- Do the detailed design for each module in some computable program design language.

PHASE 2: Make assertions
- Generate assertions for each module using either global or local technique as appropriate.

PHASE 3: Remove redundant assertions
- Identify dominating and dominated assertions
- Remove the redundant ones.

Although we described the methodology as three separate processes, in practice PHASE 2 and PHASE 3 can be overlapped to reduce design time.

The proposed methodology is compatible with the traditional software development process in the sense that the process of making the program self-checking by adding assertions is a totally separate phase in the software development process. The job of making the program self-checking can be done by a specialist, and the program designers and the programmers need not change their traditional practicing styles. Nevertheless, the assertions can serve as a communication tool between the designers and the programmers. They provide additional information to guide the programmers in programming. They are also very useful for the programmers to informally verify their code quickly.

3. ADDING ADDITIONAL PROPERTIES TO SCPs

In Section 2, all the assertions generated imply the output specifications of the programs. If the assertions are true, the outputs computed must be correct. This class of assertions therefore guarantee the self-checking properties of the programs. In this section, we will present a less rigorous technique in which the assertions do not imply the output specifications. Nevertheless our experiments (to be described) show that this technique can also be very effective.

Since some of the programming problems have their inputs and outputs share the same memory space, the outputs therefore "destroy" the input information. In order to check the correctness of the outputs we must save an extra copy of the inputs so that relationships between the inputs and outputs can be validated. Sorting is one such example. Since we need to check whether the sorted list is a permutation of the original list, the input list must be available for the validation. For this class of problems, if the size of the input data is large, then the assertions based on the input/output relationships are not very efficient.

Alternatively, we may add to the input data some properties that are supposed to be preserved by the operations of the program. The correctness of the outputs can then be verified by checking whether the outputs meet those properties. Although an incorrect algorithm may also preserve the added properties, this is unlikely if the appropriate properties are used. Usually the properties used are those which are very sensitive to small changes in the program. Since programmers do not create their programs at random, it is reasonable to assume that if a program is incorrect, it is almost correct. Assertions that are sensitive to simple coding errors therefore usually provide very good fault coverage.

One technique that adds additional properties to data is *data encoding*. A program can be viewed as a function over an input domain with values in an output range. If a program is designed to process information encoded in some error detecting code, then we can detect faults by observing the program's coded output. This technique has been used in designing self-checking circuits [1]. In the remainder of this section, we will discuss its application to self-checking programs.

A checksum technique is presented in [2] for detecting and correcting errors when matrix operations are performed on a multiple processor system. The checksum encoding is done as follows. given an n by m matrix A, we transform it into an (n+1) by (m+1) matrix. The elements $a_{i,m+1}$ for $1 \leqslant i \leqslant n$ and $a_{n+1,j}$ for $1 \leqslant j \leqslant m$ are the row checksums and column checksums, respectively and they are computed as follows:

$$a_{i,m+1} = \sum_{j=1}^{m} a_{i,j} \quad \text{for } 1 \leqslant i \leqslant n$$

(row checksums)

$$a_{n+1,j} = \sum_{i=1}^{n} a_{i,j} \quad \text{for } 1 \leqslant j \leqslant m$$

(column checksums)

The other elements are information elements and are the same as the corresponding elements in the original matrix. The strategy used in the checksum technique is to encode the input matrices; after manipulation, the output matrix is expected to be in the encoded format, otherwise, errors have occurred.

This encoding scheme can be used to design SCPs for matrix operations. It is shown in [2, 3] that the encoding scheme is preserved by the following matrix operations: addition, multiplication, scalar product, LU-decomposition, transposition, Gaussian elimination and inversion.

We show in the following a template for SCPs that use data encoding techniques:

```
procedure coding_scp(var input,output: data-type;
                     var error: boolean);
begin
    Reading input;
    Encoding input;
    output ← Data manipulation;
    if coded(output)
        then begin
            error:= false;
            output:= decoding(output)
        end   (* then *)
        else error:= true
end;  (* coding-technique *)
```

Depending on the error detecting code, the decoding of the output may not be necessary. A SCP for matrix multiplication that uses the checksum technique is given in the following. The SCPs for other matrix operations can be obtained similarly using the given template.

```
program mat_mul;
var A: array[1..l+1,1..m] of real;
    B: array[1..m,1..n+1] of real;
    P: array[1..l+1,1..n+1] of real;
    i,j,k: integer;
begin
    (* reading input *)
    for i:= 1 to l do
        for j:= 1 to m do read(A[i,j]);
    for i:= 1 to m do
        for j:= 1 to n do read(B[i,j]);
    (* encoding input *)
    call column_chksum(A,l,m);
        (* compute column checksums *)
    call row_chksum(B,m,n);
         (* compute row checksums *)
    (* matrix multiplication *)
    for i:= 1 to (l+1) do
        for j:= 1 to (n+1) do
            begin
                P[i,j]:= 0;
                for k:= 1 to m do
                    P[i,j]:= P[i,j] + A[i,k] * B[k,j]
            end;
    (* check coded output *)
    if coded(P,l+1,n+1)
        then print P
        else print "faults detected"
end;   (* mat-mul *)
```

The data encoding technique can also be used in non-numeric problems. For instance, suppose we want to sort a list of n elements:

$$L = (x_1 \; x_2 \; \ldots \; x_n).$$

We can encode the list L to get LC as follows:

$$LC = (\hat{x}_1 \; \hat{x}_2 \; \ldots \; \hat{x}_{n-1} \; \max \; C)$$
$$\text{where } \max = \text{maximum}(x_1 \ldots x_n)$$
$$C = \left(\sum_{i=1}^{n} x_i \right) \mathit{mod} \; \max$$
$$\hat{x}_i = x_j \quad \text{for some i and j.}$$

Once the list is in its encoded form, we need to sort only the first n-1 elements of the encoded list because the nth element is already in its correct location.

When the sorting process is done, we can check its correctness as follows:

(a) Check the sorting relationship of the elements in the sorted list.

(b) Compare C with $\left[\left(\sum \textit{sorted elements} \right) \mathit{mod} \; \max \right]$

The first check is to make sure that the sorted list is a monotone sequence. The second check ensures that the sorted list is a permutation of the original list.

Since most, if not all, sorting algorithms use a loop structure to process the list, each list element is processed by the same set of instructions. If a software fault in the set affects a list element, then it likely affects most other list elements as well. The same is true for permanent hardware faults because the same set of hardware components are used for each iteration of the loop. Since the probability that most elements in the output list are incorrect yet the list satisfies the proposed assertions should be almost zero, the assertions are very effective for detecting software faults and permanent hardware faults. Although a transient error might affect only one list element, we can prove that it will be detected by the assertions. The proof is given in the following.

Let L be a list and $\hat{L}$ = sorted(L) = $(x_1 \ \ldots \ x_i \ \ldots \ x_n)$. Suppose that there is a change in the value of the element at position i due to a transient error that occurred during the sort, we then have:

$$\tilde{L} = (x_1 \cdots \tilde{x}_i \cdots x_n), \qquad where\ \tilde{x}_i = x_i + e$$

$$\tilde{x}_i \text{ is undetected} <==> \left[\left(\sum_{i=1}^{n} x_i\right) + e\right] mod\ x_n = C$$

$$<==> \left[\left(\sum_{i=1}^{n} x_i\right) mod\ x_n + \left(e\ mod\ x_n\right)\right] mod\ x_n = C$$

$$<==> \left[C + \left(e\ mod\ x_n\right)\right] mod\ x_n = C$$

$$<==> e = 0$$

Comparing this technique with that of Example 1, we see that this technique does not require the inputs for the validation process. This is particularly important when the list is long.

4. EMPIRICAL RESULTS

4.1 Methodology

In this subsection, we present a fault simulation technique for the evaluation of self-checking properties with respect to both software and hardware faults. The central idea is to introduce simulated faults by applying mutation transformations to produce mutant programs. These mutants are then executed to measure the ability of the set of assertions to distinguish the program from its mutants.

The technique of mutation transformation has been used in software testing [23]. A set of 25 mutant operators that represent common programming errors are used in [24, 25]. These mutant operators can be used for our purposes to evaluate the effectiveness of the SCPs with respect to the software bugs.

For the study of hardware fault coverage, we could write a program to simulate the system for which the SCPs were written. However, since hardware systems are designed differently, this approach would require a different version of the simulator for each system. This is not very cost-effective. Alternatively, we can simply compile the source program to obtain the assembly code. Simulated physical faults are then introduced into the assembly code by applying appropriate hardware mutation transformations (to be described). The mutant programs are then executed and the effectiveness of the assertions against hardware faults can be determined. This technique is diagrammed in Figure 3. Since this scheme performs the simulation on the real system, it is therefore also more reliable than the former approach.

The proposed fault simulation technique is an error-based testing method. It requires the definition of a set of mutation transformations and classes of faults that are considered. The set of faults that constitute the fault model must correctly characterize possible physical failures in the hardware system. Our hardware fault model is based on the earlier functional fault models for complex processors [26,27]. We extend the existing fault model to include faults in the memory. The fault model is given in the following:

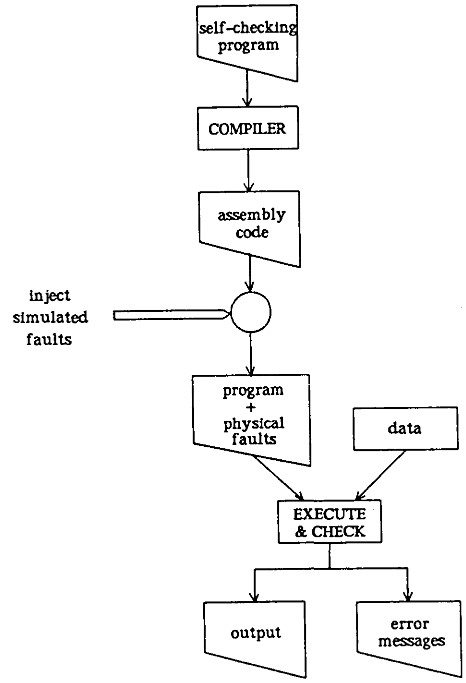

Figure 3. Strategy for evaluating SCPs with respect to hardware faults

(A) **Addressing faults:** Faulty decoding circuits can cause the following faults:
- no storage location is selected
- a wrong storage location is selected
- more than one storage location is selected.

(B) **Instruction decoding faults:** Failures in instruction decoding can cause the following faults:
- no instruction is executed
- a wrong instruction is executed
- more than one instruction is executed.

(C) **Faults in storage elements:** Some of the bits in the storage elements are stuck-at-0 (s-a-0) or stuck-at-1 (s-a-1). Transient failures can also change the contents of registers or memory locations arbitrarily.

Definition 3: A storage element (a register or a memory location) is a *sink* for an instruction if the execution of the instruction modifies its contents.

Definition 4: A storage element is a *source* for an instruction if it provides an operand for the execution of the instruction.

We now describe in the following the mutation transformations for the three classes of hardware faults described in the fault model:

(A) Addressing error:

a) No storage element is selected
- Delete from the program the one address instructions (e.g., LOAD, STORE, ...) that involve the affected storage element.
- Delete from the program the instructions that have the affected storage element as their sinks.
- If an instruction has the affected storage element as a source, replace the source with a constant zero, or a different storage element whose content is zero.

b) Selection of a wrong storage element
- Replace the correct operand by the incorrect one.

c) More then one storage elements are selected
- If the storage element is a sink, add instructions to copy its contents to the incorrectly selected storage elements.
- If the storage element is a source, add before the affected instruction instructions to logically AND its contents with those of the incorrectly selected ones.

(B) Instruction decoding errors:

a) No instruction is selected
- Remove the affected instructions.

b) Wrong instruction is selected
- Replace the affected instructions by the incorrectly selected one.

c) More than one instruction is selected
- Add instructions to logical AND the affected sources and/or sinks

(C) Faults in storage elements:

Stuck-at faults are simulated by setting or clearing the corresponding bits in the affected storage elements.

In the experiments, we assumed that shorts between wires are equivalent to the wired AND of the affected lines. Although this is true in nMOS circuits, it is technology dependent. We also assumed that when more than one instruction is executed simultaneously, the individual operations are performed correctly, and only the inputs and outputs of those operations are affected by the wired-AND faults. This is not always true. Some of the operations may share parts of the circuitry and the interference can cause the operations to be unreliable. We, however, believe that a more complex simulation will show that these faults will also be detected by our technique.

4.2 The Experiments

The experiments were done on the VAX 11/780. They included hardware faults, transient faults and software faults. Four Pascal programs were selected for the experiments based on their popularity:

(1) Sorting
(2) LU decomposition
(3) Solution of linear equations
(4) Eigenvalues and Eigenvectors of a real symmetric matrix

The first two programs use the data encoding technique described in Section 3. The third and fourth programs employ the techniques discussed in sections 2.1 and 2.2 respectively.

In order to be able to quickly perform the fault simulations reliably, we implemented a tool for the injection of simulated physical faults. For each test case, we specified a mutant operator. In response, the program asked for additional relevant information, and then performed the mutation transformation automatically by scanning the assembly code and modifying the affected instructions accordingly. For transient faults, we used the debugger ADB [28] available on the VAX. ADB is a general purpose debugging program. It provides capabilities to examine files and a control environment for the execution of UNIX programs. We ran the SCPs under the control of ADB, and transient faults were injected by setting break points and modifying the object files. For software faults, we manually modified the source code for each test case. The following relevant mutation transformations were studied in our experiments of software fault detection:

- change operators
- modify the indices of loops
- change the loop termination conditions
- change operands
- alter control structures
- modify predicates

We tried about 12,000 test cases of permanent hardware faults, 3,600 test cases of transient faults and 220 test cases of software faults. The results of the experiments are summarized in Table 1. The tables in the Appendix give the types of faults and the resulting errors detected during the experiments. We found that essentially all errors that affected the data manipulation were detected. Undetected errors were due to permanent hardware faults that caused infinite execution or which affected the execution of the assertions. For instance, if an instruction decoding fault changes the incrementing of a loop index to a decrement, then the loop will be executed indefinitely. In this situation, if the assertions are located outside the loop, then the execution will never reach them and the errors will not be detected. For another example, if an addressing fault causes the assertion to compare the wrong values, then faulty results might not be detected.

There were a few cases where the errors due to hardware faults were detected by the operating system, for example,

- tried to read pass end of file
- illegal instruction
- memory fault
- bad data found on real read
- floating exception
- bus error, etc...

before the program had a chance to check its output (counted as "detected"). Particularly, permanent s-a-1 faults, especially those at the more significant bits tend to cause floating exception. The errors due to this class of faults are generally detected by the operating system.

Table 1. Coverages of errors due to faults

Program	Type of faults		
	Hardware	Transient	Software
Sort	94.47%	100%	100%
LUdecomp	94.38%	100%	100%
Linear eqtns	98.60%	100%	100%
Eigen	99.11%	100%	100%

There are few cases of errors due to transient and software faults that are not detectable by the CED technique. They are some of those faults that affect only the input/output operations of the programs. If a transient or software fault affects only the input operations, it effectively changes the input data and the SCP cannot recognize the faulty data, unless the data were originally stored in some encoded format. Nor can a SCP detect transient and software faults that affect the outputs after the correctness of the outputs has been verified by the assertions. These classes of faults are beyond the scope of the proposed CED technique, and are not considered in the computation of the error coverages. In fact, most of transient faults that occur during the I/O operations are likely to cause memory faults, bus error, etc... and will be detected by most operating systems. We also do not consider those faults (mostly transient) that have no effect on the outcomes of the computations. It is quite interesting to know that many errors, particularly due to transient and software faults, are primarily detected by the CED technique.

5. HARDWARE SUPPORT

Although added assertions can improve significantly the reliability of the computing systems, the software redundancy also degrades the system performance. The performance overhead is from 7.27% to 32.75% for the programs used in our experiments. However, this is the price paid for the added reliability. Other reliability techniques such as duplication [29], RESO [30] or N-version programming [31] have much higher hardware or performance overhead.

To improve the performance, a dual processor architecture an be used in conjunction with SCPs. This architecture can also improve the reliability of the CED system. In a single processor system, if the processor is faulty, then the checks performed on the faulty processor may not be reliable. In our experiments, a large number of the undetected errors are of this class. The dual processor system can solve this problem by having each process and its checks executed on different processors. For instance, suppose we want to multiply two checksum encoded N by N matrices; every two rows of the product matrix can be computed simultaneously on the two processors, and each row checksum can also be checked in parallel on the other processor (i.e., if processor 1 computes row i, then the checksum properties of row i should be checked by processor 2). This scheme ensures that if one processor fails, the faulty results it computes will be detected by the good processor.

Comparing this technique with the traditional dual redundancy systems, the traditional technique has the advantages of being simpler and having slightly better hardware fault coverage. The proposed technique, however, has benefits not available in the traditional approach. Most noticeably, the traditional technique dose not detect software faults. Besides, if one of the processors fails, our experiments shows that the remaining processor of the proposed dual processor system can still rely on the self-checking capabilities of the software to perform considerably more reliable computations in a degraded manner. The performance overhead is also better in the proposed scheme. Extending this concept further, we see that the reliability of SCPs can also be improved by having the data manipulation and checks done on different processors of a distributed system. The proposed CED technique is therefore very attractive for many critical applications, particularly those which demand highly reliable software. The scheme is thus a novel type of design diversity [32].

6. CONCLUSIONS

In this paper, we presented a methodology for the design of self-checking programs in which the assertions are systematically generated from the design of the program. Software developed using the proposed methodology is guaranteed to be self-checking with respect to software faults. A less rigorous technique that adds additional properties to programs for the self-checking purposes was also discussed. This technique is particularly useful when the number of inputs is large.

We also described in this paper a fault simulation technique that can be use to study the hardware and software fault coverage of SCPs. This technique was used in our empirical study. The experimental results suggest that SCPs provide excellent coverage against both hardware and software faults. The effectiveness of higher level versus lower level error detection technique is a controversial issue. The proposed fault simulation technique allows us to study the effectiveness of the SCPs with respect to the whole spectrum of computing faults: low level faults such as stuck-at faults in the storage elements, functional level faults such as those that cause decoding errors, and system level faults such as bugs in the software.

We also proposed a dual processor technique for SCP processing. This scheme can improve both system performance and reliability. We believe that the proposed approach is superior in many aspects to the traditional redundancy methods such as duplication, N-version programming or signatured instruction streams.

ABSTRACT

Algorithms for the generation of test sets for a parity checker tree of 2-input EXCLUSIVE-OR (XOR) gates are described. A minimal test set (3 patterns) detects all single stuck-at faults at the input leads of the XOR gates. Three test sets that guarantee 100% fault coverage for double stuck-at faults are developed. Their lengths increases logarithmically with the number of inputs of the tree. Two of these tests detect all single and double faults.

1 INTRODUCTION

There is general agreement that single faults do not represent the actual circuit failures, particularly in current IC technologies. The number of faults and the frequency with which some faults occur have been affected by two main changes: the reduction in size of the devices and the increase in circuit complexity. For example, during the fabrication process a single surface defect or a variation in processing parameters can cause multiple faults. As feature size decreases, this problem becomes more severe due to the larger relative size of surface defects.

Experimental investigations to assess the goodness of single stuck-at fault test sets for detecting multiple stuck-at faults were carried out by [Hughes 84,85]. These simulation studies of the 74LS181 4-bit ALU, using 10 single stuck-at test sets and one toggle-only test set, demonstrated very high multiple stuck-at fault coverage. The actual fault coverage was significantly higher than the fault coverage bounds based on an analysis of the network structure [Agrawal 81]. In order to confirm the usefulness of single fault test sets in detecting multiple faults, there is a need to evaluate other circuits that are commonly used in digital systems.

This paper analyzes the effectiveness of single stuck-at fault test sets in detecting multiple stuck-at faults in a very widely used circuit, a parity checker. First, an optimal single stuck-at test set that is suitable for any XOR gate implementation is presented. Then a reduced test set is developed to detect single stuck-at faults at the input pins of XOR gates.

The circuit is simulated to determine the effectiveness of these tests for detecting multiple faults. Test sets that detects all double stuck-at faults are developed.

2 PARITY NETWORKS

Probably the most widely used encoding scheme is parity. Parity checkers are used with memory arrays, registers, and buses. Parity has been the most popular checking scheme in real computer systems such as the IBM 4341 [Ciacelli81], the Sperry Univac 1100/60 processor [Boone 80], and the VAX 11/780 [Swarz 78]. Although parity may not be the most cost effective code for every situation, it is very widely used either by itself or in conjunction with duplication [Sedmak 80]. Self-checking parity checkers also are used in PLA testing [Khakbaz 82].

Since parity checkers are themselves circuit modules, they are also subject to circuit failures. Thus, not only should a parity checker be able to detect errors in its inputs, it also should be testable for faults within itself.

3 STUCK AT FAULTS

3.1 Single Stuck-At Faults

The parity tree in Fig. 1 consists of 2-input XOR gates. It has been shown [Bossen 70] that such circuits are fully tested for single stuck-at faults by an optimum test set that consists of only 4 patterns. This result is based on the following assumptions: 1) no internal realization of the XOR gate is assumed, and 2) all 4 input patterns are needed to fully test the XOR gate.

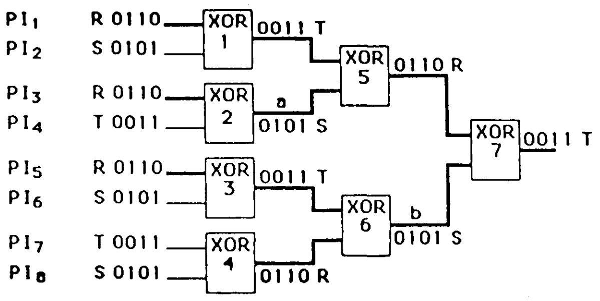

Figure 1. An 8-input parity tree.

* Also, with the Computer Engineering Department San Jose State University, San Jose, CA 95192.

CH2345-7/86/0000/0836$01.00©1986 IEEE

Three vectors, R, S and T consisting each of two '0's and two '1's are used to develop the Bossen test. The addition mod(2) of the vectors is defined by the matrix in Table 1.

Table 1. Addition table of the vectors R, S and T.

$\oplus$	0	R	S	T
0	0	R	S	T
R	R	0	T	S
S	S	T	0	R
T	T	S	R	0

0 is the all zeros vector.

The test is developed by first assigning one of the 3 vectors to the output of the tree. For the 8-input tree shown in Fig. 1, the output vector, T, at gate XOR7, is arbitrarily selected. Then employing the labeling procedure [Bossen 70] shown in Fig. 2(a), the input patterns for gate XOR7 are determined. They are the vectors R and S shown in Fig. 2(b). The patterns R and S are such that they form an exhaustive test set for XOR7. These two vectors are the outputs of gates XOR5 and XOR6, and the input vectors to these two gates are now determined in the same fashion.

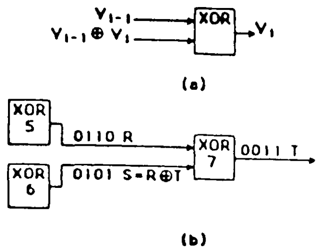

Figure 2. Gate labeling procedure (a) and example of test generation (b) for Bossen test.

The procedure is followed until all vectors have been generated. They are shown at the corresponding nodes in Fig. 1. The optimum test set thus generated (called Bossen throughout the rest of this paper) is formed by concatenating all vectors at the Primary Inputs (PI) 1 through 8. The test set is listed in Table 2. The labeling of an n-input tree may be generalized in the form of the following algorithm which is a variation of the algorithms developed by [Bossen 70] and [Seth 77].

Algorithm I

1. Let Z = {R, S, T}. Assign any vector in Z to the output of the tree.
2. Repeat until all leads are labeled: For each XOR gate whose output lead is labeled, assign to its inputs the two other vactors.
3. The vectors at the primary inputs of the tree form the test set.

Table 2. Bossen test for 8-input parity tree.

	Primary Input							
Pattern #	1	2	3	4	5	6	7	8
1	0	1	0	1	0	1	1	1
2	1	0	1	1	1	0	1	0
3	1	1	1	0	1	1	0	1
4	0	0	0	0	0	0	0	0
Vector Name	R	S	R	T	R	S	T	S

The test set listed above guarantees the detection of all single stuck-at faults at the input leads as well as at all internal nodes of the XOR gates for any gate implementation. If, however, only faults at the XOR gates input leads are to be detected, the first 3 patterns of the test shown in Table 1 are sufficient. Consider a single XOR gate. All 6 single stuck-at faults can be detected with one of the following two tests, UV or U'V', where U = {011} and V = {101}. Note that U $\oplus$ V = W, V $\oplus$ W = U, and W $\oplus$ U = V, where W = {110}, and that U, V and W are obtained from the vectors R, S and T by eliminating the last bit (which is 0 for all of them). Thus, using algorithm I and the set Z={U, V, W}, it is possible to generate a test that detects faults at the leads of the gates for any size tree. This test set will be called Mourad throughout the paper.

3.2 Double Stuck-At Faults

Although the generated test sets, Bossen and Mourad, detect all single stuck-at faults, they are not sufficient to detect all multiple stuck-at faults. This failure to detect double stuck-at faults will be explained next. For this we refer back to the circuit in Fig. 1. If node a and node b are both stuck-at-0, or both stuck-at-1, the sets of all tests that detect these multiple faults is given respectively by the Boolean functions [Breuer 76]

$$ab(d\,^2f/d(ab)) \quad + ab'\ (df/da) + a'b\ (df/db) \qquad (1)$$

$$a'b'(d\,^2f/d(ab)) + a'b\ (df/da) + ab'\ (df/db) \qquad (2)$$

where df/dx, x=a or b, is the Boolean difference of f with respect to x, and $d^2f/d(ab)$ is the Boolean difference of f with respect to a and b. The first term of either equation represents a sensitizing path from a and b, and the other terms, paths from a and from b respectively. These Boolean functions are easily evaluated [McCluskey 86] with the following results:

$$df/dx=1 \text{ for } x=a \text{ or } b, \qquad (3)$$

$$df/d(ab) = 0. \qquad (4)$$

Substituting these values, expressions (1) and (2) reduce to the same expression:

$$ab' + a'b \qquad (5)$$

The corresponding test patterns are 10 or 01. In general form, the test vectors at node a and node b cannot be equal if either of these double stuck-at faults is to be detected. It can be shown in a similar fashion, that if node a is stuck-at-1 (or 0) and node b stuck-at-0 (or 1), the set of test sets to detect these faults is given by the expression

$$ab + a'b' \qquad (6)$$

Here, the corresponding test patterns are 00 and 11. The test vectors at node a and node b cannot be complements of each other if either of these double faults is to be detected.

The constraints dictated by Eqs. (5) and (6) apply to any double stuck-at fault test. In the remainder of this section and in subsequent discussion regarding the effectiveness of single stuck-at faults tests to detect multiple faults, test Bossen will be used as an example.

Parity tree nodes that have the same label receive identical values for all vectors in the Bossen test set. Thus, if two identically labeled nodes are both stuck-at 0 or both stuck-at 1, the multiple fault will not be detected by the Bossen test set. For the example in Fig. 1 nodes PI1, PI3, PI5, and the outputs of gates XOR5 and XOR4 are all labeled with the vector R. Since no two of the Bossen's vectors are complements of each other, all double faults such that one node is stuck-at-1 (or 0) and the other stuck-at-0 (or 1) are detected by this same test.

If the two faulty nodes are along the same sensitizing path, it can be easily shown by a similar analysis that the multiple stuck-at fault will be detected by the Bossen test set because this case reduces to the detection of single stuck-at fault at one of the nodes. For the example in Fig. 1, the multiple fault PI1 stuck-at 0 and XOR5 output stuck-at 0 will be equivalent to the single fault at the output of XOR5.

Using these results, it is possible to calculate a lower bound on the fault coverage for double stuck-at faults in parity trees. This was found to be 83.33% {Mourad 86]. Comparison of these results with those reported in [Hughes84,85], shows that the multiple stuck-at fault coverage of single stuck-at fault test sets is significantly lower for the parity tree than for the 74LS181 4-bit ALU. The next section describes the development of tests that detect all double stuck-at faults.

4 DOUBLE FAULT TEST SETS

In order to detect double stuck-at faults on identically labeled nodes, these nodes of the parity tree must be assigned different vectors. That is, the labels X and Y on any two nodes must satisfy the following two properties

$$X \neq Y \quad (7), \qquad \text{and} \qquad X \neq Y' \quad (8)$$

First, tests that guarantee 100% detection of all double stuck-at faults at the leads of the XOR gates will be developed. Then test sets Bossen and Mourad will be modified and augmented to assign different vectors at the identically labeled nodes and hence to detect all double stuck-at faults.

From expressions (5) and (6) it is clear that a test set that detects double stuck-at faults on the nodes of a single XOR gate, should include a pattern holding both inputs at the same signal {00 or 11} and another pattern holding the inputs at opposite values {10 or 01}. Thus there are four possible test sets to fully detect double stuck-at faults on the input leads of an XOR gate. In vector notation, these test sets are AB, AB', A'B and A'B', where A = {1 1} and B = {1 0}. Notice that Bossen vectors can be expressed as concatenations of these two vectors: R=B'B, S=BB and T=AA'. The 4 vectors form the group, $G(Z_2{}^2, \oplus)$, where $Z_2{}^2$ is the a 2-bit, 2-symbols (0 and 1) code.

For a 4-input tree, the vectors A and B and their complements are not sufficient to uniquely label all its internal nodes. An extra bit can be appended to each vector in an effort to discriminate among them. There are 8 3-bit vectors, of these only 4 can be used because of the constraints given by Eq. (8). Hence, it is necessary to augment the bits in the vectors to 4. All 16 4-bit vectors form a group, $G(Z_2{}^4, \oplus)$. Due to the constraint given by Eq. (8), any 8 of these vectors that form a subgroup could be used in labeling the tree. Arbitrary, vectors 0 through 7 will be used. The set of these vectors will be denoted by Z_4. In general, Z_n is used to denote the set of all labeling vectors of an n-input tree. In a similar fashion it can be shown that at least 5 bits will be needed to generate the labels for an 8-input XOR tree. In general, an n-input tree (n>2) requires at least L bits, where $L=(\log_2(n)+2)$. Note however, that if the all '0' (or all '1') vector is used, the node assigned such a vector will not be tested for single stuck-at-1 (or at-0).

Next, the assignment of the vectors to the nodes will be explained. Assuming the output of an XOR gate is labeled, then the inputs to this gate can be labeled using elements of Z_n. Now these 2 labels can be used to label the inputs of their corresponding gates. However, in selecting the labels, care should be taken in order to avoid duplicating previously used labels.

Algorithm II

```
1. Let $Z_n$ be the set of all labeling vectors.
   Assign any vector from $Z_n$ to the output of the tree.
2. Repeat until all leads are labeled:
    For every XOR gate whose output is labeled with
    a vector, say x in $Z_n$, assign to its inputs
    the 2 vectors y and z such $x=y \oplus z$ and x and
    $y \ ( \{Z_n-Z_i\}$, where $Z_i$ is the set of all labels
    that were already assigned to leads other than
    those in the same sentisising path.
3. The vectors at the primary inputs of the tree
   form the test set.
```

Algorithm II is used to generate test sets for 4-and 8-input parity trees. The tests are listed in Table 5. They guarantee 100% fault coverage for double stuck-at faults. They do not, however, guarantee the detection of all single stuck-at faults.

Table 3. Minimal tests to detect all double and some single stuck-at faults.

Pattern	4-input	8-input
#	1 2 3 4	1 2 3 4 5 6 7 8
1	1 0 0 0	1 1 1 1 1 1 0 1
2	0 1 0 0	1 0 0 1 0 0 0 1
3	0 0 0 1	0 1 0 1 1 0 0 0
4	0 0 0 0	0 1 1 0 0 0 0 1
5	- - - -	0 0 0 0 0 0 0 0
Vector	B B'A'A'	A B B A B B A'A
	A'A'A'B	A'A B'B B A'A'B'
		0 0 0 0 0 0 0 0

It is desirable to develop tests that yield high coverage for both single and double stuck-at faults. The approach is as follow: start with the Bossen test (exhaustive test for every XOR gate) or the Mourad test (detection of faults at the input leads of the gates) then augment this test in such a way that all the nodes are assigned unique vectors.

As was demonstrated earlier [Mourad 86], an n-input parity tree has at most J nodes labeled R, S or T, where J=k or k+1 and 2n-1=3k or 3k+1. Therefore, at least J distinct vectors that pairwise satisfy Eqs. (7) and (8) need to be appended to the Bossen (or the Mourad) vectors in order to distinguish between identically labeled nodes. To form the required J vectors at least $\lceil \log_2 J \rceil = \log_2(n)$ bits are needed. Hence, the minimal test that detect all single stuck-at and all double stuck-at faults on a n-input tree is $\log_2(n) + 4$.

Algorithm II is used to label the tree. Here, the vectors of the set Z_n, are formed by concatenating the Bossen's vectors and Z_2^J. Algorithm II was used to generate test sets for the 4-input and an 8-input parity trees. The test sets are listed in Tables 4 and 5.

Table 4. Tests to detect all single and double faults at the input leads of the XOR gates.

Pattern	4-input	8-input
#	1 2 3 4	1 2 3 4 5 6 7 8

	B'A A B'	A B B'B A'B'A B'
		0 1 1 1 0 0 1 1

A summary of all test sets discussed in this paper is given in Table 7. The fault type is listed in the first column. Then the number of patterns for parity trees with inputs ranging from 2 to 16 are listed in the next columns.

Table 6. Summary of all tests for the parity tree.

	Number of primary input leads			
Type of stuck-at fault	2	4	8	16
Single at pins only	3	3	3	3
Single at pins and internal	4	4	4	4
Double mainly	2	4	5	6
Double and single at pins	3	5	6	7
Double at pins and single at pins and internal nodes	4	6	7	8

5 SUMMARY AND CONCLUSIONS

This paper reports a study on the effectiveness of single stuck-at faults test sets in detecting double stuck-at faults for a parity tree, and the development of double stuck-at fault tests for this circuit. Such circuits are extensively used as code checkers in logic circuits and communication systems. The parity tree is completely tested for single stuck-at faults with a 4-pattern test [Bossen 70]. However, this test yields unacceptable fault coverages for multiple stuck-at faults. For a more practical tree size, 32-input, the coverage is 85%. The coverage is estimated to decrease with increased number of primary inputs to 83.33%.

The results reported here are significantly lower than those obtained for the 4 bit ALU [Hughes 84,85]. However, this is not surprising because the circuit is symmetric, has one output and, naturally, comprises many XOR gates.

Although single stuck fault tests appear to provide adequate multiple fault coverage for some circuits, the analysis of the parity tree demonstrates that such high fault coverage is not guaranteed for all circuits. Thus, further experimentation is needed on other circuits in order to fully evaluate the effectiveness of single stuck-at fault test sets in detecting multiple stuck-at faults.

Three test sets for double stuck-at faults are developed in this paper for parity trees. The first test set guarantees 100% detection of double stuck-at faults but misses some single stuck-at faults. The second test set fully detects single as well as double stuck-at faults but only at the input leads of the gates. Finally, The third test set detects all single stuck-at faults and double faults at the leads. Unlike the results reported in [Seth 77], the length of these test sets increases logarithmically with the number of inputs leads of th

ABSTRACT

A heuristic for guiding ATPG algorithms is presented based on a two-level view of the circuit, functional and topological. The heuristic eliminates many of the drawbacks of previous guidance measures since it reduces the number of potential conflicts that may arise due to reconvergent fanout. The procedure for calculating the guidance measure is explained and the selection rules are illustrated.

INTRODUCTION

The use of search algorithms for Automatic Test Pattern Generation (ATPG) raises questions concerning the most efficient way to organize the search to produce a test in the shortest possible time[1,2,3]. These questions are usually answered, at least in part, by some type of guidance measure, such as controllability and/or observability[2,4]. However, most of the measures used to date have been derived by a single-level algorithm which computes values based only on locally derived information such as the SCOAP measure[5]. This process is easy to program and executes rapidly, but misses many important details about the overall topology of the circuit. As we will show, the topology affects the potential for conflict in node assignments during ATPG and, therefore should be included in any heuristic measure used for ATPG guidance. First, we must look at the types of error introduced by measures based only on local information. Then we describe a two-level measure that eliminates or reduces the potential for conflict during the backdrive process of ATPG.

We assume that a search algorithm is being used for ATPG that requires choices to be made during backdrive from the fault site. This algorithm could be the D-Algorithm, PODEM, FAN, or any similar method that searches a node space until a test is found or it is determined that none exists. Whenever more than one node is a candidate for inclusion in the search tree at a given point in the process, a choice must be made. These choices can be made randomly, but the use of node weights can provide much better choices, thereby reducing the computing time required to find a test. A node weight based on controllability is often used for this purpose, usually based on the SCOAP measure. We will assume that such a measure is used, although the errors we discuss are not specific to this particular choice, but rather exist in all measures that compute new weights only from local information. This measure will be the first level in the two-level heuristic and will be called the C measure in subsequent discussions. The C measure will attempt to measure the minimum number of inputs that must be set to control a given node.

LOCAL INFORMATION ERRORS

Any weighting based on propagating local measures fails to account for the presence of multiple paths in a circuit. These multiple paths introduce dependencies in the weights that are not accounted for by the local computation process. Consider the circuit shown in Figure 1 which illustrates the computation of controllability values for a partially uncontrollable network. The process begins by assigning to each input a zero and one controllability value of 1. This is denoted by the pair of numbers separated by a slash with the zero value before the slash and the one value after it. The process then computes the controllability of every other gate in the network on the basis of the values of its inputs. Of course, only those gates whose inputs are known are current candidates for computation. Therefore, propagating the 1/1 values from input A through inverter B is done by swapping the zero and one values. However, when we attempt to compute the controllability of AND gate C, we realize that the process will cause an error. Blindly using the input values of C, we compute a controllability of 1/2, but an examination of the circuit reveals that the output of C cannot be controlled to a one at all.

CH2345-7/86/0000/0841$01.00 © 1986 IEEE

The error illustrated in Figure 1 will be called Type 1 error. This error results in a controllability figure that is overly optimisitic. The optimism is caused by the assumption that the input weights of a gate are independent. In the presence of reconvergent fanout, this assumption is not valid. Another type of error that also results from this independence assumption is illustrated in Figure 2. Once again, the controllability weights are given for the same circuit but with the inverter removed. The method will compute the controllability of C to be 1/2, and once again it is wrong since it is just as easy to control C to a one as to a zero. This type of error, which causes a pessimistic value, will be called Type 2 error.

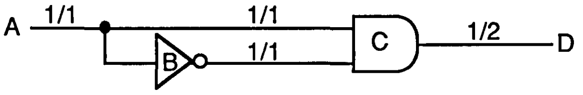

Figure 1. Type 1 Error

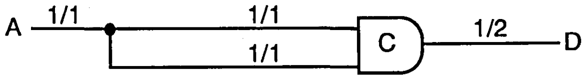

Figure 2. Type 2 Error

While the circuits used to illustrate the errors have been simplified to reveal the error in a graphic way, they are not contrived. Consider the circuit of Figure 3, which illustrates a more complex Type 1 error. The one controllability of gate L is computed to be 2, while in fact it should be 4. This error is due to the fact that the computation assumes that D can be a one and a zero at the same time. This can be seen more clearly by looking at Figure 4, which shows the assumptions made at each stage of the controllability calculation. Capital letters indicate an assumed true value for the variable while small letters indicate an assumed complemented value for the variable. As can be seen by examining the lists of assumptions at the inputs to L, both D and D-bar (d) are present. This means that along one path D was assumed to have a true value (1), while along the other path it was assumed to be false (0). Obviously, both assumptions cannot be true at the same time, and the result is a Type 1 error at L.

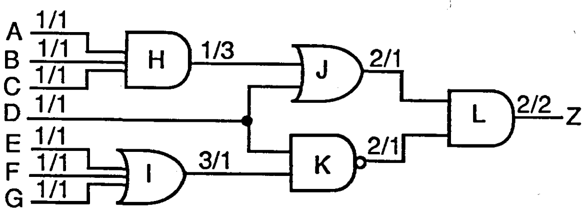

Figure 3. Non Local Type 1 Error

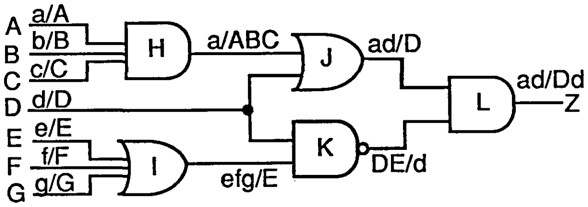

Figure 4. Controllability Assumptions

It is possible to correct for Type 1 error by a process illustrated in Figure 5. By carrying along the assumptions associated with each zero and one controllability value, Type 1 error can be detected whenever an inconsistent set of assumptions is found. In Figure 4, for example, when the one controllability of L is about to be computed, the input assumption lists are compared. Since a one at L requires a one on every input, all the input assumptions must be consistent. As we have already seen, they are not. Therefore, one or more of the input assumptions must be changed before the one controllability of L is computed. To change an assumption requires backtracking in the circuit and selecting a different assumption at a previous node. For our example this backtracking carries us to J, where it was possible to choose either D or H as the source for controlling J to one. Previously we chose D, which caused the conflict. During backtracking we will choose the other alternative, H, since it does not contain any terms that conflict with the other input assumptions of gate L at which the conflict was detected. By carrying this new choice forward to L, we resolve the conflict by controlling L to a one with H and D-bar. The conflict has been resolved and a consistent one controllability has been found for L.

This backtracking process does introduce additional complexity into the controllability computation, but, if efficiently implemented, does not consume much computer time for most circuits. In many systems, this information is at least partially available from other sources such as simulation of manually or randomly generated patterns. Since the elimination of Type 1 error is so essential to the development of a good guidance heuristic it is worth the extra computation time. It must be realized that this backtracking must be done at some point, since, if left uncorrected, the ATPG algorithm will encounter the same conflict and backtrack itself. The difference is that the ATPG may backtrack many times from the same node because of the same conflict. It is better to resolve the conflict once and for all. If we assume that every stuck-fault in the circuit is to be tested, then the ATPG must find a way to control each node to both a zero and a one at some time. It is best to find at least one way to do this in a single computation rather than resolving it over and over again during ATPG. Later, we will give some rules for selecting assumptions during the forward computation which reduce the need for backtracking and the burden of deciding which path to backtrack when a conflict is found.

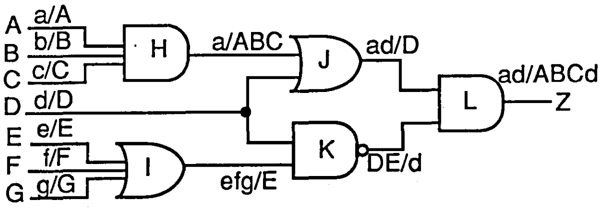

Figure 5. Correcting Type 1 Error

If we carry the assumption lists along during the controllability calculation, we can also use them to correct for certain Type 2 errors. It should be realized that Type 2 errors do not cause as much trouble for ATPG guidance as Type 1 errors, and therefore their correction is useful, but not essential. Type 2 errors result from "double counting" during the controllability calculation when the same variable appears with the same parity in more than one input assumption list. If we simply add the input controllability values the sum will include the same variable more than once, resulting in a pessimistic value for controllability. This pessimism can be partially eliminated by taking the union of the input lists and then computing its length. This value includes each variable only once due to the union operation and thereby eliminates double counting.

It should be noted, however, that this process does not eliminate all Type 2 error. It is possible for some Type 2 error to remain which we call invisible Type 2 error. This is illustrated in Figure 6. Because of the choice of K to control R to a zero, it is not possible to detect the Type 2 error that occurs at T. As can be seen, the zero controllability of T has been calculated as 2. This is clearly an error since holding L to a zero will force T to a zero regardless of the values of any other inputs. Therefore, Type 2 error exists at T which is invisible to the process set out above. This invisible Type 2 error occurred because L was not used in both path choices from L to T. If it had been, then the error would not have remained invisible. Due to the rules for selection of nodes which we will give later, it is possible for invisible Type 2 error to exist in the final result. This is not serious, however, since the presence of Type 2 error only causes slight inefficiency when used to guide an ATPG algorithm. Let us examine the ATPG's use of values containing Type 2 error to see why this is so.

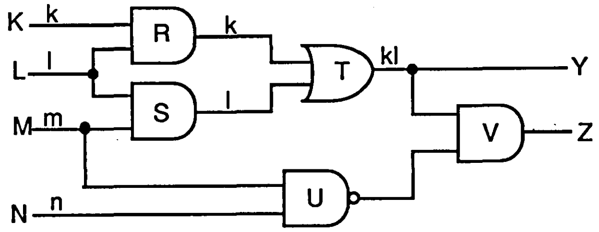

Figure 6. Invisible Type 2 Error

Once again consider the circuit of Figure 6, and assume that the ATPG is trying to set T to a zero. Since both inputs to T must be set to zero, the ATPG will establish its goal of T-0 and attempt to achieve it by trying each input path in turn. Assume that it first tries to set a zero on R. The guidance heuristic will cause it to do this by setting K-0. Since this is a primary input, the backdrive will stop and check if K-0 achieves the goal, which it does not. Therefore, assume that K-0 remains and the ATPG tries along the path from S. To set S-0, the guidance heuristic will indicate that L must be zero. Once again we have reached a primary input and the ATPG will now try to determine if K-0 and L-0 will achieve the goal. This time the goal is satisfied and a way to set T-0 has been found. If the guidance heuristic had indicated that it would be better to backdrive along S to begin with, then the goal could have been satisfied with L-0 alone. Therefore, our measure caused an extra input to be set to achieve the goal. We will return to this point later, but for now it is sufficient to note that the ATPG was not misled by the invisible Type 2 error; the value was pessimistic but still achievable. The fact that a better way existed did not cause backtracking, merely a slight loss of efficiency.

FREE LINES AND HEADLINES

The second level of the heuristic is based on an extension of the concept of free lines and headlines[3]. A free line is a node in a circuit whose predecessors are fanout free. Obviously all primary inputs are free lines. Also, the output of any gate which has only free lines as inputs is also a free line. The free lines of a circuit form trees with only one path from any primary input to any point in the tree. Looking again at Figure 3, we can see that A, B, C, D, E, F, and G are free lines. Also, since all inputs to H and I are free lines, their outputs are also free lines. The outputs of J and K are not free lines since at least one of each of their inputs is a reconvergent fanout branch.

A headline is a free line that enters a reconvergent fanout loop. Input D in Figure 3 is a headline, as are H and I. The importance of headlines can be appreciated when it is noted that outputs of a circuit can be completely characterized on the basis of the values at the headlines of the circuit. Therefore, headlines can be thought of as a reduced but complete set of independent inputs to a circuit. Each headline can be assigned an arbitrary value, independent of all the other headlines, and a complete specification of headline values will completely determine all output values of the circuit.

Since the headlines of a circuit are independent, it is possible to terminate the backdrive process of ATPG at headlines with complete confidence that the value assigned can later be justified, regardless of any other values assigned later to another headline. This can reduce the computation in ATPG significantly if the headline "covers" many inputs. Headline H in Figure 3, for example, "covers" inputs A, B, and C. Therefore, once a value has been determined for H, the backdrive process can defer work along this path, thereby saving the cost of assigning values along the input paths of H. Later, after all other tasks have been resolved by the backdrive, these values can be justified by assigning values backward from their inputs without fear of conflict. The larger the cover of a headline, the larger the savings. Unfortunately, the cover of headlines is usually small.

PSEUDO HEADLINES

It is possible to extend the concept of headlines, however, to allow for larger covers[6,7]. Consider the circuit of Figure 3 again, but assume that it is a subcircuit of a much larger circuit. If no fanout branches exist in this subcircuit other than the one shown, then it is possible to consider the output of L as a Pseudo Headline with respect to the part of the circuit driven by L, since L has all the salient properties of a headline with respect to the things it drives. Further, L covers all the inputs shown in Figure 3, a total of seven. The subtree represented by these seven inputs contains 128 possible binary input combinations. Clearly, if an ATPG algorithm is atempting to find a way to justify a goal which requires L to assume a value, and it can stop as soon as L is reached, a great deal of search time is saved. If an efficient way can be found to identify pseudo headlines it could be used to greatly improve the guidance heuristic for an ATPG. We now illustrate such a procedure.

Identifying Constrained Headlines

A process similar to the computation of the C measure mentioned earlier can be used to identify constrained headlines. To do this two pieces of information are needed: (1) which fanouts actually reconverge, and (2) with respect to which outputs do they reconverge. The calculation of the number of reconvergent branches is done by means of a backward pass to propagate output tags as illustrated in Figure 7. Each output is assigned a unique tag; these tags are then propagated backward, computing the tags of each fanin, until the primary inputs are reached. When a fanout stem is encountered the union of all the branch tags is assigned to the stem. It can be seen that this will yield a measure of the number of reconvergent branches at each fanout stem, as well as the outputs with respect to which those fanouts reconverge. Determination of these tags is called RFO analysis and is used in the calculation of the R measure which we will now describe.

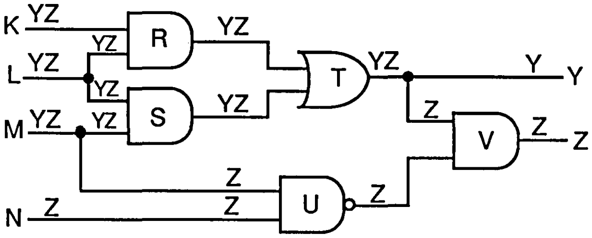

Figure 7. RFO Measure

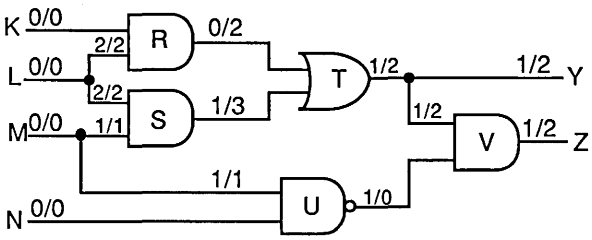

Figure 8. R Measure Computation

Once the RFO analysis is made for each fanout, it is possible to determine the R measure. This process is illustrated in Figure 8. The notation employed is similar to that used earlier where the figure before the / is the zero value and that after the / is the one value. To compute the R measure values, inputs are given an initial assignment of 0/0 instead of the 1/1 of the C measure. The same equations are used to compute the R measure of a gate as the C measure, except when fanouts are encountered. At each fanout, values are assigned to each branch based on the sum of the count on the stem plus the number of occurrences of reconvergent output tags in the pairwise intersection of the branch of interest and every other branch. This yields an approximate measure of the potential conflict that this branch will encounter downstream, and is called the R measure. For example, fanout L in Figure 8 has two branches, which contain output tags for both Y and Z. The stem count of L is 0/0 and the intersection of the branch tags contain 2 entries (See Figure 7). Therefore, each branch is assigned a 2/2 value. This results in a 0/2 value on the output of R.

In circuits with multiple outputs, the computation of the R measure requires that more attention be paid to the value assigned to a particular fanout branch. Consider fanout M in Figure 8; the value of 1/1 is assigned to each branch since only one potential conflict exists downstream, and that with respect only to output Z. This results in a 1/3 assignment to the output of S, based on its input values. The remainder of the calculation uses the same procedure as that for the C measure computation, with appropriate adjustment for the additional output values. As can be seen, the final R measure of a line is proportional to the potential conflict of that line and the number of outputs that the conflict affects.

Once the R measure has been determined for each node in the circuit, it is possible to identify headlines by simply looking for nodes during backdrive that have a 0 R-value. For example, in the circuit of Figure 8 if a value of zero is required by the ATPG backdrive at the output of gate R, the backdrive can immediately defer further work along this path since the R-zero value for that line is zero. Similarly, if backdrive wished to set the output of gate U to a one, it could defer further work since its R-one value is zero. These points in a circuit where one logic value can be independently assigned but the other logic value cannot will be called constrained headlines. In Figure 8, R is a constrained zero headline while U is a constrained one headline. This concept allows us to move the headlines further into the circuit than previous methods. After the constrained headlines have been determined we proceed to identify an additional property which we will call pseudo headlines.

Identifying Pseudo Headlines

A pseudo headline is defined to be a line that can be treated as a headline during backdrive since it can be independently assigned with respect to all other pseudo headlines. Pseudo headlines contain headlines as a subset. The determination of pseudo headlines is similar to the concept of identifying dominators in flow graphs[8,9]. A similar idea has been used to identify points of maximal reconvergence in networks[10]. Since the procedure was originally developed for single output graphs, it must be modified in our case to allow for the calculation of reconvergence with respect to each circuit primary output. The calculation is done by means of a set of counters associated with each fanout that potentially reconverges. One counter per output is used at each fanout. In the circuit of Figure 8, for example, two counters would be assigned to fanout L since two output tags appear there (See also Figure 7). One counter is for output Y and one counter is for Z. Similarly, only one counter is needed at M, since only Z is affected by M's reconvergence. This is known since the intersection of M's branch tags contains only Z. Fanout T, on the other hand needs no counters since none of its branches reconverge.

When the proper number of counters has been assigned each is initialized to the number of reconvergent branches for the particular output. A forward pass is then begun from each reconvergent fanout, in level order, to propagate fanout tags and increment/decrement the counters until the primary outputs are reached or the counters reach zero. When a subsequent fanout is encountered, the counters are incremented by the number of fanout branches less one. When a point of reconvergence is reached, the counters are decremented by the number of inputs that contain the same fanout tag. When all counters associated with a given fanout reach zero, this tag is dropped from further propagation. The gate at which a particular counter reaches zero is the point of complete reconvergence for that fanout with respect to that output. When all such counters at a node reach zero the R value for that node can be set to zero as shown in Figure 9. The propagation of the fanout tags for this process of identifying pseudo headlines is illustrated in Figure 10, and the actual counter manipulation is shown in Table 1. As can be seen, gate T is the point of complete reconvergence for L with respect to Y and Z, while gate V is the same for M with respect to Z.

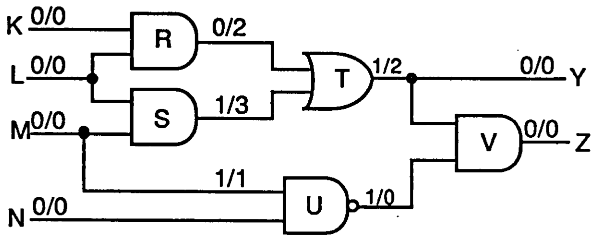

Figure 9. R Measure Adjustment

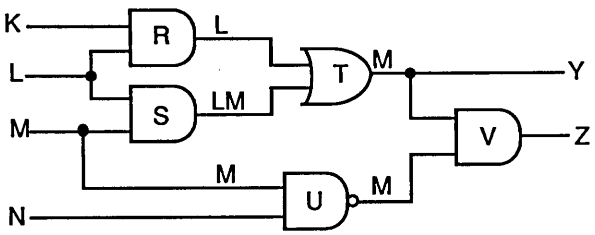

Figure 10. Fanout Tag Propagation

TABLE 1. Pseudo Headline Calculation

STEP	GATE	L-Y	L-Z	M-Z
Initialize	-	2	2	2
1	R	2	2	2
2	S	2	2	2
3	T	0	0	2
4	U	-	-	2
5	V	-	-	0

Once the points of reconvergence are found for each output it is possible to determine if a node is a pseudo headline. To be a pseudo headline requires that the node be a point of complete reconvergence for all fanouts with respect to all outputs of interest. For example, in Figure 10, if the backdrive wished to know whether gate T is a pseudo headline, it needs to know if the backdrive arrived at T along the path from Y or Z, since T is a point of complete reconvergence for all fanouts with respect to Y but not with respect to Z. Thus, T with respect to Y is a pseudo headline, while V with respect to Z is a pseudo headline. When a node is found which is a pseudo headline with respect to all outputs, its R-value can be set to 0 for both zero and one guidance since that node must be independent of all other headlines and pseudo headlines that might be encountered in backdrive with respect to any possible backdrive path.

CHOOSING ASSUMPTIONS

So far we have deferred discussion of the actual method of choosing which assumptions to propagate. Now that the C and R measures have been explained it is possible to state the rules for such choices. As we do, an attempt will be made to justify each rule on the basis of the effect on ATPG backdrive guidance. Obviously, since headlines are completely independent nodes, they should be chosen over any other node when a choice is available. Similarly, pseudo headlines that are completely reconverged with respect to all outputs are almost as good as true headlines and should be given high priority. Also, constrained headlines should be chosen if no headline is available since they are an extension of a headline or pseudo headline. But what if a pseudo headline is not completely reconverged with respect to all outputs? In this case if a pseudo headline can be found that is reconverged with respect to a particular path, then that one should be chosen. If no such pseudo headline can be found, then the pseudo headline with the fewest unreconverged outputs should be chosen on the assumption that it represents the smallest potential for conflict downstream. Finally, if ties result from the rules as given, they are resolved on the basis of the C measure.

Therefore, the priority of rules is:

1. Choose a true headline.
2. Choose a pseudo headline completely reconverged with respect to all outputs.
3. Choose a constrained headline for the value desired.
4. Choose a pseudo headline with smallest unreconverged output list.
5. Choose a node with smallest output list.
6. Choose a node with smallest C measure.

(Ties are broken on the basis of the C measure)

It should be noted that rules 1, 2 and 3 all cause a node with an R value of zero to be chosen while rule 4 chooses a node that is a pseudo headline with respect to the largest number of outputs and rule 5 chooses a node with the smallest number of reconvergent output paths. If all of these rules produce a tie, the C measure is used to break the tie by choosing the node with the smallest C measure.

RESULTS

The heuristic described has been programmed on a Symbolics 3600 in conjunction with an ATPG system using a modified version of the FAN algorithm. While the performance of a heuristic can only be truly measured over a large number of examples, preliminary results with several combinational circuits indicates significant improvement over the traditional controllability guided ATPG. The specific circuits used for this analysis include the 74181 ALU and seven of the circuits proposed at ISCAS 85 as benchmarks for ATPG. The characteristics of these example circuits are given in Table 2. The results of these experiments as well as theoretical analysis indicate that the two-level heuristic becomes more efficient as the size of the circuit grows since the depth of the search stack and thereby the number of remade decisions at each backtrack grows exponentially with circuit size.

TABLE 2. Circuit Characteristics

#	CKT	GATES	PI's	PO's	FAULTS
1	74181	63	14	8	212
2	C432	160	36	7	524
3	C499	202	41	32	758
4	C880	383	60	26	942
5	C1355	546	41	32	1574
6	C1908	880	33	25	1879
7	C3540	1669	50	22	3428
8	C7552	3512	207	108	7550

The results of using the new heuristic to guide ATPG are given in Table 3. While it should be stressed that these results are not completely representative since they represent a small sample of circuits, they are interesting. The number of backtracks is probably the better indicator of the value of the heuristic, but normalized run times on the 3600 are given for comparison as well. The run times should not be taken too literally, however, since overhead such as garbage collection and paging greatly influences these figures, while the number of backtracks is machine independent.

TABLE 3. Heuristic Performance

	C/O MEASURE		C/R MEASURE	
#	BKTRKS	TIME	BKTRKS	TIME
1	167	2.1	78	1
2	355	1.7	126	1
3	567	2.7	178	1
4	714	3.1	223	1
5	1283	3.7	327	1
6	1526	3.8	390	1
7	2774	4.1	693	1
8	6374	4.2	1613	1

AUTOMATIC INTRA-DEVICE PIN & ELEMENT REASSIGNMENT (AIDPER) ALGORITHM

Holmdel, New Jersey 07733

ABSTRACT

The completion rate of printed circuit board (PCB) routing depends on the complexity of net interconnections presented to the router. The PCB layout functions before routing, namely, partitioning and placement, and the order that they are performed help simplify this problem. We took a constructive approach, where partitioning is divided into two functions: the assignment of elements to parts before placement; and repartitioning of elements within a part (or intra-device) following placement. This paper focuses on the intra-device reassignment and it describes our AIDPER algorithm for achieving this function. The innovation here is that AIDPER ensures not only that each element within a part is reassigned to its optimum position, but also that it constraints are satisfied. The algorithm has been incorporated in the IDS Design Station, AT&T Bell Laboratories internal PCB CAD system, and accrues these benefits: emphasizes horizontal and vertical connection, forces nesting of long connections, reduces cross-overs, and increases intra-device connections. The illustrative problem presented, shows the contributions of AIDPER algorithm in simplifying interconnection problems.

1. INTRODUCTION

The ability to obtain higher completion rate of printed circuit board (PCB) routing depends on the complexity of net interconnections that are presented to the router. The PCB layout functions before routing are partitioning and placement. These functions help simplify the interconnection problem, and the order that they are done is important. At AT&T Bell Laboratories, we have taken a constructive approach in the development of these functions for our internal PCB CAD system, IDS Design Station. In the approach, we divided partitioning into two functions: the assignment of elements to part instances before placement; and repartitioning of elements to positions within a part instance (i.e., intra-device reassignment) following placement. As a result, we create synergism among element assignment, placement, and repartitioning functions.

This paper focuses on the intra-device reassignment and it describes the AIDPER algorithm developed for this function. The AIDPER algorithm consists of two assignment models: the classical linear assignment model, applied to reassign elements, and a directional assignment model, based on sorting routines, to reassign pins of an element. The innovation of AIDPER algorithm is that it accounts for the positional constraints imposed on the elements and their associated pins; and it considers the need for elements to co-exist based on the interconnection requirements.

2. BACKGROUND

Several algorithms have been developed for element (or gate) assignment[1], and[2], and for pin assignment[3],[4],[5]. It is not our intent to dissect the algorithms developed by the above authors, rather, to briefly review a couple of them, to introduce the concepts used in our AIDPER algorithm.

Leah Mory-Ranch developed a pin assignment algorithm[3] that is invoked after placement. The objective of Mory-Ranch's algorithm is to reduce the amount of wire cross-overs. It is deficient in two areas. First, the algorithm does not account for the positional constraints imposed on the elements and their associated pins. Second, Mory-Ranch's algorithm does not consider the need for elements to co-exist based on interconnection requirements.

Ikuo Nishioka et al developed a gate assignment algorithm[1] used before placement, and a pin assignment algorithm that is invoked after placement. Referring to their pin assignment algorithm, it is an application of the linear assignment model. The shortcomings of their algorithm are the same as that of Leah Mory-Ranch. In our approach (i.e., AIDPER algorithm), we not only addressed the above pin assignment shortcomings, we also reassign elements within a part.

3. AIDPER ALGORITHM

The automatic intra-device pin and element reassignment (AIDPER) algorithm is a combination of two models: element reassignment which is an application of the linear assignment algorithm, and pin reassignment that is a directional assignment model based on sorting routines. The assignment algorithm and its intricacies have been fully addressed in[6,7,8,9,10]. For a thorough understanding of the modified version of the linear assignment algorithm, let us briefly review its application to the **machine assignment problem.** This will show our departure from the classic linear assignment algorithm. Consider the assignment of m jobs (or workers) to n machines. A job $i(=1,2,\ldots,m)$ when assigned to machine $j(=1,2\ldots,n)$ incurs a cost C_{ij}. The assignment **cost matrix** shown in Table 1 provides the general cost of processing job i on machine j. The objective, then, is to assign the jobs to the machines (one job per machine) to minimize total cost.

	2	C_{21}	C_{22}	.	.	.	C_{2n}
Job	3	C_{31}	C_{32}	.	.	.	C_{3n}
	.	.	.	.	.	.	.
	.	.	.	.	.	.	.
	m	C_{m1}	C_{m2}	.	.	.	C_{mn}

Table 1: Cost Matrix

The linear assignment model is mathematically expressed as follows:

Let X_{ij} = 1, if job i is assigned to machine j
= 0, otherwise.

Objective function:

$$\textbf{minimize} \quad X_0 = \sum_{i}^{m}\sum_{j}^{n} C_{ij}X_{ij}$$

subject to:

$$\sum_{i} X_{ij} = 1, \quad j = 1,2,\ldots,n$$

$$\sum_{j} X_{ij} \leq 1, \quad i = 1,2,\ldots,m$$

$$X_{ij} = 1 \text{ or } 0$$

$$(n \geq m)$$

These constraints will assure that each machine is assigned no more than one job and all jobs will be assigned. They also require that the number of jobs not exceed the number of machines for a feasible solution.

Now consider the assignment problem in Table 2, with three jobs and three machines.

		Machine		
		1	2	3
	1	5	8	10
Job	2	6	4	9
	3	17	13	11

Table 2: Cost Matrix

The optimal dual solution is the X_{ij} path where the reduced costs entries ($\bar{C}_{ij}$) all equal zero. Our contrived example is simple with an optimum solution $C_{11} + C_{22} + C_{33} = 20$ as depicted in Table 3. However, applying the linear assignment algorithm to reassign elements and their pins within a part is not that simple. The difficulties arise in constructing the assignment **cost matrix** and in determining the **zero path** for the optimum solution. The difficulties are attributed to the positional constraints applied to the part, and its elements with their associated pins.

		Machine		
		1	2	3
	1	0	3	5
Job	2	2	0	5
	3	6	2	0

Table 3: Reduced Cost Matrix

We developed the AIDPER algorithm to emphasize the intra-device reassignment of elements and pins to achieve as many horizontal and vertical connections as possible. Long connections are forced to nest with shorter and/or assigned connections. As a result, AIDPER depends on the knowledge of the direction of each span (or edge) leaving a part. The AIDPER algorithm uses a "cellular" direction function for determining the spans' directions. Referring to Figure 1, with a part at the center (i.e., direction 9), a span will connect in one of nine directions. Note that direction '9' implies a connection within a part (i.e., intra-connection).

We developed the following mathematical expression for determining the x- and y-directions of each span leaving a part:

$$CELL_x = (X_t - X_c)\,\frac{|X_t - X_c| + 0.5\delta x}{\delta x}$$

where $CELL_x$ = cell count in x-direction

X_t = x-coord of target node

X_c = x-coord of part body center

δx = cell size (i.e., mesh) in x-direction

Note:

a) Span length = $CELL_x + CELL_y$

b) Span direction = $(X_t - X_c) + (Y_t - Y_c)$

3.1 ELEMENT REASSIGNMENT

Although the AIDPER algorithm is an applied classical linear assignment model, the development of its **cost matrix**, and the determination of the optimum assignment differ from the classical approach.

3.1.1 AIDPER Cost Matrix. The cost of reassigning element i to position j is the sum of two cost functions, namely, constraint and positional. Mathematically:

If S_{ij} = cost of spare element i in position j.

F_{ij} = cost of fixed element i in position j.

I_{ijk} = cost of connection k of element i in position j.

For example, an intra-connection between an input and an output pin of two elements, within a part, may require that the pins of these two elements be adjacent or opposite to one another. Figure 2 depicts the hierarchy and the priorities used by AIDPER to process interconnections.

Z_{ijst} = zone cost of span t, pin s, element i in position j.

The penalty for a span not being in the ideal zone (or position). Note that there are four zones, generated by dividing the region around a part, about its center, into four quadrants.

M_{ijst} = length cost span t, pin s, element i in position j.

The distance penalty of a span, determined by its cell counts.

D_{ijst} = direction cost of span t, pin s, of element i in position j.

The nine span directions (Figure 1) are weighted to penalize connections to the immediate regions that cannot be achieved in one wiring track, and/or penalize long connections that cannot nest to existing ones.

CON_{ij} = constraint cost of element i in position j.

Related, but independent to the constraint cost is the formulation of a **co-existence matrix** for specifying co-existence requirement(s) amongst elements. For example, if an input pin element y has an intra-connection to an output pin of element z, for optimum reassignment, it may be required to assign the two elements such that their pins are adjacent to one another for horizontal connection. Therefore, if element y is in position '1' then element z must be (say) in position '2' to satisfy co-existence requirement. And this data is reflected in the **co-existence matrix** accordingly.

POS_{ij} = positional cost of element i in position j.

The **cost matrix** is developed by first seeding it with the constraint costs, i.e.,

$$CON_{ij} = S_{ij} + F_{ij} + \sum_{k} I_{ijk}$$

The positional costs are then added to the **cost matrix**, i.e.,

$$POS_{ij} = \sum_{ijs} \sum_{ijt} (Z_{ijst} + M_{ijst} + D_{ijst})$$

3.1.2 AIDPER Optimum Assignment. From the **cost matrix** we have to determine the optimum reassignment of the elements by minimizing the objective function:

$$EFOM_o = \sum_{i} \sum_{j} X_{ij} \sum_{ijs} \sum_{ijt} (Z_{ijst} + M_{ijst} + D_{ijst})$$

$$+ \sum_{i} \sum_{j} (S_{ij} + F_{ij} + \sum_{k} I_{ijk}) X_{ij}$$

subject to:

$$\sum_{i} X_{ij} = 1, \quad j = 1,2,\ldots,n$$

$$\sum_{j} X_{ij} = 1, \quad i = 1,2,\ldots,m$$

$$X_{ij} = 1 \text{ or } 0$$

$$(n = m)$$

These constraints will assure that each element is assigned to one and only one position and the number of elements is equal to the number of positions.

In the classical linear assignment algorithm, the optimal dual solution is when the reduced costs of the basic variables is zero. In contrast, our algorithm applies the co-existence requirements (or *co-existence matrix*) to the reduced **cost matrix** to determine the minimum reassignment cost. The **co-existence matrix** ensures that not only should each element be reassigned to its optimum position, but also that its constraints are satisfied. This matrix is necessary to properly handle the intra-device connections; particularly, the adjacent I/O condition with no external leads continuing the net.

3.2 PIN REASSIGNMENT

The objective here is to constructively refine the interconnections associated with pins from the element reassignment. The pin reassignment model is a series of four sorting routines that results in reassigning connections to pins to reduce cross-overs, and to promote connection nesting. First, the pins are sorted based on their x-coordinates and y-coordinates for x-oriented and y-oriented parts respectively. Second, the pin connections are sorted by their direction priorities. This sort ensures that spans in directions '1' and '5' (see Figure 1) are at the extreme *LEFT* and *RIGHT* respectively. And the remaining spans' directions are between these extremes. Third, the pin connections in one direction are sorted by span length (in cell counts). This sorting routine also helps break ties in spans of the same direction. Lastly, the spans with the same direction and same span length are further sorted by the opposing pin location criterion which allows the reassignment of element pins that are in opposing sides of a part.

4. AIDPER FLOW

The AIDPER flow consists of three phases, namely, preparation, point source, and refinement. This flow helps simplify the net interconnection problem to achieve a higher percentage of final automatic routes. We will use an illustrative problem depicted in Appendix A to present AIDPER flow and its results.

4.1 PREPARATION PHASE

The preparation phase formulates the reassignment problem of interest. This involves: 1) scope definition, i.e., the entire PCB, a region of the PCB, specific parts within a region, or a single part; 2) determination of each part's relative position within a scope; 3) specification of each placed part's properties, i.e., is the part fixed, or are its terminals and/or elements fixed; and 4) determination of the order which the parts are to be processed. The part order is based on the degrees of freedom for each part and are processed most constrained to least constrained.

For our illustrative problem, we are processing a single Quad 2-Input NAND gate, with swappable elements and input pins, see Figure A-1.

4.2 POINT SOURCE PHASE

The objective of this phase is to process each part as a point source, where all the net interconnections emanating from a part are considered to be from the part's body center. The point source phase is necessary since we must assume that the element and pin assignment have been arbitrary to this stage of the layout process (i.e., element assignment assigned an element to a part instance; but not to a particular position within the part, and the placement algorithm treated the part as a point source). The flow of the point source phase is as follows:

1. Determine the spanning tree of all the nets in the realization scope.
2. Based on the order which the parts are to be processed, derived in the preparation phase, each part is processed as follows:
   - Determine the direction(s) of all the spans leaving a pin of a part. Use the "cellular" directional function described in the previous section.

     Following our illustrative problem, the direction of the spans are shown in Figure A-1.
   - Reassign the elements within a part by applying the AIDPER algorithm. Note that both the elements and their associated pins are reassigned at this stage.

     Continuing with the problem, Figure A-2a shows element assignment only, with no regard to element positional constraints and co-existence requirements. Figure A-2b depicts the advantage of AIDPER's approach.
   - Reassign the pins of an element for refinement using the pin reassignment algorithm described in the previous section.

     Figure A-3a illustrates only pin reassignment condition; without element reassignment, and no regard to positional constraints and co-existence requirements. On the other hand, Figure A-3b shows further simplification of the problem when AIDPER's pin reassignment is done in addition to element reassignment.
   - Store the results of the point source phase for use in the next phase. Note that the point source phase has reformulated the routing problem by performing a crude improvement of the interconnections.

4.3 REFINEMENT PHASE

The objective of this phase is to improve on the results of the point source phase. The refinement phase flow is similar to the point source with the following exceptions:

- The exact direction and location of each span associated with a pin is determined. As a result, we can determine whether the direction suggested at the point source phase as RIGHT is actually going to the top of the part on the RIGHT, or the bottom of the target part.

  Following our illustrative problem, Figure A-4 shows the reduced interconnection problem presented to the refinement phase with exact direction of each span. Referring to the span directions in Figure 1, using 'T' and 'B' to designate the top and bottom edges of a part; an exact span direction of (say) '5T' implies connection going to the LEFT and terminating at the TOP edge of the target part.
- The cellular size used for calculating the direction is finer.
- Recalculate the spanning tree on completion of this phase.

  Figure A-5 shows the final simplified interconnection problem that will be presented to the router.

5. FUTURE WORK

Like any system, the automatic intra-device pin and element reassignment algorithm has its limitations. Therefore, the following areas of further work surfaced during the design and implementation of the AIDPER algorithm.

1. The algorithm can only handle components such as DIPs, RES, and CAPs. Therefore, there is need to investigate how the algorithm can be extended to process surface mounted components, connectors and bus bars.
2. Finally, future work is needed for the automatic reassignment of pins and/or elements of parts considering internal connections.

6. CONCLUSIONS

A description of the algorithm used for automatic pin and element reassignment function that exists in the AT&T Bell Laboratories internal PCB CAD system, IDS Design Station, has been presented. The AIDPER algorithm provides the following benefits:

- Improves the nesting of connections, thus, promoting more row connections that is particularly beneficial when row routers are employed.
- Significantly reduces cross-over of nets, thus, reducing the number of vias for interconnections.
- Improves intra-device connections, while considering inter-device connections.

As demonstrated in Appendix A the algorithm is producing expected results and it supports the synergism among element assignment, placement, and repartitioning functions.

A Knowledge Based TDM Selection System

Xi-an Zhu and Melvin A. Breuer[1]

Department of Electrical Engineering-Systems
University of Southern California, Los Angeles, CA 90089-0781

Abstract

In designing a testable VLSI circuit, numerous testable design methodologies (TDMs) can be used, such as LSSD and BILBO. A designer is thus faced with the problem of selecting the appropriate TDM to match his goals and constraints. One way to aid the designer in this selection process is to employ a knowledge based system. In this paper we will describe a prototype of a knowledge based consultant system for TDM selection, called PLA-TSS (Programmable Logic Array TDM Selection System), which emulates a human expert in assisting a designer in selecting a suitable TDM for a given PLA and a set of requirements. Key factors affecting selection are identified. A *knowledge base* containing the TDMs for PLAs has been constructed, where TDMs are represented by frames. Based on this knowledge, *ramification analysis* is carried out, which reveals the relationship among requirements and TDM attribute values. A *score function* is defined to evaluate and compare TDMs. A dynamic selection process is controlled by *reason directed backtracking*. The principles used in PLA-TSS are also applicable to other selection problems of a similar nature.

1 Introduction

In order to solve the VLSI test problem, many testable design methodologies (TDMs) for different type of digital circuits have been developed[1, 2, 3]. As a typical example, we will mainly consider programmable logic arrays (PLAs). More than 30 TDMs for PLAs have been proposed in the last decade. An exclusive survey can be found in[4]. Note that in making a circuit testable under given design constraints, a designer often employ some well known technique for design for testability rather than create his own TDM. The ever-growing number of TDMs for PLAs introduces a new problem to PLA designers and users who want to make a PLA testable: how to select the most suitable TDM for a given PLA and application? Intensive study concerning the TDMs shows that they have multiple and conflicting attributes. The performance of TDMs vary with a PLA's parameters. No TDM is absolutely better than others in every aspect for all PLAs and requirements. Simply applying one TDM to all PLAs will sometimes result in poor designs. Therefore in order to obtain a good testable design, dynamic selection of TDMs for specific circuit and application is necessary. This kind selection problem will soon confront most digital system designers, and the genetic version of this problem can be found in everyday life.

1.1 Main factors affecting selection

Usually a selection problem involves a selector, a receiver and a selection domain.

The selector. A **selector** is an element which initiates and controls a selection. In TDM selection, the selector may be a designer or a synthesis program. The main functions of the selector are to specify a set of requirements for the selection, search for a solution in the domain, and either decide which alternative to select or end the selection process with no solution. A selector's personal preference and knowledge about the solution space greatly affects the result of selection.

The receiver. A **receiver** is the element for which the selection is made. In TDM selection the receiver is a digital circuit. A circuit influences selection because it may partially determine the goodness of the TDMs, since many attribute values of TDMs depend on a circuit's size, aspect ratio or personality.

The domain of selection. The collection of alternatives from which a choice can be made is called the *domain* D of the selection. The domain for TDM selection is a set of available TDMs. In addition to the large number of alternatives, the size of D is usually not fixed. The size of the TDM selection problem for PLAs is about 30 and increasing each year. Without being known by every selector, new TDM may be added to the domain as they are created or made available. Therefore the selector often does not have a complete knowledge of the domain.

The TDM domain is characterized by a set of attributes which include the testability characteristics, effects on the original design, requirements on test environment, and design cost. The *dimension of the solution space* refers to the number of attributes of the domain.

Let ATT $= (att_1, att_2, ..., att_n)$ be a set of attributes of the TDM domain. Every TDM can be represented in terms of the n attributes. An evaluation vector

$$TDM_i = (v_{i1}, v_{i2}, ..., v_{in})$$

can be derived for every TDM from knowledge about the domain attributes and the TDM, where v_{ij} is the value of TDM_i with respect to att_j, and each v_{ij} is either a constant or a function of the receiver's parameters. For a specific receiver, the value of each v_{ij} can be determined.

Each attribute has a *unit* of measurement, and all values for an attribute use the same unit. Most attributes have incommensurable units, hence their values are not directly comparable. Translating these attribute values into a comparable scale is an important step in making a selection.

[1] This work was supported in part by the National Science Foundation under Grand MCS-8203485, and by the Defense Advanced Research Projects Agency, and monitored by the Office of Naval Research under Contract No. N00014-84-K-0649.

CH2345-7/86/0000/0854$01.00 © 1986 IEEE

In an n-dimensional solution space, if the individual dimensions are mutually independent, a selection problem can be divided into n sub-selection problems in n unidimensional subspaces. Unfortunately, the multiple attributes often interact and conflict with each other. Thus finding a globally optimal solution becomes a hard problem.

Requirements. Requirements represent the criteria for selection in terms of the desired attribute values of the selection domain, which contain both the goals and constraints of selection. The selection process is requirement-driven. There is no reason for a TDM to be good or bad unless a requirement is specified. Since the domain is multi-dimensional, the requirements consists of multiple subrequirements, each for a subdimension. A set of requirements can be represented by a *requirement vector*

$$R = (r_1, r_2, ..., r_n),$$

where r_i is the subrequirement for the ith attribute. In practice, not all attributes need to appear explicitly in R, and a requirement may be single valued or a value range $r_j = [r_{j1}, r_{j2}]$. However in the following we will mainly consider single valued requirements.

Priorities of attributes. In general, attributes of TDMs do not have the same importance to all designers and applications. Priorities among attributes will greatly affect the result of selection. To indicate these priorities, a weight vector

$$W = (w_1, w_2, ... , w_n)$$

should be specified by the designer, where w_j is the relative weight of the jth attribute. The w_i's are non-negative numbers, and $w_i > w_j$ implies that att_i is more important than att_j. The relative value of the weights w_j's can be converted into normalized weights nw_j's using the formula

$$nw_j = \frac{w_j}{\sum_{j=1}^{n} w_j}. \qquad \text{Thus } 0 \leq nw_j \leq 1.$$

1.2 The selection problem and selection process

Given the TDM domain D, an initial requirement vector R, and a circuit C, a TDM_i is called a solution if TDM_i satisfies R. A good solution is a $TDM_i \in D$ such that TDM_i satisfies R, and for any other $TDM_j \in D$ such that TDM_j satisfies R, TDM_i is no worse than TDM_j. The precise definitions of "satisfy" and "worse" require a deep discussion, and will be given in the next section. The selection problem S can be stated as follows: select a $TDM_i \in D$ such that TDM_i satisfies R and TDM_i is a good solution for R and C. If no solution exists, adjust R until a good solution is found and as long as R remains acceptable to the selector. If no such R can be found, no solution exists.

Selection is usually not a simple straightforward task, but rather a dynamic process which involves exploring the solution space, changing goals and constraints (requirements), and backtracking. We call this a selection process. Usually the selector first specifies an initial requirement vector $R_0=(r_{01}, ...,r_{0n})$. Search in the solution space is carried out using these requirements. If a satisfactory solution is found, the selection terminates with success. Otherwise, alternative solutions (if any exists) are examined by the selector. If there is no acceptable solution and the selector wants to continue, one or more of the requirement values must be changed, and the search restarts using the new requirement vector $R_1=(r_{11}, ...,r_{1n})$. This process is repeated until a satisfactory solution is found or the selector decides to quit with no solution.

A selection process is mainly controlled by the selector and constrained by the requirements. There is no deterministic algorithm which guarantees finding the most satisfactory solution when conflicts exist. The general characteristics of a selection process are as follows.

- The result of selection is dependent on the requirements specified by the selector, the characteristics of the receiver, and the alternatives in the domain. There is usually no universal or absolutely optimal solution.

- Requirements are changeable. The initial requirements may often be too difficult to satisfy. However as we frequently experience in shopping, failing to satisfy initial requirements does not mean no selection can be made. A selector can modify the requirements until a satisfactory result is obtained. Intelligent decisions on how to change the requirements is crucial to the efficiency of a selection.

- In a multi-dimensional solution space, satisfying one requirement may invalidate another. Tradeoffs between different requirements are often necessary.

- Complete domain knowledge is required to make the best choice. However most selectors are not experts in the domain of selection. Therefore advice from expert consultants concerning the domain is often needed.

- Human factors, such as a selector's preference, are important in a selection.

These characteristics make the selection problem unique and non-trivial. It is difficult for a designer to make a good selection because of his lack of knowledge about TDMs and limited ability to handle a large amount of complicated information involved in a selection. People usually solve such problems with the help from domain experts. Unfortunately, such experts are not always available. Our goal is to build a knowledge based expert consultant system, as shown in Figure 1, which helps to solve selection problems. By introducing the consultant, the function of the selector is greatly reduced, and a better result can be expected if the knowledge based system is suitably constructed.

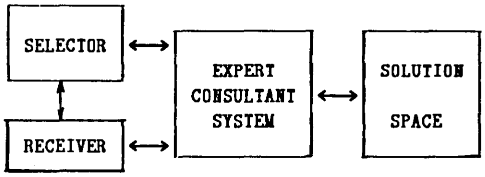

Figure 1: Selection with help of an expert consultant system

Basically, the consultant system has two kinds of knowledge.

1. **Domain specific knowledge** which includes knowledge about the attributes of the selection domain and the properties of the attributes, and knowledge about all alternatives in the domain of selection.

2. **Domain independent knowledge** such as knowledge about the art of controlling a selection process.

Domain specific knowledge is contained in a knowledge base. Domain independent knowledge is incorporated in a controller. A prototype system, PLA-TSS has been built which helps a designer to select a TDM for a PLA. In the following we will discuss the main features of PLA-TSS. In section 2 we briefly describe the knowledge base of PLA-TSS. Then in the next three sections we will elaborate on the major functions of PLA-TSS, namely how to evaluate TDMs, how to reason about the interactions among attribute values, and how to control backtracking. Finally we will give a overview of PLA-TSS.

2 The knowledge base

The knowledge base is an important part of an expert consultant system. The knowledge base should be designed in such a way that it contains all information needed for both the expert and the designer, and it is easily accessible, understandable and changeable.

The knowledge base of PLA-TSS is a knowledge repository which contains all information about the TDM domain. The main body of the knowledge base is the TDMs. It appears that TDMs are most suitably represented by frames. A frame provides a number of *slots* which contain various pieces of information concerning a TDM. The slots correspond to the generic concepts which define the domain. Every TDM in the domain can be characterized by the same set of concepts. The multi-dimensional domain of selection naturally matchs into a frame, in which each attribute corresponds to a slot in the frame, and its value is the entry in the slot which may be a constant or a function of a PLA's parameters. The TDM frame defines a general representation of a TDM. It may not be unique because slots can be organized into different hierarchies. It may not be fixed because new slots can be added to the frame. However, once a frame is defined, all TDMs should be represented in a uniform way. Each particular TDM_i defines a specific *instance* of the general TDM frame. The number of instances is not limited.

For a given PLA, the attribute values of each TDM can be determined. Thus a completely specified evaluation matrix

$$\text{EM} = \begin{array}{c} \begin{array}{ccccc} \text{att}_1 & \cdots & \text{att}_j & \cdots & \text{att}_n \end{array} \\ \left(\begin{array}{ccccc} v_{11} & \cdots & v_{1j} & \cdots & v_{1n} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ v_{i1} & \cdots & v_{ij} & \cdots & v_{in} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ v_{m1} & \cdots & v_{mj} & \cdots & v_{mn} \end{array} \right) \end{array} \begin{array}{c} \\ \text{TDM}_1 \\ \cdots \\ \text{TDM}_i \\ \cdots \\ \text{TDM}_m \end{array}$$

can be built in which rows correspond to TDMs and columns correspond to attributes. Each entry v_{ij} is the value of TDM_i which respects to att_j for the given PLA. This evaluation matrix forms the solution space for a specific selection process.

3 Evaluation functions

The general goal of TDM selection is to choose a "good" TDM for a set of given requirements and a given circuit. What is a "good" TDM? Given a set of TDMs with multiple attribute values, how does one judge which is better? To answer these questions, a function for evaluating TDMs in the solution space must be defined.

3.1 Properties of attributes

Since TDMs have multiple attributes, to compare different TDMs we must first define how to compare values for each attribute which corresponds to one subdimension in the multi-dimensional solution space. The ordering relation in each subdimension is dependent on the properties of the corresponding attribute. In the TDM domain there are several different types of attributes.

An attribute is a **simple attribute** if it only takes on single values. Non-simple attributes are called **complex attributes**, whose values are sets which may be a singleton.

A simple attribute may be either numeric or binary. A simple attribute is **numeric** if its values are in the real domain $\mathcal{R}$. Attributes which only take binary values (YES or NO) are called **logical attributes**.

A numeric attribute att_i is an **upper-bound** attribute if the requirement r_i specifies an upper bound for its value. A numeric attribute att_j is a *lower-bound* attribute if the requirement r_j specifies a lower bound for att_j's values.

The value of a logical attribute att_i may be either YES or NO. One value is stronger than the another if the former is more favorable. A logical attribute att_i is an upper-bound attribute, if for att_i YES is stronger than NO. Similarly, a logical attribute att_j is a lower-bound attribute, if for att_j NO is stronger than YES.

A complex attribute att_i is an upper-bound attribute, if, for any requirement r_i, acceptable values of att_i are all subsets of r_i. A complex attribute att_j is a lower-bound attribute, if, for any requirement r_j, acceptable values of att_j contain r_j.

3.2 The comparison function

Knowing the properties of attributes, a partial ordering relation can be defined for each subdimension of the domain which indicates how to compare any two values of the same attribute. In a selection process, another type of comparison is more important, namely the comparison between a value and a requirement for an attribute, because the real goodness of a value is relative to the requirement. A function *compare* is defined which returns the *distance* between a value v_{ij} and a requirement r_j. *Compare* is a complex function due to the fact that attributes of a domain have various properties.

Definition 1: Let R_j be a set of possible requirement values for attribute att_j, and V_j be a set of possible values of att_j which the TDMs may possess. *Compare* is a function from $R_j \times V_j \rightarrow \mathcal{R}$ defined as follows, where $\mathcal{R}$ is the domain of real numbers.

For any $r \in R_j$, $v \in V_j$ and any j,

$$\textit{compare}(r, v) = 0, \text{ if } r = \text{don't care}.$$

Otherwise,

$\textit{compare}(r, v) = r - v$, if att_j is upper bound numeric;

$\textit{compare}(r, v) = v - r$, if att_j is lower bound numeric;

If att_j is upper bound logical,

$$\textit{compare}(r, v) = \begin{cases} -1, \text{ if } r = \text{YES}, v = \text{NO}; \\ 0, \text{ if } r = v; \\ 1, \text{ if } r = \text{NO}, v = \text{YES}; \end{cases}$$

If att_j is lower bound logical,

$$\textit{compare}(r, v) = \begin{cases} -1, \text{ if } r = \text{NO}, v = \text{YES}; \\ 0, \text{ if } r = v; \\ 1, \text{ if } r = \text{YES}, v = \text{NO}; \end{cases}$$

If att_j is upper bound complex,

$$\textit{compare}(r, v) = \begin{cases} -1, \text{ if } r \cap v = \emptyset; \\ 0, \text{ if } r \cap v \subset v; \\ 1, \text{ if } r \cap v = v. \end{cases}$$

If att_j is lower bound complex,

$$\textit{compare}(r, v) = \begin{cases} -1, \text{ if } r \cap v \neq r; \\ 0, \text{ if } r = v; \\ 1, \text{ if } r \subset v. \end{cases}$$

If $compare(r_j, v_{ij}) \geq 0$, we say v_{ij} satisfies r_j. If $x < 0$, v_{ij} does not satisfy r_j. A $TDM_i = (v_{i1}, v_{i2}, ..., v_{in})$ satisfies a set of requirements $(r_1, r_2, ..., r_n)$ if for all $1 \leq j \leq n$, $compare(r_j, v_{ij}) \geq 0$.

3.3 The penalty-credit function

The *compare* function determines the distance between a requirement and a value in a subdimension of the solution space. In many cases, however, not the magnitude of the distance but the effect of the difference dictates the selection. The actual effect may not be proportional to the distance.

A selection process is not simply matching the requirements and attribute values of TDMs. The key consideration in making a selection is how much each attribute value affects the final solution. Usually, if a value v just satisfies a requirement r, it will be accepted. If v is better than r, it may be accepted with extra credits. Such credits may increase with the positive distance between v and r but saturate after some point. If v does not satisfy r, it may still be partially acceptable with some degree of penalty. However after certain point, v may become absolutely unacceptable. To describe the impact of an attribute value with respect to a requirement value, a **penalty-credit function** (PCF) should be established for every attribute.

Definition 2: Let PC_j denote the PCF for att_j. PC_j is a function from $R_j \times V_j$ to $\mathcal{R}$. $PC_j(r_j, x1) > PC_j(r_j, x2)$ if and only if x1 is a more preferable value than x2 for att_j.

Definition of PCFs are completely dependent on the selector and the application. There is no universal PCF that suits every case. However knowledge about the general forms of PCFs can be used to help designers in defining appropriate PCFs. In PLA-TSS, there are three ways for a designer to specify PCFs.

1. Define own PCFs.
2. Modify the standard PCFs.
3. Use the default PCFs.

These methods differ in how to divide the possible values into groups, and what functions are used in each group to produce the desired penalty or credit.

3.3.1 Custom-defined PCFs

The main features of a custom-designed PCF is that the value range of an attribute can be divided into any number of regions, and any meaningful function can be used in each region.

Example 1. Consider a PCF for fault models. Assume there are four fault models: a, b, c and d. If the designer wants faults in class a to be definitely detected, and prefers faults in class b and c to be detected as well, but does not care about faults in class d, the PCF for fault models can be defined as follows.

$$PC_{fm}(r, v) = \begin{cases} 40, & \text{if } \{ a, b, c \} \subseteq v; \\ 30, & \text{if } \{ a, b \} \subseteq v \text{ or } \{ a, c \} \subseteq v; \\ 20, & \text{if } a \in v; \\ -300, & \text{if } \{ b, c \} \subseteq v \text{ and } a \notin v; \\ -500, & \text{if } b \in v \text{ or } c \in v\text{, but } a \notin v; \\ -2000, & \text{if } v \text{ does not contain a or b or c.} \end{cases} \quad (1)$$

Example 2. The PCF for fault coverage can be defined as follows.

$$PC_{fc} = \begin{cases} A + compare(r,v) \times 10, & \text{if } v \geq 97; \\ A + compare(r,v) \times 20, & \text{if } v < 97. \end{cases} \quad (2)$$

Note that a custom defined PCF may be independent of the requirement, although it should imply the requirement. It may include the weight factor in it, since the value of PC(r, v) is arbitrary. This provides a way of non-linear weighting.

3.3.2 Standard PCFs

Since there is usually some commonality in most PCFs, a parameterized standard form of a PCF is defined for each type of attribute. A designer can use his own parameters to modify these standard forms. For example, let us consider numeric attributes. Assume r_j is the requirement for att_j. The designer should specify a *saturation point* (SP) and an *unacceptable point* (UP). The entire value range of att_j is then divided into five segments, namely,

1. the saturation segment consisting of values better than or equal to SP,
2. the credit segment consisting of values from r_j to SP,
3. the acceptance segment defined by r_j,
4. the penalty segment consisting of values from r_j to UP,
5. the unacceptable segment consisting of values worse than or equal to UP.

The designer can then choose the function to be used in each segment, which can be a constant or a function of r_j and values for att_j.

Example 3. Assume SP = 10 and UP = 50. Using the standard PCF for numerical attributes, a PCF for area overhead can be defined as follows.

SEGMENT	VALUE RANGE	FUNCTION USED WITHIN THE SEGMENT
SATURATE	[0, 10]	C
CREDIT	[10, r]	$A \times e^{\ln(C/A) \times compare(r,v)/compare(r,10)}$
ACCEPT	[r, r]	A
PENALTY	[r, 50]	$- [compare(r,v)]^2$
UNACCEPTABLE	> 50	D

C > A > 0, D << 0.

This function is plotted in Figure 2.

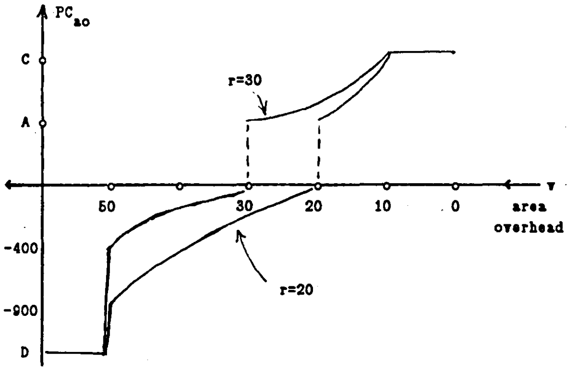

Figure 2: The PCF for area overhead.

3.3.3 Default PCFs

Being an expert consultant, default knowledge is necessary. PLA-TSS has a procedure for automatically defining default PCFs according to the user's requirements. The system defined PCFs are designed to accommodate general situations and be fair to all attributes. For numeric attributes, the default PCF is defined below, where A, B, C and D are constants and can be changed by the user or an expert. As an example the system's default PCF for the requirement "extra I/O pins is 5" is shown in Figure 3.

$$PC_j(r_j, v) = C, \text{ if } compare(r_j, v) > 0.5r_j.$$

$$PC_j(r_j, v) = A + \frac{C-A}{0.5r_j} \times compare(r_j, v),$$
$$\text{if } 0 < compare(r_j, v) \leq 0.5r_j.$$

$$PC_j(r_j, v) = A, \text{ if } compare(r_j, v) = 0.$$

$$PC_j(r_j, v) = B - \frac{B-D}{0.5r_j} \times compare(r_j, v),$$
$$\text{if } 0 > compare(r_j, v) \geq -0.5r_j.$$

$$PC_j(r_j, v) = E,\ E << 0, \text{ if } compare(r_j, v) < -0.5r_j.$$

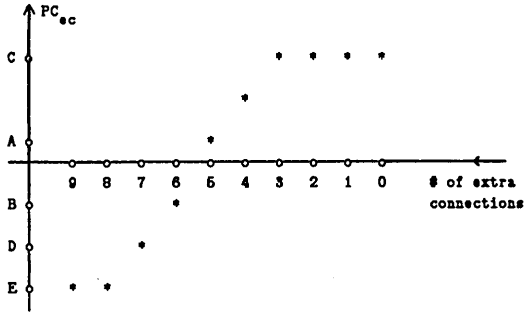

Figure 3: The PCF for extra connections

For logical attributes, there are only four combinations of requirements and values. The differences among PCFs lie in the choices for penalty or credit for each of the four cases. For complex attributes, numerous combinations exist. However they can be classified into three cases, namely a value either exceeds, satisfies or fails a requirement. The default PCFs for logical and complex attributes are defined uniformly as follows.

$PC_j(r_j, v) = D$, if $compare(r_j, v) < 0$.
$PC_j(r_j, v) = A$, if $compare(r_j, v) = 0$.
$PC_j(r_j, v) = C$, if $compare(r_j, v) > 0$.
Here A, C and D ($D < 0$) are the same as for the numeric attributes.

Example 4. The default PCF for self-testing is shown in Table 1. For this case a large credit is given to a value YES when r = NO to increase the attractiveness of self-testing even when not specified as a requirement.

Default PCFs do not imply any priorities among attributes. Priorities are specified via the weight vector. The three methods for defining PCFs provide enough capability and flexibility for a designer to conveniently specify most meaningful PCFs.

requirement	value	credit	penalty
YES	YES	A	
YES	NO		D
NO	YES	C	
NO	NO	A	

Table 1: The default PCF for self-testing

PCFs define the tightness or looseness of the requirements, and play a multiple role in making a selection.

- PCFs convert incommensurable attribute values into a common measure — the resulting penalty-credit on the final solution.

- PCFs translate attribute values of different magnitudes into a comparable scale.

- PCFs specify the fuzziness of the requirements and provide more precise information about the criteria for selection which cannot be represented by the requirements alone.

It is the combination of requirements and PCFs that completely defines the criteria for selection. It should also be noted that in defining the PCFs we assume that each PC_j can be assessed independent of other attribute values.

3.4 The score function

So far we have only considered evaluation of values in individual dimensions. In practice, a solution space is multi-dimensional. Comparisons among TDMs and between TDMs and requirements take place in multiple dimensions. A problem then is how to combine n attributes with different characteristics, meanings and units. Our solution is to first convert each of the n attribute values of a TDM into a numeric value representing the contribution of that attribute to the global solution, then combine the n unitless values into a single numeric *score* representing the overall quality of the TDM. The first problem is solved by the PCFs defined in the last subsection. The second problem is solved using a score function which should have the following properties.

1. For any two TDMs, TDM_i and TDM_k, $score(c_i) \leq score(c_k)$ if and only if $(v_{k1}, v_{k2}, ..., v_{kn})$ is more or equally preferable than $(v_{i1}, v_{i2}, ..., v_{in})$.

2. The score should reflect precedences among attributes. The attributes with higher weights make more positive or negative contribution to the total score.

3. The score should reflect tradeoffs in satisfying different requirements. Each TDM's advantages and disadvantages tend to cancel each other in the score function. The TDMs which offer more weighted credits than penalties should have higher scores.

Using the normalized weights, the PCFs and the compare function, many evaluation functions can be defined to combine multiple features of a TDM into a single score. Two score functions are used in PLA-TSS.

1. The total score is defined by the equation

$$score(TDM_i) = \sum_{j=1}^{N} PC_j(v_{ij}, r_j) \times nw_j.$$

The total score reflects tradeoffs between different features of a TDM so as to represent the overall performance of the TDM.

2. The loss score (LS) is defined by the equation

$$LS(TDM_i) = \sum_{j=1}^{N} \delta(compare(r_j v_{ij})) \times$$
$$[PC_j(v_{ij}, r_j) - PC_j(r_j, r_j)] \times nw_j,$$

where $\delta(x) = 1$ if $x < 0$, otherwise $\delta(x) = 0$.

The loss score of a TDM indicates the degree to which a TDM does not satisfy the requirements. It is the summation of the weighted negative distance between a TDM and the requirement vector. If TDM_i satisfies all requirements, $LS(TDM_i) = 0$, otherwise, $LS(TDM_i) < 0$. The larger the value of $LS(TDM_i)$, the closer the TDM is to the requirements.

These two score functions have different properties. Under the assumption that the goal of selection is to choose a TDM with the best overall performance, the total score is used to compare and rate TDMs. The total score indicates a relative ranking of TDMs. It not only helps identify the "best" TDM, but provides a broad range of choices. In case a designer wants to make a minimal change to the requirements in order to obtain a solution, the loss score will suggest the best TDM.

Example 5. Suppose there are five TDMs and five attributes as shown in Table 2. We will use the PCFs defined in Table 1, equation (1) and (2), and Figures *2* and *3*, respectively. Let A = 20, C = 30, B = -5 and D = -2000. For the given requirements shown in row "Req." of Table 3, and the relative weights given in row "R.W.", the normalized weights (N.W.) and scores are as shown. Each entry corresponding to TDM_i and att_j is the value of $PC_j(r_j, v_{ij})$. The total scores for the TDMs are listed in the last column.

	att_1	att_2	att_3	att_4	att_5
TDMs	self-testing (st)	fault model (fm)	fault coverage (fc)	area overhead (ao)	extra i/o connections (ec)
TDM1	no	{a, b}	99	0	0
TDM2	yes	{a, c}	95	35	2
TDM3	yes	{a,b,c}	100	42	4
TDM4	yes	{a, d}	98	17	7
TDM5	no	{a,b,c,d}	100	300	5

Table 2: A small fully specified evaluation matrix

	self-testing	fault model	fault coverage	area overhead	extra i/o connections	total score
Req.	yes	{a}	97	30	5	
R.W.	3	1	6	8	4	
N.W.	0.125	0.042	0.25	0.333	0.167	
TDM1	-2000	30	40	50	20	-218.75
TDM2*	20	30	-20	-25	20	-6.225
TDM3	20	40	50	-144	15	-28.767
TDM4	20	20	30	26.03	-2000	-314.49
TDM5	30	40	50	-2000	10	-646.40

Table 3: Calculation of scores [I]

These scores show that no TDM completely satisfies the requirements, though TDM2 comes closest. Now if we change the weight of fault coverage and area overhead to 9 and 5, respectively, and re-calculate the scores as shown in the Table 4 (a), the score of TDM3 becomes the largest. This means that if fault coverage is more important than area overhead, TDM3 is the best. If the constraint for extra connections is not very tight, and we change a part of the PCF for extra I/O connections to

$$PC_{ec} = - (B * compare(r,v)), \text{ if } v > 5 ,$$

then the scores are as shown in Table 4 (b). In this case, TDM4 is the best.

TDM	Total score
TDM1	-200
TDM2	-5.6
TDM3*	-4.517
TDM4	-313.996
TDM5	-390.15

(a)

TDM	Total score
TDM1	-200
TDM2	-5.6
TDM3	-4.517
TDM4*	18.334
TDM5	-390.15

(b)

Table 4: Calculation of scores [II]

This example shows how the scores change with weights, requirements and PCFs, and aids in identifying the most suitable TDMs. In general, the better a TDM satisfies a requirement vector, the higher will be its score. Scores are the main criteria used by the consultant system to evaluate a TDM, to sort the TDMs to identify potential solutions, and to select a TDM with optimal overall performance.

4 Ramification analysis

The domain of selection has multiple attributes with various relations existing among them. These interrelations cause conflicts between requirements, which then lead to failures in finding a solution. To be intelligent and efficient in selection, it is important to understand the relations among various attribute values. This is the task of ramification analysis. We developed a systematic method for finding interactions among attribute values in a given evaluation matrix. The basic concept can be illustrated by **ramification trees**.

4.1 Ramification trees

A ramification tree is a knowledge structure for representing relationships among attribute values upon which ramification analysis can be carried out.

Definition 3: Let $T = \{TDM_1, TDM_2, ...\}$ be a set of TDMs where $TDM_i=(v_{i1}, ..., v_{in})$, and (att, v) represent an attribute value pair where v is a value of att. The direct consequence of (att_j, y) on att_p is (att_p, x), if (1) all v_{ip}'s are known, (2) $y \neq$ unknown, and (3)

- att_p is logical, and $\forall$ TDM_i, $TDM_k \in \{TDM_l \mid TDM_l \in T$ and $y <= v_{lj}\}$, $v_{ip} = v_{kp} = x$.

- att_p is numeric, and $x = range\{ v_{ip} \mid TDM_i \in T$ and $y <= v_{ij}\}$, where $range\{n_1,...,n_x\} = [\min\{n_1,...,n_x\}, \max\{n_1,...,n_x\}]$.

- att_p is complex and $x = worst\{ v_{ip} \mid TDM_i \in T$ and $y <= v_{ij}\}$.

Here for numeric and complex attributes x "<=" y if *compare*(x,y) $\geq$ 0, while for logical attributes, "<=" stands for "=". Otherwise, the direct consequence of (att_j, y) on att_p is $(att_p$, unknown).

Definition 4: Given a set of attributes $ATT = \{att_1, ..., att_n\}$ and a set of TDMs T. A ramification bush (R-bush) for an attribute att_j, denoted by $RB(att_j)$, is a two level directed tree in which

- there is a root node att_j which points to all internal nodes;

- there are t $(1 < t \leq k)$ internal nodes labeled (att_j, v_i), for $1 \leq i \leq k$, where k is the number of different known values $v_1, ..., v_k$ which att_j can take, i.e., $\forall\, 1 \leq l \leq k$, $v_l = v_{ij}$ for some $TDM_i \in T$;

- each internal node of the R-bush links to at most n leaf nodes corresponding to the n attributes in ATT;

- each leaf node connecting to an internal node (att_j, v_i) is labeled (att_p, x_{ip}), where (att_p, x_{ip}) is the direct consequence of (att_j, v_i) on att_p. In particular, (att_j, x_{ij}) is a leaf node if and only if $x_{ij} \neq v_i$.

Example 6. For the evaluation matrix in Table 2, the complete R-bush for self-testing is given in Figure 4. The leaf nodes represent the direct consequences of the possible values of self-testing on other attributes.

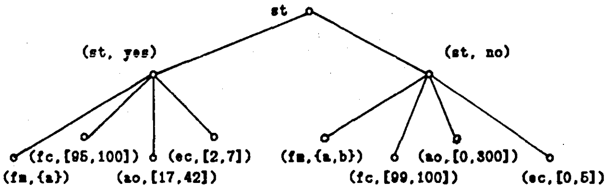

Figure 4: The complete R-bush for self-testing

Definition 5: A conditional R-bush RB(att_j, v) is an incomplete R-bush for att_j which only contains one internal node (att_j, v).

Definition 6: Let RB_1(att_j, v_1), ..., RB_t(att_j, v_t) be distinct conditional R-bushes for att_j. The union of RB_1, ..., RB_t is the R-bush for att_j, which has t internal nodes (att_j, v_1), ..., (att_j, v_t).

Conditional R-bushes are very useful when one is only interested in a particular value of an attribute. A complete R-bush is the union of all conditional R-bushes for the same attribute. Each internal node of an R-bush defines a *branch* of the R-bush. For the R-bush shown in Figure 4, the conditional R-bush RB(st, no) is the right branch of the R-bush defined by the internal node (st, no).

A ramification bush indicates the impact of one attribute's value on others. Individual R-bushes for different attributes can be concatenated together into a *ramification tree* (R-tree) to show the ramification of multiple attribute values on remaining attribute values.

Example 7. Again consider Table 2. Suppose we start with the attribute self-testing (st). Initially the R-tree is the complete R-bush for st as shown in Figure 4. Since the complete R-tree is large, we only expand one branch of the R-tree. First expand the leaf node (fc,[95,100]) under (st,yes) in the left branch. Since under the condition that st = yes, fc has only three possible values 95, 98 and 100, we replace the leaf node (fc,[95,100]) in Figure 4 by a 3-branch R-bush RB = RB(fc,95) ∪ RB(fc,98) ∪ RB(fc,100) which is for the TDM set T1 = {TDM2, TDM3, TDM4} (since only these three TDM satisfies st = YES) and the attribute set {fm, fc, ao, ec} since st has been considered. In the similar way, we continue to expand the leaf node for ec under (fc,98) until no more expansion is possible along alone that branch of the R-tree. A fully expanded branch of the R-tree is shown in Figure 5.

Definition 7: A *stage* of an R-tree is a two-level subtree of the R-tree which forms an R-bush. A *branch* of an R-tree is a subtree of the R-tree that (1) contains the root, (2) consists of no more than one branch of the R-bushes from each stage, and (3) has leaves all of which are leaf nodes of the R-tree.

Every branch of a static R-tree defines a set of consistent requirements. A completely specified requirement vector R = (r_1,..., r_n) can be satisfied if there exists a branch in which there is no node (att_j, x_j) such that x_j does not satisfy r_j, for $1 \leq j \leq n$.

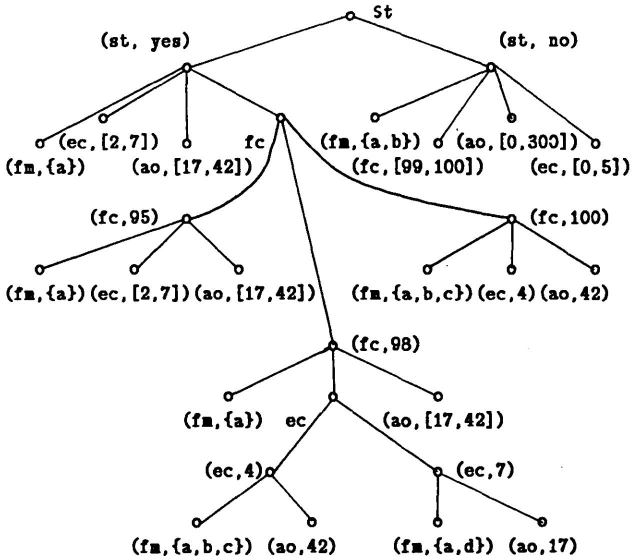

Figure 5: A static R-tree

Static R-trees provide information concerning possible combinations of feasible requirements. In a real selection process, however, only one requirement vector is active at a time, and most parts of the complete R-tree may never be accessed, therefore there is no need to generate a complete R-tree. To represent the useful relations among attribute values in a dynamic selection process, dynamic ramification trees are defined.

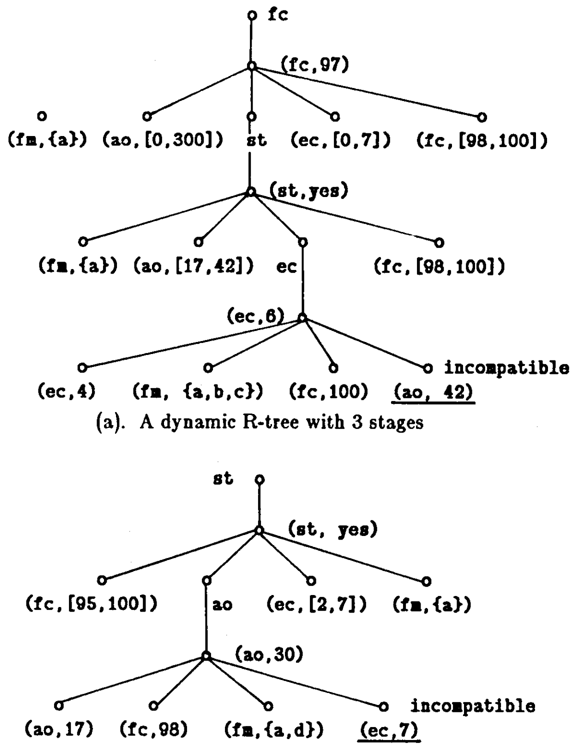
Definition 8: A dynamic R-bush (DRB) for a requirement r_j, is an R-tree having only one internal node (att_j, r_j).

A dynamic ramification tree (DRT) corresponding to a requirement vector R=(r_1, ..., r_n) is a single-branch R-tree consisting of a cascade of DRBs in which internal nodes are in the set {(att_1, r_1), ..., (att_n, r_n)}.

Definition 9: A set of requirements is consistent if there exists a TDM which satisfies it, otherwise the requirements are inconsistent.

Example 8. Consider the evaluation matrix in Table 2. Let the requirement vector be (st, fm, fc, ao, ec) = (yes, {a}, 97, 30, 6). Two different dynamic R-trees are shown in Figure 6. The first stage of the dynamic R-tree in (a) corresponds to a dynamic R-bush DRB(fc, 97). At the third stage the R-tree has a node (ao, 42) which implies that if the requirements fc=97, st=yes and ec=6 are satisfied, area overhead must be 42%. This, however, is incompatible with the requirement ao=30. Both R-trees contain incompatible nodes, since this set of requirements is inconsistent.

The size of a dynamic R-tree is a function of the order in which attributes are selected. Heuristics can be employed to generate dynamic R-trees having different attributes. For example, if satisfying some requirements is important, one can sort the attributes by their weights, and then expand the R-tree using the sorted attribute order. Thus the ramifications of the more important requirements will be processed first, and the less important requirements may be adjusted using the information from the dynamic R-tree. Several procedures for constructing various R-trees for any given evaluation matrix have been defined[4]. Next, we will discuss some applications of ramification trees.



(a). A dynamic R-tree with 3 stages

(b). A dynamic R-tree with 2 stages

Figure 6: Two dynamic R-trees for a requirement vector

4.2 Ramification analysis

One problem in a selection process is that the consequences of the various requirements are not obvious, hence it is difficult to avoid inconsistent requirements or to determine the best way for making tradeoffs. Ramification analysis is aimed at revealing relationships among different attribute values and helping a selector in specifying and changing requirements.

To test if the values in a requirement vector $R = (r_1, r_2, ..., r_n)$ are consistent, a dynamic R-tree based on R can be built. For a domain of n attributes, an R-tree has at most n stages. There may be up to N! different dynamic R-trees for the same requirement vector, each corresponding to a permutation of the n attributes. An important question is: in order to detect consistencies among a set of requirements, does it matter which R-tree is generated? To answer this question, we present the following theorems. Proof for these theorems can be found in[4].

Theorem 10: Any dynamic R-tree DRT(R,T) contains incompatible node(s) or is empty if and only if the requirement vector R is inconsistent for the set of TDMs T.

Definition 11: Let Level[*node*] equal the length of the path from the *node* to the root in an R-tree DRT. Let SN be the set of nodes in the DRT. A node (att_j, x_j) in a DRT is an essential node if

$$\text{Level}[(att_j, x_j)] = \max\{ \text{Level}[(att_j, x)] \mid (att_j,x) \in SN \}.$$

Definition 12: Let EN1 and EN2 be the set of essential nodes for DRT1 and DRT2, respectively. DRT1 and DRT2 are said to be equivalent if EN1 = EN2.

Theorem 13: If $R = (r_1, r_2, ..., r_n)$ is a consistent requirement vector, all dynamic R-trees DRT(R,C,A) are equivalent.

The above theorems indicate that although there are many dynamic R-trees for the same requirement vector, TDM set and attribute set, it is sufficient to generate only one of the R-trees in order to detect inconsistency among requirements. If the R-tree has "incompatible" nodes, then these requirements are inconsistent, otherwise they are consistent. The ramifications of a requirement vector $R = (r_1, r_2, ..., r_n)$ can be specified by the set of essential nodes of a dynamic R-tree. When requirements are inconsistent, tradeoffs have to be made in order to obtain a solution.

Ramification trees can also be used to predict the consequences of changing requirements, and to aid in incremental requirement specification, i.e. starting from the most important attribute and trying to infer as many other implied requirements as possible. In this way, some requirements can be automatically defined, inconsistency among requirements can be detected while the requirements are specified, and a set of totally qualified TDMs are found at the end of requirement specification, if any exists.

5 Reason directed backtracking

Selection is a process which often requires backtracking. In a selection process, failures are usually caused by one or more components of the requirement vector. Backtracking always involves modifying requirements. There are two primary kinds of failures:

1. **search failure**: no solution is found in a search,
2. **confirmation failure**: a solution is rejected by the designer.

Example 9. Consider the evaluation matrix in Table 2. If the requirements are (st, fm, fc, ao, ec) = (yes, {a}, 97, 30, 6), no TDM is completely satisfied. Let

$$\text{FAIL}(\text{TDM}_i) = \{ (att_j, v_{ij}) \mid \text{TDM}_i \text{ fails to satisfy } r_j \}.$$

The FAIL lists associated with the five TDMs are shown in Table 5.

TDM	FAIL(TDM$_i$)
TDM1	(self-testing, no)
TDM2	(area overhead, 35), (fault coverage, 95)
TDM3	(area overhead, 42)
TDM4	(extra connections, 7)
TDM5	(self-testing, no), (area overhead, 300)

Table 5: The FAIL lists

Each row in Table 5 represents a reason for failure. For example, the third row indicates that the requirement for area overhead is too high. If it is changed to 42, TDM3 will be a solution. The fourth row implies that the requirement for extra connections causes the failure. If one more extra connection is possible, TDM4 will be a solution. However the first row suggests that if self-testing is not required, TDM1 will be a solution without increasing the requirements on area overhead or extra I/O connections.

This example shows that there usually many reasons for a failure, and there are many ways to revise requirements. It is necessary to identify the most critical reason for failure, and find out how to backtrack such that a good solution can be found. In PLA-TSS, **reason analysis** is used to classify failures into a few categories and then identify the most critical failure category containing the current failure mode. For each failure category there is a pre-defined *remedy*. Once the main reason for a failure is understood, the system informs the designer of the reason, suggests possible ways to recover from the failure, then restarts a search process if the designer accepts the advice and/or adjusts the requirement values. We call this control structure *reason directed backtracking*. To demonstrate this method, we will show how search failures are handled next.

5.1 Reason analysis for search failures

A search failure occurs when no TDM completely satisfies a requirement vector R. Since TDM attribute values are fixed for a given circuit, the only way to resolve a search failure is to change R such that a solution can be obtained. How to change R depends on why the failure occurred.

Five classes of search failures are defined, namely three types of critical conflicts, a single conflict and multiple conflicts. There is a specific way for resolving each class of failure.

Critical Conflicts

1. First class critical conflict: There is a requirement r_j that no TDM can satisfy.

Remedy: When such a critical conflict occurs, the only way to continue the selection process is to relax the corresponding requirement to below the best value for att_j. The system will request that the designer modify the critical requirements shown in a conflict table, and then restart the search process. If the designer does not change the requirements, the selection process ends with no solution.

2. Second class critical conflict: There is a requirement r_j such that no TDMs which are close to the requirements can satisfy it.

Given a circuit and a requirement vector R, the TDMs can be divided into the two sets

$T1 = \{ TDM_i \mid score(TDM_i) > L \}$, and

$T2 = \{ TDM_k \mid score(TDM_k) \leq L \}$,

where L is a preset lower bound for TDM scores. T1 contains TDMs which we refer to as being relatively close to R, and therefore is referred to as the set of potential solutions. When T1 is not empty, a TDM will most probably be chosen from within T1, and TDMs in T2 are very unlikely to be selected unless some requirements are significantly changed. The difference between first and second class critical conflicts is that the critical requirement r_j can not be satisfied by any TDM in T1, although it can be met by some TDMs in T2.

Remedy: In this case, there are two ways to solve the problem. First, relax the requirement on att_j to below the best value in $\{v_{ij} \mid TDM_i \in T1\}$, such that it can be satisfied by some TDMs in T1 and a solution may be found. Secondly, change other requirements such that some TDMs in T2 which satisfy r_j will become close to the new requirements. However, since all TDMs in T2 have poor scores, any such TDM which satisfies r_j must have some very bad or unacceptable value in at least one attribute other than att_j. Comparing these two choices, the second one requires radical changes in order to lead to a solution, while the first one may only involve small changes. The system will inform the user of these two ways of changing requirements, and suggest the user change r_j.

3. Third class critical conflict: No TDM is close to R.

Remedy: This is the case where every TDM has a very bad score. Major changes to some requirements are necessary, and these may involve changing an unacceptable value to an acceptable one. The system first determines the necessary changes which have to be made, and then suggests the easiest change in order to obtain a solution using information from reason analysis and the scores.

Single conflict: There exists a TDM which meets all but one requirement.

Remedy: If a single conflict occurs, a solution can be obtained by changing a single r_j. In this case, a conflict table is displayed which shows which TDM fails which requirement. The designer is advised that if he is willing to change the value of a requirement to the extent shown in the table, a solution is obtained. If several single conflicts occur simultaneously, the system can suggest which change leads to the best solution. Since the designer can see how close he is to a solution, he may decide which requirement to change or which TDM to choose.

Multiple conflict: A TDM fails to satisfy at least two requirements.

Remedy: If a multiple conflict occurs, many alternatives exist, especially when all TDMs have multiple conflicts. The designer is informed that tradeoffs must be made among the various attributes. A conflict table is presented which informs the designer as to what conflicts exist. Several TDMs with high scores are suggested as possible solutions. Advice about the most beneficial tradeoffs is given, which is based on the TDM scores. The designer can select a TDM, or ask the system to select the best one, or change some requirements and let the system search again.

5.1.1 Ordering of failure classes

It is not enough to only classify failures, because several classes of failures may be present at the same time and the failure classes may not be disjoint. Precedences among failure classes must be defined such that an intelligent decision about which failure to solve first can be automatically made. In PLA-TSS, the search failures are ordered and processed according to the following rules.

1. Critical failures are dealt with first. Among them, the precedence is first class critical conflicts, followed by the second class, and finally third class.

2. If there are no critical failures, single failures are handled before multiple failures. But if the failure class associated with the best (highest score) TDM is a multiple failure, it is treated together with single failures, since such a multiple failure may lead to a minimal degree of changes.

Example 10. Consider the evaluation matrix in Table 2 and the requirements and weights specified in Table 3 and the PCFs used at the beginning of Example 5. In searching for a solution, four single failures and a multiple failure occur simultaneously. After reason analysis, the system will inform the user that he may change a single requirement on area overhead from 30 to 42 in order to obtain a solution. However if he can lower the requirement on fault coverage a little bit from 97 to 95 and relax the requirement on area overhaed from 30 to 35, the best solution can be obtained. At this point it is up to the user to decide which way to go.

The prototype PLA-TSS has demonstrated that reason analysis directed backtracking is a suitable control strategy for the selection process. This is because a selection process is often failure-driven. Actions to take depend on what kind of failure has been encountered. Reason analysis, combined with scores and ramification analysis, provides intelligent information on where and how to backtrack after a failure has occurred, and thus lead to a efficient selection process.

6 PLA-TSS overview

The basic structure of PLA-TSS is given in Figure 7.

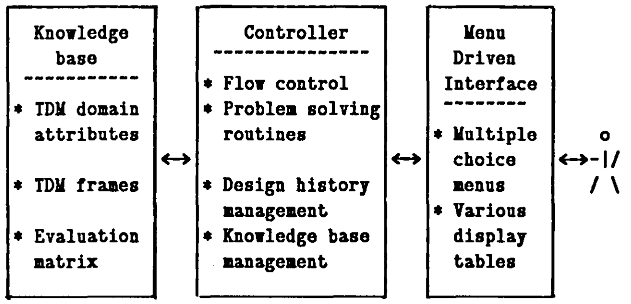


Figure 7: Overview of PLA-TSS

The knowledge base

An important part of PLA-TSS is a knowledge base which contains information about the domain of TDMs. To insure changeability and expandability, the knowledge base is separated from the controller, and is relatively static. TDMs are represented by TDM frames. Currently, there are fifteen TDMs in the knowledge base. New TDMs or attributes can be readily added to the knowledge base without changing the program.

The controller

The controller of PLA-TSS gets information from the knowledge base, reasons with this knowledge, and interfaces with the user. It has four basic functions.

1. Control a dynamic selection process. The controller is responsible for determining when to do what. The basic control flow is shown in Figure 8.

2. Make a selection. To simulate a human expert, the controller embodies the knowledge about the art of selection in a set of problem solving procedures, such as ramification analysis, search routines, and the comparison, PC and score functions for evaluating TDMs. These procedures are called at the appropriate time to allow the system to make a good decision or give intelligent suggestions.

3. Keep track of design data and history. In order to allow backtracking in a selection process, the controller keeps a record of the entire design history. A history consists of a sequence of states in a selection process. Each state is represented by the values of global variables. At every decision point or when the system state is changed, the old state is recorded so that a designer can trace back (review) or back up to any earlier state and undo some actions.

4. Manage the knowledge base. Tools are provided for maintaining the knowledge base, such as changing information, reviewing the contents of the knowledge base, deleting information or acquiring new TDMs.

The interface

An important feature of PLA-TSS is that the consultant system and the designer act at the same functional level, i.e., the control of the selection process may switch between the two parties. This feature implies that the control flow in a selection process cannot be unidirectional. To implement such a system, PLA-TSS uses a combination of sequential control, reason directed control and multiple branching. Interaction between a designer and the system is through status report plus menu driven interface. Many different tables are used to display system states in various situations. Menus with multiple choices are shown which allow a designer to select his most preferable actions.

7 Conclusion

In this paper we described a knowledge based system for TDM selection. Such a system contain two kinds of knowledge, namely knowledge about the alternatives to be selected and knowledge about how to make a selection. In our prototype system PLA-TSS, the domain specific knowledge is represented by frames, and the domain independent knowledge is represented by procedures. By loading in different domain specific information into the knowledge base, the same scheme can be used to select TDMs for other circuits, or select other objects for different purposes. PLA-TSS is implemented in LISP and runs on a TOPS-20 machine. This research shows that requirement constrained selection is a good field for applying knowledge based systems, because extensive knowledge and heuristic reasoning, which often fall beyond the capability of human selectors, are required to make a good selection.

Deriving Module Interconnectivity from Behavioral Specifications, and Coupling a VLSI Layout Editor for Error-free Routing

Ganesh C. Gopalakrishnan, Nai Chi Lee, David R. Smith, and Mandayam K. Srivas

Department of Computer Science, State University of New York, Stony Brook,
NY, U.S.A.

ABSTRACT

The problem of inconsistencies among multiple, and independently originated manual specifications is a serious one in VLSI design. This paper proposes an integrated VLSI design system that solves this problem.

High-level behavioral specification is the major source of design information in our system. We can infer from it many pieces of information needed for low-level tools, including module interconnectivity ("netlist") information for layout routing. All manual input will be checked against the derived information.

In this paper, we outline an algorithm to infer module interconnectivity among the submodules of a module from (a) the behavioral specifications of the module, and (b) knowledge of the names of the ports used by submodule-operations. We also describe a VLSI layout editor that is driven by the automatically generated netlist.

1 Introduction

Most current VLSI design methodologies are "tool-kit" based. Human designers are required to provide inputs to the individual tools separately. The problem with this approach is that independently originated manual specifications can have inconsistencies among them. For instance, using layout editors such as [SMHO85] and [MCN], users can inadvertently create layouts that would behave quite differently from the original high-level behavior specifications. Although complete design automation using a "silicon compiler" seems to be the long-term solution, we don't have any practically viable tool of that nature yet.

With the tool-kit based approach, the above-mentioned errors would get discovered only very late during the design. Inconsistencies may even remain undetected because extensive (or exhaustive) simulation may be unacceptably expensive.

We argue that all the activities of designing a circuit module ought to stem from one high level specification written for it. In order to do this, the traditional role of high-level specification languages must be extended beyond design documentation and high-level simulation to include the roles of (i) automatic control synthesis, (ii) providing information for low-level simulation tools, (iii) providing module interconnectivity information for layout tools, etc. More importantly, the high-level specification language itself ought to be designed with formal verification of design correctness and extraction of information for low-level tools in mind. Unfortunately, most of today's high-level specification languages do not meet these objectives.

We have designed a high-level specification language with these objectives in mind. Our language (called "Structure and Behavior Language" (SBL)) supports viewing hardware modules as *abstract data types* [GH78,GTW78]. Modules are specified in a purely applicative language. SBL supports the formal verification of high-level specifications, and high-level simulation. In addition, we have developed algorithms for extracting information from SBL specifications and passing it on to low-level tools that perform controller synthesis and chip layout. In future, a switch-level simulator will also be driven (in part) by the information generated from SBL.

In this paper, we present an algorithm to infer module interconnectivity and module hierarchy from behavioral specifications. We also describe a VLSI layout editor that is guided by the human designer, and that verifies the actions of the designer against the automatically generated hierarchy and interconnectivity information. In addition, our system operates hierarchically. This means several things:

- Behavioral specifications are written and verified hierarchically;
- Module interconnectivity is generated hierarchically;
- Routing is performed hierarchically.

With these provisions, we hope to demonstrate a design system that guarantees correctness of both behavior and layout, as well as performing the complex task of routing efficiently, by operating hierarchically.

Figure 1 illustrates our design approach. Assume that a module M is to be designed. Two specifications are writ-

CH2345-7/86/0000/0864$01.00© 1986 IEEE

ten for it: (a) An *abstract* specification, that specifies the desired behavior of M without assuming anything about its implementation; (b) A *realization* specification that specifies the submodules (M_1 and M_2 in this case) and an algorithm to implement the operations of M using the operations supported by M_1 and M_2. All the interconnections needed to support the algorithm of the realization specification in hardware—specifically, all the wires needed to support all the data movements between M_1 and M_2—will be automatically generated by the parser of the realization specification. (The boxes labeled 'C_x' are controllers. In our system, these controllers will also be derived automatically from realization specifications. Once synthesized, the controllers are similar to the other modules as far as routing goes.)

The main advantages of this approach are the following. Assuming that M_1 and M_2 are correct, the structural correctness of M depends only on the realization specification of M. (We have shown in [GSS86] how a realization specification may be shown with respect to an abstract specification. Once we show a realization specification to be correct, it can be used as a basis for deriving the interconnections among M_1 and M_2.

For example, consider a FIFO module. The abstract specification of the FIFO (not shown) specifies the invariants to be satisfied by any implementation of the FIFO. Figure 2 shows the realization architecture and the algorithms to implement the submodule operations, chosen by the designer. The realization specification will be verified against the abstract specification.

In our approach to designing VLSI systems, we would refine a module's specification enough times so that the leaf modules of the hierarchy are present in a module library, or are simple enough to be built outside our framework. It is using these library modules that the circuit of M is constructed. The actual routing would be carried out bottom-up in the hierarchy.

Details of our research have been reported in [GSS85,GSS86]

Organization

The algorithm to infer module connectivity will be illustrated on a simple example. The human-interface to the layout editor is then explained. Finally, we present our concluding remarks.

2 The Connectivity Inference Algorithm

We illustrate the connectivity inference algorithm with the aid of a simple example—that of the implementation of a First In First Out (FIFO) queue. Explanation will be simplified, and made at a high level, with emphasis only on the port and interconnection related details.

The FIFO supports three operations:

1. `ins`, which enqueues a data item coming in via input-port `FIFO.?d` (input port `?d` of module FIFO) and creates a new queue state (line 10);
2. `rem`, which removes the front element and returns a new queue state (line 13);
3. `front`, which reads the front element and brings it out via port `FIFO.!d` (line 14).

We will study the implementation of the `ins` operation, and derive a netlist for it. The implementation uses the submodule memory `MEM` as a circular buffer into which two pointers (contents of `WC` and `RC`) point, indicating the location to be next written (when items are inserted into the FIFO) and the location to be next read (when the front of FIFO is to be examined). The unit `SB` is a status block which (i) records whether the last operation performed on the fifo was *ins* or *rem*; (ii) compares the outputs of `RC` and `WC`; if these are equal, it sets status output `!full` to true if the last operation performed was *ins*, and `!empty` to true if the last operation performed was *rem*.

The meaning of *ins* as declared on lines 10 and 11 may be understood as follows:

> Given a state $<< M, R, W, S >>$ (a tuple of the states of the submodules) of the FIFO and given a value *val* to be inserted, the *ins* operation creates a new state of the FIFO in which:
>
> - The memory's state has advanced to one in which *val* has been written into it, at an address obtained by reading the write counter W.
> - The state of W advances to $up(W)$.
> - The state of R is unaffected.
> - Information regarding the last operation is recorded in the status block.

Port-Operation Association

The key feature of SBL is that each module is characterized solely via its operations. This means the following:[1]

- The operations ("services") provided by a module are captured by associating one operation for each service. In the present example, `ins`, `rem` and `front` are some of the operations provided by the FIFO;
- The ports used by module operations for data I/O are associated with the operations.

For example, the `ins` operation will have two pieces of information associated with it:

[1] Timing characteristics are also associated with module operations

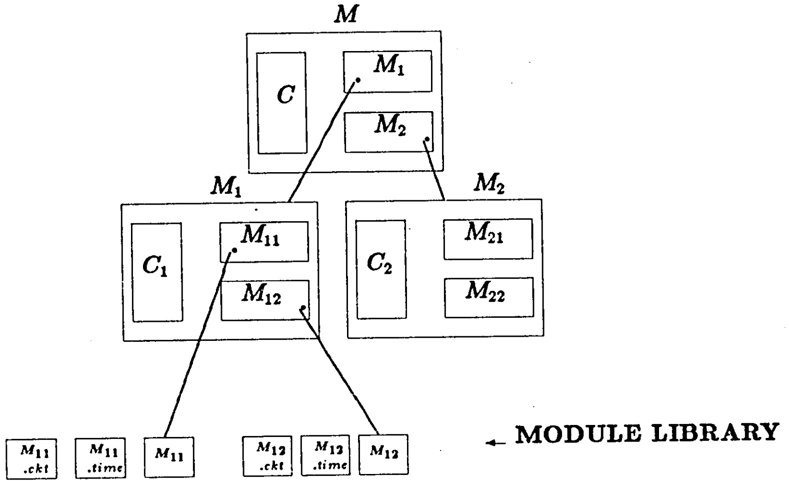

Figure 1: Hierarchical Design of Controllers and Datapaths

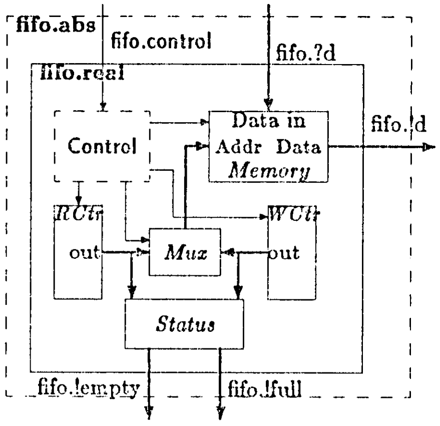

```

Figure 3: Port-Operation Association for the Submodules of FIFO

- The way it is implemented: This is as given on line 11 of figure 2;
- The port(s), and the type or the port(s) that it uses: This information will be specified in the abstract specification of the FIFO, as shown below:

```
PORT
 ?d : ARRAY [8] OF BIT
OPERATION
 ins : FIFO, ?d ==> FIFO
```

  In this example, we assert that the port ?d of FIFO carries items of type ARRAY [8] of BIT, and further, the operation ins is associated with the physical module FIFO, and that it consumes a data item through the physical port ?d of FIFO and returns a new FIFO state.

In general, the type of a port such as ?d would depend on the *size-parameters* of a module. For example, the size parameters of FIFO are datasize and capacity (figure 2, line 1). This helps us to *resize* an entire realization by changing the value of one or more size-parameters and deriving a new netlist.

We now list the port-operation association for the operations of all the submodules used in FIFO (figure 3). This will be the basis for the connectivity inference algorithm presented in the next section.

Connectivity inference for ins

The connectivity inference will be demonstrated for the expression on line 11 of figure 2, consulting figure 3 in the process.

Let us consider the subexpression `write(M, selw(MUX, read(W)))` . This expression uses specific instances of modules (the instantiation done on line 4, for example, says that MEM is a module that is of type mem tailored for sizes addrsize and datasize). We can convert the subexpression being considered into one in which the types of the modules (and not instances) are used. Doing so gives us the subexpression `write(mem, selw(mux21, read(ctr)))`

At this point, we can consult figure 3 and start deducing connectivity. For instance, the expression read(ctr) produces its result on port W.!o. This expression forms the argument to operation selw on module mux21, which expects its input to come via port mux21.?w. At this point we do the following:

- Check that the type of the port W.!o matches that of port MUX.?w; in this example, both of them are of type "addr-type", and hence the types agree;
- Infer that port W.!o must be connected to port MUX.?w

In a similar fashion, we can infer the entire connectivity of FIFO as illustrated in the schematic shown in figure 2.

Notes:

1. The user can (for documentation purposes) provide connectivity assertions in a realization specification by providing "CONNECT" declarations. These will be checked against the inferred connectivity, and only if these agree will the user-given connectivity be used for routing.

2. The "CONNECT" construct also gives the user a facility to introduce sharings of busses—for instance, ports SM1.!o and SM2.!o of two submodules can be attached to a common bus by declaring that they are both connected to an node "BUS".

3. There are additional details involved in connectivity inference. They are: (a) Propagating connectivity assertions through "helping" functions and recursive definitions. (b) Detecting (rare) inconsistencies that a user can inadvertently cause. We have worked out (but do not present) such details.

An excerpt from a terminal-session that shows the inference of module interconnectivity at a high level is shown in figure 4.

3 Interface With Layout Editor

In order to make use of the information in SBL's realization specification during the layout stage, a correspondence between SBL descriptions and the layout has to be established. The following relationships exist:

- There is a one-to-one association maintained between its physical layout of a module and the module instance declared in an SBL specification (for example MEM, on line 4, figure 2);
- The hierarchy of modules correspond in the layout and the SBL descriptions;
- External ports in these realms also correspond.

We generate an intermediate file, *CELL.info* from the SBL specification of a module, *CELL.abs* and *CELL.real*. This *.info* file contains essential information about submodules, ports, inter-module connections and hierarchy. The format of *.info* file is shown in figure 5.

We are currently using *magic* [SMHO85] version 4.1 with the following local enchancements that help in interfacing with SBL.

Hierarchy enforcement

In our modified layout system, any magic command that may cause changes in the current cell's hierarchy (such as :getcell and :array) are first verified against the *.info* file before execution. Checks are also performed at the end of each layout editing session to warn the user about missing subcells, if any. By this, we ensure that the current cell *M.mag* includes a subcell *A.mag* if and only if *A* is a submodule of *M* (as specified in *M.info*).

Port labeling

Magic by itself lacks the concept of *ports.* To map the SBL port specification of a module M onto its magic file, the user has to manually mark each port on the layout. Complex ports in SBL (such as arrays and records) are first converted into simple bit-ports. In general, the type-information associated with a module's port is used in determining the actual number of wires needed in hardware to convey objects of that type.

We have added a :port command which makes use of the label construct in Magic to denote ports. This command ensures that port names and indices (if any) marked on the layout agree with that specified in the *.info* file. By modifying magic's :label command, we can also avoid conflict between SBL port names and other user-defined labels.

This port labeling scheme is utilized by magic's router. In future, we plan to make this information available to other CAD tools such as *crystal* [SMHO85] or *rnl* [Ter83], which at present require the user to provide the port-labels separately.

Routing Assistance (currently being implemented)

Magic comes with a powerful switchbox router, *detour*, that is suitable for hierarchical routing. What is currently missing is the capability to specify the netlist required by this router in high-level description language. The process of generating a netlist manually (either by writing a netlist file or interactively marking it on the layout) is tedious and error-prone. In our layout system, we overcome all these shortcomings by using the inferred netlist in conjunction with the above mentioned port-labeling scheme.

Routing involves a top-down phase and a bottom-up phase. During the top-down design stage, the interconnections between the datapath submodules at each level of the hierarchy are generated. A magic-compatible netlist can be compiled from this. During the bottom-up phase, detour is used to perform routing. Routing would proceeds bottom-up over the hierarchy.

Note that the controller is not one of the datapath submodules. In our system, the controller specification (in some FSM description language such as *meg* [SMHO85]) is compiled from SBL realization specifications and timing requirements. The netlist involving the control path is also generated during this compilation process. A locally modified version of *mpla* [SMHO85] can then be used to produce the layout of the controller in PLA form. The resulting controller module is now ready to be used in the layout, just like one of the subcells.

A Typical Routing Session

In the following session, it is assumed that the user is attempting to layout the cell *FIFO.* We assume that all subcells of *FIFO* are available as library cells (since layouts are built bottom-up), and that all essential SBL information have been already extracted and stored in the *FIFO.info* file (since SBL specifications are top-down).

Once the user loads *FIFO.mag* into magic, the connectivity information is extracted from *FIFO.info.* A magic-compatible netlist file is then created as *FIFO.net,* which includes netlist for data-path, controller, clock and power. The user may now issue the command :netlist FIFO in magic to use this netlist.

The user then has to perform manual placement of subcells in FIFO, and manually routes the power nets first before invoking magic's router (these may not be necessary in the future when tools for automatic cell placement and power net routing become available). Our routing approach is incremental and interactive. The user can selectively route groups of special nets, *e.g.* busses, or manually draw the wire for certain critical nets.

When the user is ready to invokes the *detour* router via the :route command, our routing assistant has to first verify any existing layout connections against *FIFO.net* and construct a new netlist consisting of only those nets that are not yet connected. The assistant then call up *detour* to route the layout.

As with any other router, there is a chance that *detour* may fail to complete some of the connections. Therefore the user should always examine the correctness of routing results by using the :verify command in magic. To an experienced user, a visual inspection on the layout can usually suggest possible problem areas and means to improve routing quality.

If the result of routing is not satisfactory, the user must either completely undo the previous routing, or selectively remove some of the nets from layout (there is a :ripup command in magic just for this purpose). The user must now offer some help to the router by
— improving cell placement,
— allocating larger routing area, and/or
— manually routing some critical nets
before invoking the :route command again.

The cycle then continues until the user is satisfied with the layout of *FIFO.mag*

4 Concluding Remarks

We have presented a VLSI design system that infers connectivity from high-level behavior specifications. Its main features (combining type-checking, maintaining consistency with behavior and error-free routing) were pointed out. In addition, the following features will also be present in our implementation:

```
<> read "FIFO.real"          % Compile the realization spec.
   ...compilation messages...
<> inst FIFO (8,15)          % supply size parameters to FIFO
<> netlist

FIFO.?d --> MEM.?data    : (SUBRANGE-TYPE (INT-TYPE 0) (INT-TYPE 15))
WC.!o --> MUX.?w         : (SUBRANGE-TYPE (INT-TYPE 0) (INT-TYPE 7))
MUX.!o --> MEM.?addr     : (SUBRANGE-TYPE (INT-TYPE 0) (INT-TYPE 7))
RC.!o --> MUX.?r         : (SUBRANGE-TYPE (INT-TYPE 0) (INT-TYPE 7))
MUX.!o --> MEM.?addr     : (SUBRANGE-TYPE (INT-TYPE 0) (INT-TYPE 7))

        % The above interconnections and their types were inferred
        % during compilation. This will be converted to Magic's
        % netlist and used for routing. Type of data is 0..15
        % and address is 0..7 (since first param of FIFO = capacity)
<>
```

Figure 4: Terminal session that demonstrates connectivity inference

- Arrays of modules are ubiquitous in VLSI. Behavior specifications that use arrays of modules are written in SBL by using recurrence equations. We plan to infer connectivity among the arrays of modules directly from the recurrence equations.

- It is a common practice in hardware systems to split a bus and connect it to two different modules. Although this may seem to be purely a structural operation, it has an important bearing on *behavior* as well. For example, a connection shifted one by mistake will introduce an un-intended shift operation into the behavior, undermining the behavioral correctness.

  Due to the above danger, we absolutely prohibit manual bus-splitting at the structural level. Instead, the user is required to ascribe a record type to the bus, and then use *field selection operations* on record values conveyed to the module (via the bus). From the field selection operations in the behavioral specification, we will infer the necessary bus splittings required. Thereby the interconnections and the behavioral specification would remain consistent.

We are at the moment able to run the SBL compiler on non-array modules, generate their net-list and route their submodules in accordance with this net-list. The main tasks that lie ahead of us include generating netlists for arrays of modules and the implementation of the controller synthesis procedure, which would allow us to route the generated controllers also, to make complete chips.

1. Introduction

Before the mid 1970s, integrated-circuit designs were comparatively simple, and the limits to complexity of an integrated circuit were imposed by semiconductor technology. Advances in semiconductor technology, however, have made it possible to put more on a single chip than can be designed easily and simply by a small group of people. As a result, for the past ten years or so, as the complexity of the designs has increased, the construction of integrated systems has been limited by both the fabrication technology and the cost of full custom design. As today's design crisis is solved, it is expected that the complexity limits will also include our inability to envision the types of systems to deploy in integrated form. The field will become system-limited, as well as technology-limited and design-limited.

MIT has responded to all this with a program of research and education in microsystems aimed at three principal areas: fabrication technology, design, and systems. This paper is devoted to a discussion of some of the recent results in the area of VLSI CAD. This work is carried out in the context of research in other areas of VLSI, and so interactions are both possible and desirable.

This paper discusses only research carried out on the MIT campus. MIT Lincoln Laboratory has a strong program of research in VLSI which is separate.

2. VLSI Research Program

MIT recently opened a state-of-the-art VLSI fabrication facility on campus. It includes a fully equipped 6800 square-foot integrated-circuit laboratory, with about 2800 square feet of class 10 clean space and all the equipment necessary to process wafers from starting material through to final packaging and testing. Its purpose is to provide a stable, base-line process to support research in processing and process control, and to fabricate systems that require unusual process steps. There is also a 3600 square-foot class 100 lab dedicated to novel process technology development, and a 2000 square-foot Submicron Structures Laboratory, including 1000 square feet of class 10 space.

It is convenient to consider the MIT VLSI research program as being composed of seven interrelated parts: submicron technology, electronic materials, semiconductor processing, semiconductor devices, VLSI CAD, VLSI systems, and VLSI theory. The total program is, roughly half devoted to the "electron-oriented" activities, and half to the "bit-oriented."

Much of the research in semiconductor processing and devices could not even be attempted without the new facilities mentioned above. This work includes a program, sponsored by the Semiconductor Research Corporation, on process technology for mixed analog and digital circuits. The research vehicle is a high-accuracy, high-speed A/D converter. It also includes a plan to develop software control systems for IC fabrication facilities. The purpose of the proposed Computer-Aided Fabrication system is to improve flexibility of fabrication, repeatability of processes and experiments, portability of processes, yield and efficiency of process development, thereby reducing overall cost and latency time in IC fabrication. These benefits arise from more complete documentation, elimination of paper in the clean environment, avoidance of human errors, optimal scheduling, environmental monitoring, inventory management, cost accounting, direct equipment drive, and convenient process-development and process-analysis environments—in short by management of all the data associated with VLSI fabrication. This CAF work is part of the VLSI program and it is also part of a broader program of research in manufacturing.

At the other end of the spectrum, there is interest at MIT in highly parallel architectures, since such architectures match the capabilities of VLSI to provide massive amounts of logic. This work includes the development of dataflow machines, and particularly the languages and software systems necessary to make effective use of highly parallel systems, and of algorithms that are particularly well suited for such an environment.

Although most of the VLSI research can be conveniently classified as belonging to one of the seven areas men-

CH2345-7/86/0000/0871$01.00 © 1986 IEEE

tioned above, some of the more interesting projects seem to defy such categorization and are truly interdisciplinary. One of the best examples is the development of a special content-addressable memory whose architecture has been designed to be usable in a wide variety of different applications [24, 29]. Making full use of this architecture is the subject of continuing research. To achieve the desired density and performance goals, novel circuits and a low-resistance interconnect technique have been developed. This effort is funded by a consortium of eight industrial firms, and involves three faculty members from diverse areas (L. R. Reif, processing; C. G. Sodini, circuits; and R. E. Zippel, architecture).

A paper this short cannot discuss research results from all these areas; instead, the focus is on recent results in VLSI CAD.

3. Recent results in VLSI CAD

Nine recent results or projects in VLSI CAD are discussed below. These include particular design tools, and also approaches that support the development of new tools.

3.1 CAD Tool Frame

SCHEMA [30] is an integrated design system for electronic designs being developed by a group led by Richard Zippel. Also involved in SCHEMA's development is a group of researchers at Harris Corp. being led by George Clark. Building VLSI systems is very complex undertaking. The complexity of the task is manifest in two fashions. First, the designs themselves are quite complex and the designers need help managing the complexity of the design. Second, the design tools themselves are becoming more and more complex. SCHEMA has been developed to address both of these types of complexity.

SCHEMA addresses the design complexity issue in three ways. First, SCHEMA provides a complete design structure in which the designer can store schematics, layouts, simulation results and all other artifacts of the design. Thus it captures the *complete* design. In order to understand the impact of different design decisions, the designer needs to examine the design from different perspectives. SCHEMA allows the designer to walk around the design laterally (through the schematics, layouts and simulation results) or vertically (from block diagram through logic and circuit schematics). Furthermore, SCHEMA maintains consistency between the different viewpoints of the design, if possible, and marks the different components incompatible if not.

The second approach SCHEMA uses to simplify large designs is to encourage the development of a library of *simple tools*. Simple tools perform a single, simple task to help the designer. Some examples are a *delay estimator* that calculates the delay between two nodes in a circuit or a *power estimator* that computes the average power dissipated by a set of devices. This information can be easily derived with a simulator or calculated by hand, but in either case requires enough effort on the designer's part that it is not often done. The purpose of the simple tools is to make this information available to the designer whenever and wherever it is needed so that design decisions can be made in a confident fashion. Another simple tool would convert a boolean equation into a pull-down or pull-up structure. Again an easy operation for a designer but somewhat time consuming. None of these tools is a major CAD advance in and of themselves but it is our belief that cumulatively they have a major impact on the designers productivity.

Finally, the big tools: simulators, routers and compactors, almost always have several variants. Simulations can be done using a switch level simulator, a logic simulator or a transient simulator. Routing can be done using any of a number of channel or switch box routers. Each of these techniques is appropriate for a different segment of a design. They should be built to be interchangeable, so that the designer can choose which one to use at different points in the design. The best example of this type of CAD tool currently in use is a mixed mode simulator, though the decision process is controlled by the program not the designer.

To support these types of tools, the components of SCHEMA must be more thoroughly integrated than is of true most other CAD environments. This is accomplished by having the entire design and most design tools coexist in a common address/namespace. To encourage interchangeability in the software tools and to minimize the effort required to build CAD tools, a "Layered Language" software organization is used. Finally, a fairly complete and uniform toolbox of user interface tools is provided. Thus it is relatively rare that a tool designer need be concerned with developing a user interface to his or her tools.

3.1.1 Software Organization

The most common approach used in building a software system is to use a *structured design* methodology. With this methodology, a specification for the problem to be solved is given. Using this specification, the problem is decomposed into sub-problems, which are solved independently to encourage modularity. This approach is then applied recursively to each of the sub-problems. This leads to a tree-like decomposition of the problem into sub-problems. This modular resolution of the problem makes it relatively easy to measure progress on the orignal goal and provides accountability for faults, important issues in developing large software systems.

We feel that this approach is weak for a number of reasons. First and most important, invariably the problem posed is not the problem that should be solved. Either the problem's specification is incomplete or inaccurate, or by the time the system is built the needs will have changed and a slightly different system is required. Second, the modularity imposed by structured design leads to duplication of effort as each team builds the tools necessary to solve their problem. If they choose to share modules with groups working on other subproblems, then hidden dependencies will appear among the modules sharing code, reducing their modularity. Finally, the accountability benefits of structured design are really illusory. Hard problems in the resulting system are more often due to poor decomposition of the problem; thus the responsibility for the problems is collective.

In SCHEMA we have chosen to use what we call a "layered language" approach to building systems. To solve a problem using this approach, one generalizes the problem to be solved into a class of related problems and then develops a "mini-language" for solving problems in this class. This new language has two components: (1) new data types and operations on the data types and (2) new control structures (abstractions). Collectively these tools should make the solution of problems from the original class easy. The resulting system consists of many language layers, each providing narrower, semantically richer mechanisms for describing the solution to a problem.

For instance, instead of building a single schematic entry system in SCHEMA, we have chosen to construct a language that makes it easy to construct graphics editing systems. This language includes spatial management data structures, icons and connectivity structures. New control structures exist for tracking the mouse, moving objects and synchronizing screen updates. This language is then used not only to build the schematic entry system, but also is the basis for the layout and waveform entry systems also.

The new data structures are often built using the Lisp Machine's "flavor system" and the new operations using "flavor methods" [17]. The multiple inheritance and sophisticated method combination mechanisms allow for greater sharing than many other approaches. New control structures are built using macros and functional arguments. A more detailed paper on this approach is in preparation.

3.2 Optimal Sizing of Transistors

Power consumption and signal delay are crucial to the design of high-performance VLSI circuits. Mark Matson and Lance Glasser have developed CAD tools for the modeling and optimization of digital MOS designs [14]. The tools determine the transistor sizes that minimize circuit power consumption subject to constraint on signal path delays. If a signal path constraint is unachievable then the tool returns the fastest possible design. Computational efficiency is obtained through macromodeling techniques and a specialized optimization algorithm. The macromodels are based on device equations and encapsulate logic gate behavior in a set of simple yet accurate formulas. The macromodels are valid for complex MOS gates with the limited use of pass transistors. Typical accuracies are in the 5–10% range. The optimization algorithm exploits properties of the digital MOS domain to convert the primal optimization problem into a dual form which is much easier to solve. It handles the case of multiple constraint paths and transistor size constraints. Not all constraints need be active. The result of this research is a pair of CAD tools that can optimize a circuit in roughly the amount of time needed to perform a transistor level simulation of the circuit.

3.3 Reliability Simulation

RELIC [2, 3] is a reliability simulator developed to analyze stress and wear in MOS VLSI chips. Unlike its predecessors, RELIC is not designed around any particular failure phenomena or model but around the idea of reliability simulation in general. RELIC is the first reliability simulator to encompass several different failure mechanisms. RELIC is designed to be used in the circuit design phase to identify devices which are under excessive stress and to determine the worst-case reliability of the circuit. It is also helpful in comparing the median time to fail (MTTF) of different circuits and in determining whether or not a part can be effectively screened by accelerated testing.

RELIC uses a simple methodology for analyzing the stress caused by many different failure phenomena. A device which is stressed over time accumulates wear. The probability of device failure at time t depends on how much wear the device has collected by time t and the critical value of wear for that failure phenomenon or for that circuit. This critical value of wear might be the amount of trapped charge a gate oxide can take before undergoing TDDB; it can also be the threshold shift of a transistor under hot electron stress which causes the circuit to malfunction.

RELIC provides a number of features to aid the user in performing reliability analyses. A circuit device may be analyzed for any number of failure mechanisms, and multiple tests may be run with variations of model parameters. The circuit designer has the option of analyzing the entire circuit for reliability hazards, or concentrating on a few critical devices. RELIC employs a circuit simulator so that the voltages and currents used in stress calculations are worst-case operating waveforms and not just the maximum voltages and currents. This feature will become increasingly important as devices scale to the submicron regime.

The present implementation of RELIC includes three failure phenomena: metal migration, hot electron trapping, and time dependent dielectric breakdown. The metal migration model predicts and includes the effects of thermal transients in the wire. RELIC has been used to analyze several circuits. The most illustrative example is a bootstrapped superbuffer. The simulator successfully determined that one of the transistors in the circuit was being stressed at a rapid rate by both hot electrons and time dependent dielectric breakdown. RELIC also verified that a redesigned version of the superbuffer had a lower wear rate and hence larger MTTF.

3.4 Waveform Bounding

The purpose of this project is to develop theoretical foundations and practical algorithms for a new approach to fast timing analysis and simulation of monolithic digital VLSI circuits. The method is based on easily computed bounds for transient node voltages and signal propagation delays. It is intended as an alternative to the two methods that are currently standard practice: "exact" numerical solution and approximate delay formulas. It is an attractive alternative in many cases because exact numerical solution requires prohibitive amounts of computer time for VLSI circuits, and approximate delay formulas can result in large uncontrolled errors for some practical circuits.

The starting point for this work is the original paper by Rubinstein *et. al.* [21]. That paper provided computationally convenient upper and lower bounds for the step response of linear RC tree networks, which are useful as network models for the branching interconnect lines in MOS IC's. We have extended the usefulness of these results by generalizing them to include interconnect networks with closed loops [26], such as the gate electrodes for large driver transistors. And we have proved theorems on the dynamics of RC networks that reduce the region of uncertainty in the original bounds. Tighter bounds have been achieved for all interconnect networks by exploiting slew rate limits on the node voltages, and further improvement was obtained for tree networks by using the spatial convexity of interconnect voltage during transients in a novel way [28,22]. Both these bound improvements have been successfully incorporated in a commercial CAD system for MOS standard cell design [23].

A project currently underway aims to extend the original work, intended for MOS applications, to include appropriate models for bipolar circuits [18]. The base-emitter junction in, e.g., ECL logic, provides a d.c. path to ground, not present in MOS, that invalidates the original bound formulas. The entire effort has been unified by the discovery [27] that the mathematical foundation of waveform bounding resides in the properties of linear dynamical systems governed by a special class of matrices, called "M-matrices."

A more broadly focussed and ambitious project is underway to develop a method for iterative bound relaxation, which will allow the user to flexibly trade off tightness of bounds for computer time as required at different stages in the design [31].

3.5 Network Extraction

A network extractor is a program which accepts an IC layout as input, and produces from it a machine-readable circuit representation, with sufficient information to perform detailed circuit simulation. The network extractor must be told about the fabrication technology and the meaning of the various layers; typically this is done through a "technology file" which is also treated as input. The output is typically in a form directly usable by a circuit simulator such as SPICE, but can also be used for layout verification, circuit schematic drawing, and electrical rule checking.

The network extractor EXCL has been developed by MIT by Steven P. McCormick and Jonathan Allen [15, 16]. The program has general extraction algorithms capable of accurate computations of interconnect resistance, inter-nodal capacitance, ground capacitance, and transistor size. However, where possible the general algorithms are replaced with simpler, faster techniques.

First, non-manhattan geometry is converted to staircase orthogonal geometry, since EXCL does not deal with arbitrary angles. Then comes a geometric decomposition phase, during which intersecting rectangles are grouped together, using technology-dependent intersection rules that are user-definable. Next is the extraction phase. Each transistor is transformed into its lumped equivalent. Each interconnect is also given a lumped representation. Separate algorithms for extracting capacitances and resistances are used. Again the extraction phase is user-controllable through technology-dependent extraction descriptions. Finally, the result is formatted for the desired use (logic simulation, timing simulation, circuit simulation, graphical presentation, etc.).

To extract interconnect resistance, EXCL uses three techniques. The most general technique works for arbitrary shapes, and solves Laplace's equation in two dimensions. The numerical techniques used are Gaussian elimination and successive over-relaxation. The second technique is valid for long straight wires with right-angle corners. This uses the standard formulas involving length and width, and standard corner corrections. The third technique uses a table lookup to handle commonly encountered geometry, such as tees, crosses, or vias.

To extract capacitance in the most general case is quite difficult. EXCL finds ground capacitance through calculations of areas and perimeters in a standard way. Coupling (internode) capacitance is calculated when EXCL judges that it will be significant. Three special techniques are used. For overlapping areas, the parallel-plate formula is used, with fringe correction. Parallel runs in the same or different layer are handled with a capacitance proportional to length, the constant of proportionality being a precomputed function of layer, separation, and technology. The third technique uses a lookup library to handle frequently occurring shapes. Besides these three special techniques, EXCL uses a Green's theorem approach for arbitrary geometry, if this is necessary.

3.6 Regular Structure Generation

A regular structure generator is a program which creates a VLSI layout of circuits which are repetitions of smaller circuits. Examples are n-bit adders which might be implemented as n full adders placed adjacent and wired together. Other regular structures include systolic arrays, multipliers, PLAs, and register files.

A regular structure generator has been developed at MIT by Cyrus S. Bamji and Jonathan Allen [BamjiRef]. This program does much more than merely place leaf cells adjacent to each other, since in practice regular structures always have special edge or end conditions, and for optimum performance the leaf cells should be personalized according to the size of the array. For example, in an n-bit adder, the LSB can be a half adder rather than a full adder because there is no carry in.

The RSG uses previously defined cells to hierarchically build larger cells. It accepts a library of leaf cells, a parameter file, and a design file, and produces a circuit layout. The design file is a parameterized, procedural description of the architecture. The parameter file contains the parameters for the particular design desired. Hierarchy is used to enable the RSG to deal with macrocells, which are built up from subcells using legal interfaces. RSG can effectively deal with reflections and rotations of layouts. The legal ways of placing, orienting, and connecting cells are represented in an interface table.

The RSG operates as follows. First, a sample layout is read. From this, the RSG determines the leaf cells and some of the legal interfaces. Then new cells are created by building a connectivity graph for the new cell, and the converting this into a layout. The result is a new cell. If this new cell is to be itself used in a larger cell, new interfaces must be created. This process is repeated as necessary to hierarchically build up the final layout.

The RSG is written in the language CLU and consists of approximately 6000 lines of source code. It has been used to create a variety of layouts.

The previous results have been proven feasible by implementation in the form of CAD programs, either within MIT or outside. The results mentioned in the remaining sections have not yet been incorporated into working code.

3.7 Retiming

The goal of VLSI design automation is to speed the design of a system without sacrificing the quality of the implementation. A common means of achieving this goal is through the use of optimization tools that improve the quality of a quickly designed circuit. A group of researchers led by Charles Leiserson have developed a class of optimization techniques for clocked circuits called *retiming*, that relocate registers so as to reduce combinational rippling [9, 10, 11]. Unlike pipelining, these techniques do not increase circuit latency.

These techniques are most appropriate for circuits with a relatively large number of clocked stages such as signal processing systems. This sort of problem can be represented as a weighted graph where the vertices are the computational elements, and the weights on the edges indicate the number of registers between computational elements. A delay associated with each computational element is included as a vertex weight. The minimum clock period is the maximum sum of vertex weights between any pair of registers. The usual *ad hoc* pipelining techniques insert additional registers between computational elements to decrease the clock period. The retiming techniques try to find an optimal placement of the registers by phrasing this problem as a particular integer programming problem that can be solved quickly.

The general ideas behind retiming provide a broad framework in which clocked circuit optimization problems besides clock period minimization can be considered, and it allows one to bring the powerful combinatorial optimization techniques to bear on these problems. Retiming seems to be a valuable technique that could be incorporated into both circuit and compilers and interactive design tools.

3.8 Wafer-Scale Wiring

VLSI technologists are fast developing wafer-scale integration. Rather than partitioning a silicon wafer into chips as is usually done, the idea behind wafer-scale integration is to assemble an entire system (or network of chips) on a wafer, thus avoiding the costs and performance loss associated with individual packaging of chips. A major problem with assembling a large system of microprocessors on a single wafer, however, is that some of the processors are likely to be defective. Thus a practical procedure for integrating wafer-scale systems must have the ability to configure networks around faults.

Recently, a group headed by Tom Leighton has developed improved and provably efficient algorithms for constructing two-dimensional systolic arrays on a wafer [6, 7]. Systolic arrays are a desirable architecture for VLSI because all communication is between the nearest neighbors.

In a wafer-scale system, however, all the nearest neighbors of a processor may be dead, and thus the prime advantage of adopting a systolic array architecture may be lost if a long wire connects electrically adjacent processors. In general, the longest interconnection between processors will be a bottleneck in the system. Of the many possible ways in which the live cells on a wafer can be connected to form a systolic array, therefore, the one that minimizes the length of the longest wire is most desirable.

The new algorithm for integrating two-dimensional arrays is based on a matching process. In particular, we find a matching between the functioning processors and points in an imaginary grid with evenly spaced rows and columns for which the length of the longest distance between matched points is minimized. Assuming independent cell failures, we prove that the longest matching length is $O(\log^{3/4} N)$ with very high probability. Initial experimental evidence confirms that the matching distances are quite small, and that the wire lengths in the resulting $N \times N$ array are within a factor of two of $\log^{3/4} N$.

The new algorithm is dramatically superior to row/column elimination approaches to wafer-scale integration (which fail for large N and/or high probability of cell failure), and moderately better than previously discovered divide and conquer algorithms. The algorithm requires roughly $O(N^2)$ time for N processors in the worst case, but appears to run much faster on average.

3.9 Compaction

An automatic compaction procedure is an effective tool for cutting production costs of a VLSI circuit at low cost to the designer, because the yield of fabricated chips is strongly dependent on the total circuit area. In order to perform any sort of compaction, the components of the layout must be differentiated into *modules*, which are fixed in size and shape, and *wires*, which are flexible. Common procedures for generating design rule constraints [4, 5, 12] assume that wires are simply rectangular regions of variable length, and otherwise identical to modules. A vertical wire, for example, would be assigned an x-coordinate during horizontal compaction, and could only be moved rigidly from side to side. But one would often like a previously straight wire bent around an obstacle during compaction, if the are of the circuit could thereby be reduced.

This problem is not easily overcome. Many systems [4, 25] attempt to solve it by allowing the designer to specify *jog* point at which wires my bend. Compaction then becomes an interactive procedure in which the designer repeated examines the compacted layout, adds more potential jog points and retries the compaction. Miller Maley, a student of Charles Leiserson has developed a new polynomial-time compaction algorithm that automatic introduces jog points in an optimal fashion [13]. Automatic jog insertion is achieved by treating wires not as solid objects, but only as indicators of the topology of the layout. Constraints between modules no longer express design rules directly; instead, they will ensure that there exist paths for the wires, having the given topology that satisfy the rules. The new constraints, called *routability conditions*, can be formulated as simple linear inequalities, and are easily solved. When the optimal placements have been established, the new wire paths are determined by a single-layer router [8]. This router does not generate "unnecessary U's," and therefore minimizes wire lengths, given that the layout topology is fixed.

Earlier work by Ron Rivest and his students introduced a theoretical approach to placement and routing. This work was embodied in a demonstration system called PI [19, 20], and is now being transferred to industry for practical implementation.

4. Conclusions

As with the larger MIT VLSI effort, we have stressed interdisciplinary approaches to VLSI CAD. This can be seen from the work described here: SCHEMA, which applies novel software engineering techniques to building a CAD frame; retiming, where integer programming ideas are applied to pipelined architectures; compaction, where we are using new combinatorial optimization techniques for jog insertion. The work on macromodels and reliabilty analysis is an example of tools that span the usual design boundaries. We are guided by the principle that the most challenging and needed work is that which crosses or even obliterates conventional design boundries.

We have summarized our most important recents results in VLSI CAD. Additional information on specific efforts may be found in the references.

Highlights of CMU Research on CAD, CAM and CAT of VLSI Circuits

John Paul Shen

SRC-CMU Research Center for Computer-Aided Design
Department of Electrical and Computer Engineering
Carnegie Mellon University
Schenley Park, Pittsburgh, PA 15213

The primary goal of the Semiconductor Research Corporation-Carnegie Mellon University Research Center for Computer-Aided Design is to carry out a comprehensive research program that will result in the development of an integrated methodology and associated computer aids for the design, manufacture, and test of VLSI circuits and systems. Currently the research center has ten faculty members associated with it. There are also about forty graduate students currently pursuing research in the center as well as a number of visiting researchers. This paper outlines the ongoing projects in the center and highlights a number of these projects.

1. OVERVIEW

Three disciplines are involved in the realization of a VLSI circuit: design, manufacture, and test. Each of these disciplines involves a number of activities and requires the use of various computer aids. Because Computer-Aided Design (CAD), Computer-Aided Manufacture (CAM), and Computer-Aided Test (CAT) traditionally have been viewed as separate disciplines, the aids that have been developed for them are by and large unrelated and noninteractive. In our view, it is essential that an integrated approach be used for the design and implementation of computer aids for these three disciplines.

Taking into account the fabrication process, four major steps are involved in the realization of a VLSI circuit chip, namely process design, circuit design, nanufacture and test. Traditionally CAD tools are used to speed up the circuit design step and CAT tools are used during the test step to guarantee circuit performance. The SRC-CMU research center for CAD has a broad-based program aimed at developing an integrated approach to CAD, CAM and CAT. Our first step towards this integration involves the concepts of manufacturing-based CAD and manufacturing-based CAT; see Figure 1. Manufacturing-based CAD supports both process design and circuit design with the aim of achieving short design time, fast turn-around and high manufacturing yield. Manufacturing-based CAT utilizes technology and process information to effect accurate screening of defective chips during fabrication test.

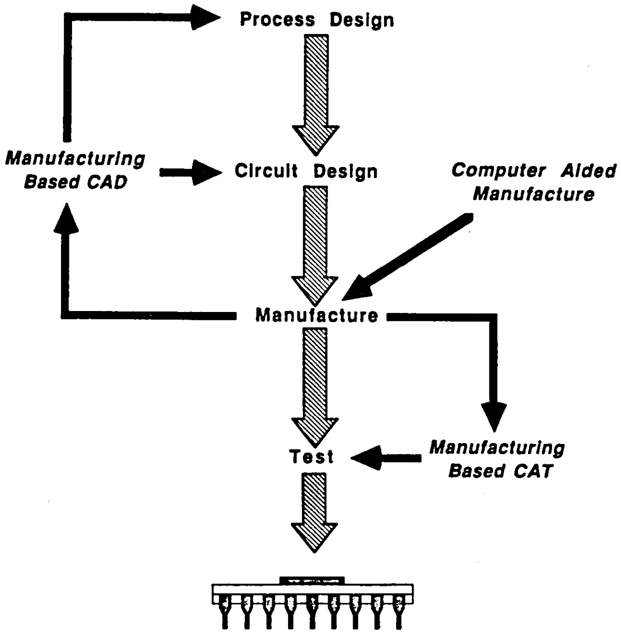

Figure 1. Integrated CAD/CAM/CAT - First Step.

Currently, the center has approximately forty ongoing projects, which are loosely grouped into the following areas:

- **Design**
  - Synthesis
  - Verification
  - Simulation
- **Manufacturing**
- **Testing**
- **Design Environment**

A representative, though not comprehensive, set of projects is described in this paper. Some projects are described in more detail to highlight recent results and future directions. This paper represents an abridged and updated version of an earlier paper [1]. Only a sample of references appears in this paper; a comprehensive list of references can be found in [1].

2. DESIGN

The goal of our CAD research is to develop a design automation system that involves a design methodology and a supporting set of computer aids that can take a behavioral description of the desired VLSI circuit, a description of the target technology, and a set of constraints, and then produce a set of masks that could be used to fabricate the circuit. The design produced should be testable and comparable in cost, speed, and reliability with manually produced designs. Availability of such a design automation system would significantly reduce the time required to design a VLSI system as well as produce designs which are correct the first time and manufacturable with acceptable yield. Figure 2 illustrates this overall objective.

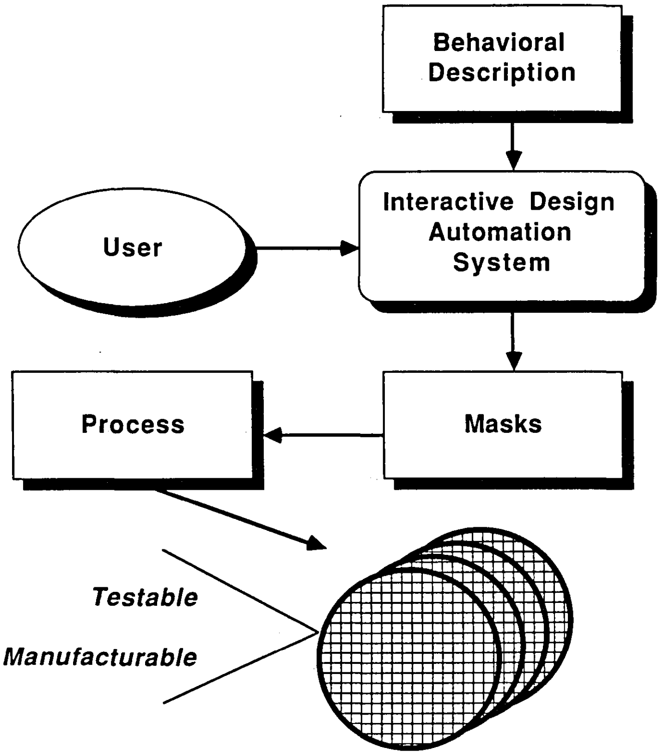

Figure 2. CAD Research Objective.

Our research activities have been aimed at developing new techniques to aid in a wide range of CAD tasks, and can be categorized around several main thrusts which include:

- An investigation into the use of Knowledge-Based Expert Systems (KBES) as an aid in synthesis and analysis.
- Development of top-down synthesis methods at the system and physical design levels which can make use of bottom-up information.
- Development of simulation tools to span all levels of the hierarchy.
- Development of a consistent multilevel representation to provide a means for our programs to communicate and as a basis for multilevel analysis aids such as multilevel simulation.
- Development of special purpose hardware for CAD tasks.

These research thrusts are being applied across the hierarchy of VLSI design. We view the design hierarchy to be composed of eight levels:

1. Task level
2. Architecture-definition level
3. Behavioral level
4. Functional-structure level
5. Logic-structure level
6. Transistor or switch level
7. Mask layout level
8. Process level

These levels are described in detail in [1]. Design can be viewed as involving synthesis, verification and simulation. Ongoing CAD research projects in these three areas are described.

2.1. SYNTHESIS

A synthesis tool takes a description of a desired system at one level in the design hierarchy and generates a description at the next lower level in the hierarchy. A number of synthesis tools have been developed or are under development now.

2.1.1. System Synthesis

Design Representation and the System Architect's Workbench

R.A. Walker, D.E. Thomas

The objective of this research is to develop a model of design representation, and then use that model to provide a designer's workbench that will allow manipulation of designs at high levels of abstraction. The model of design representation being developed is characterized by three separate but coordinated domains of description - the behavioral domain, the structural domain, and the physical domain - each characterized by a particular design decision. Using the SCS language, developed at CMU, we can coordinate these domains to represent the entire design. We are also developing a system architect's workbench that uses this model of design representation, and that will allow a designer to transform and analyze the design, particularly in the behavioral and structural domains. This workbench will extend our current system to higher levels of abstraction, and will include such transformations as structural partitioning, process creation, and support for instruction-level pipelining.

Interface Synthesis

J.A. Nestor, D.E. Thomas

This research investigates the description and synthesis of digital systems with complicated interface requirements. Previous work in high level synthesis has successfully developed tools that can automatically generate designs from an abstract specification. However, these tools have neglected the issues involved in designing interfaces. A method of describing systems with interfaces has been developed. A new system of tools building on previous research uses these extended descriptions to automatically generate designs with interfaces. The system of tools is nearly complete. Currently, we are evaluating its effectiveness with several examples of real interface specifications.

Compilation of Interprocessor Communication for Multiple Processor Systems

R.P. Bianchini Jr., J.P. Shen

Recent research on parallel systems has clearly shown that the most difficult problem faced by the system designer is interprocessor connection and communication. A methodology for the automated design and implementation of interprocessor communication for special-purpose multiple processor systems has been developed. It is shown that for many special-purpose and mission-oriented systems the interprocessor communication is deterministic and can be specified at system inception. This specification, identified as the target architecture, can then be automatically mapped or compiled onto a physical multiple processor system, identified as the host architecture, using a network traffic scheduler. Algorithms for such a scheduler have been implemented. It is shown that the order of complexity of network scheduler components is polynomial rather than exponential as in classical solutions.

Towards Knowledge-Based Synthesis of Analog Circuits

R. Harjani, R.A. Rutenbar

Although analog circuits do not exhibit the same rigid hierarchical structure as digital circuits, hierarchy maybe exploited by analog designers. Design still proceeds at different levels of abstraction, but the coupling between levels and between objects within a level is much stronger, and the interactions that must be planned for and designed (i.e., not logic values, but electrical, parasitic, electromagnetic and thermal considerations) are richer and more varied. Analog designers rely strongly on experience with partial circuit topologies that meet classes of constraints, and knowledge-intensive strategies for choosing the parameters that define each module or primitive device. We are investigating design representations for a knowledge-based analog synthesis tool in the restricted domain of CMOS analog-to-digital converters. The goal is to develop a representation that will not limit design to a set of fixed modules, but will help design fully custom analog circuits.

2.1.2. Logical Synthesis

Synthesis by Delayed Binding of Decisions

J. Rajan, D.E. Thomas

A program called SUGAR is currently being developed to investigate the automatic synthesis of single chip microprogammed microprocessors from behavioral descriptions. Subtasks in complex problem solving activities like synthesis often interact. As a result, decisions made prematurely can lead to poor designs. A least-commitment style of binding decisions has been developed that allows better design choices to be made by postponing important decisions until adequate information is available to make them. This design style partitions the design task into a sequence of temporally ordered subtasks that cooperate during design. The subtasks consist of flow analysis, control flow transformations, control flow partitioning, data path model selection, and hardware allocation. Most subtasks have been implemented and the project is nearing completion.

A Knowledge Source Based Synthesis System : A Feasibility Study

D.L. Springer, D.E. Thomas

This project investigates the organization of programs to automatically synthesize VLSI systems from the behavioral level to the register-transfer level. In particular we are exploring knowledge source based systems and an organization structuring language. Knowledge source based systems are composed of a set of independent knowledge sources which communicate via a software blackboard. Present knowledge source based systems include Hearsay-II which is a speech recognition program and ULYSSES (discussed below) which is a design environment for the logical and physical design of VLSI systems. Present synthesis systems for the upper levels of the design hierarchy do not allow the flexibility to: change knowledge, integrate different implementation styles, or deal with conflicting data, which a knowledge source based system would provide. This flexibility is highly desirable since this domain of the synthesis task is still largely in the research stage.

Instruction Processor Pipeline, Design and Analysis

R.J. Cloutier, D.E. Thomas

The design of the stages and the control structures of a pipeline, for an instruction processor, are weakly supported by existing tools. The manual methods used today are similar to those that were originally used to describe the IBM 360/91. This lack of tools is hindering the development of advanced pipelined processors. The major problem is the diversity of control structures and the inability to deal with them in computer aided tools. Take for example, the partitioning of a processor into stages. Stage boundaries are proposed by considering timing relations and resource conflicts. A simulator is then written for that particular partitioning and the proposed control structure. Potential instruction streams are then run through the new pipeline model. The simulator is used to search for unexpected delays caused by specific combinations of instructions and external signals (such as interrupts) flushing the pipeline. Instead of simulation, analysis can be performed to find the combinations of instruction sequences and signals that will cause problems. Combining this analysis with synthesis tools avoids the problem of building a unique simulator for each proposed pipeline configuration.

2.1.3. Physical Synthesis

Logic Synthesis System

M. Trick, S.W. Director

The purpose of this research is to develop a system that takes a structural level specifications of a system and generates the necessary layout. It is our intent that this synthesis system will allow a structural synthesis tool or the designer as much freedom as possible in specifying the structure of the circuit. It will be able to handle a variety of interconnection patterns, clocking schemes, and functional blocks. This freedom puts an additional burden on the synthesis system because it must analyze the connectivity and the shapes of the modules in the circuit and choose appropriate physical implementation for the modules. Many chips can be implemented very efficiently as a single row of modules of the data path connected to a logic array which implements the control of the data path as was done in Bristle Blocks and MacPitts. The layout synthesis system should recognize such designs and implement them in that style, but if a design is specified that contains modules or interconnect not amenable to layout in a single row of modules, the system will be able to perform the layout of the IC using an appropriate style.

A Multiple Expert System Approach for Placement

M. Hirsch, D.P. Siewiorek

It is recognized that the activities performed during physical design fall into three main categories: partitioning, placement and routing. These three categories of activities are deeply interrelated in that if one considers any without considering the others, then the results will most likely be unacceptable. Existing tools approach the problem from a single point of view. For instance, min-cut will view physical design from a top-down point of view, whereas some graph-theoretic techniques which cluster components view the problem from the bottom up. It is believed that human designers attack the problem from a multiplicity of viewpoints. That is, the viewpoint of the problem dynamically changes between bottom up, top down and middle out as the solution to a physical design problem is refined. It is also believed that while human designers use metrics such as congestion estimates, number of wire crossings between partitions and balance of area between partitions, these metrics are only guidelines. Human designers also look for recognizable design situations such as busses, locations of pads on the periphery of the chip and familiar interconnections of components and handle these situations in a manner that their experience has shown to be most effective. A new approach will be investigated which combines a variety of metrics and viewpoints and will be implemented with a multiple expert system.

Floorplanning Using Simulated Annealing on a Multiprocessor

R. Jayaraman, R.A. Rutenbar

The floorplanning task for VLSI chip layout determines the relative placement of circuit macro modules on a silicon surface. The basic objective is to optimize critical layout parameters, for example, interconnection length, total chip area, and bus placement. This project studies simulated annealing algorithms as applied to floorplanning. Annealing algorithms applied to physical design problems have yielded excellent solutions, but they are computationally very intensive. In this research we are studying the implementation of an annealing-based floorplanner on a multiprocessor. Our goals include floorplanning for modules with a range of alternative shapes, modules with varying degrees of constraint on their final position in the floorplan, and explicit consideration of busses. After completing the serial version of the proposed floorplanner, this research will focus on identifying parallelism and multiprocessor partitioning strategies appropriate to speed up the execution times.

Multiprocessor-Based Placement by Simulated Annealing

S.A. Kravitz, R.A. Rutenbar

This project is developing multiprocessor-based standard cell placement tools based on simulated annealing algorithms. Placement of standard cell ICs by simulated annealing produces results of high quality, but at a very high cost. The goal of this research is to reduce the high cost of the iterative improvement phase of annealing-based placement by mapping the algorithm onto a shared-memory multiprocessor. The key issue in parallel tool implementation is the partitioning of an algorithm across communicating processors. We have developed a taxonomy of possible multiprocessor decompositions of simulated annealing algorithms. This provides a systematic framework for extracting parallelism in annealing-based layout algorithms. In particular, we have shown that the choice of multiprocessor annealing strategy is strongly influenced by the annealing temperature parameter. We introduce the idea of *adaptive strategies* which change dynamically as annealing proceeds through different temperature regimes to best exploit parallelism. Three implementations of multiprocessor standard cell placement have been completed and their performance evaluated. An adaptive strategy which switches from one parallel decomposition to another at the optimal temperature yields speedup significantly better than any single strategy approach. Practical speedups for benchmark problems have been achieved for a four processor machine.

2.2. VERIFICATION

Linking Design Representations

R.L. Blackburn, D.E. Thomas

This research is concerned with the development of a means for linking design representations at different levels of abstraction. The linkage should provide the means of identifying corresponding values and operators in two or more different representations. Linkage will be accomplished by adding additional information to design representations to describe how they relate to each other. This work has applications in interactive debugging and formal verification of synthesized data paths and controllers.

A Data-Structure Processor for VLSI Geometry Checking

E.C. Carlson, R.A. Rutenbar

A critical step in the verification of VLSI chip designs is the geometric analysis of IC masks. This geometric analysis performs the functions of design rule checking, connectivity analysis, transistor identification and parasitic extraction from the integrated circuit mask geometry. Scanline algorithms are at the base of many geometric analysis functions, and appear to be the best available solution both in speed and memory requirements to the needs of these verification tasks. Bigger machines to run these compute-intensive programs are an obvious solution, but are not necessarily the most cost effective. The design of special-purpose hardware is attractive since much of VLSI mask verification is based on similar scanline primitives. We have proposed an architecture that implements two fundamental scanline operations: boolean operations between mask layers, and region numbering within a mask layer. The proposed architecture is a pipeline that implements directly the basic operators needed to manipulate a scanline data structure. Using edges as its primitive operands, the architecture is capable of handling arbitrary polygon geometry. Preliminary simulations of the proposed hardware suggest that it is significantly faster than a VAX 11/780.

A Localizing Circuit Extractor

M. Chew, A.J. Strojwas

Process disturbances during the fabrication of a digital integrated circuit might affect the equivalent electrical circuit of the resulting chip. Unfortunately, the circuit extraction of the complete layout of a digital circuit layout is too computation-intensive a task to perform if one wants to see the effects of a given set of process disturbances. The goal of this project is to develop an extractor which, given the disturbance region and the type of the disturbance, will extract from the altered layout only the electrical components which might have undergone a change. The results of this tool will then be used to update a previously extracted circuit of the undisturbed layout.

2.3. SIMULATION

Simulators developed at CMU span most of the levels in the design hierarchy. One trend in the design of CMU's simulators is the use of abstractions for controlling detail. Abstraction can define a new level which approximates the details of a lower level but with simulation cost of a higher level. An example is WASIM, a waveform simulator that allows device and circuit properties at the cell level.

Another trend is the use of hierarchy. Hierarchy can be used within a single design level by taking advantage of the natural hierarchy of the system under design. Hierarchy can also be used to mix two or more design levels. SAMSON, a mixed-level simulator, bridges the circuit and logic levels with more than two orders of magnitude performance increase over a traditional circuit simulator.

A third trend is the increased use of statistical techniques. FABRICS uses statistics to model process variations. The Hierarchical Statistical Simulator summarizes detailed behavior with a probability distribution function. A fourth trend is the use of symbolic and compile-driven techniques. An example of this trend includes the switch level simulator COSMOS which is currently being developed at CMU. A number of simulation projects are described below in roughly the top-down order.

2.3.1. Functional Level Simulation

Functional Specification Simulation of Computers

S. Bose, D.P. Siewiorek

This project is concerned with the functional description of computers. All constructs of a computer system can be based on such functions, which can be written and incorporated into a general purpose language. Lisp has been used for this purpose. A pseudo language called the Functional Specification Language (FSL) was designed to incorporate the features of functional languages as well as special constructs for Hardware Description Languages (HDL). FSL is actually Lisp with an added set of functions. These functions are arranged in two layers. The upper layer functions build on the lower layer and capture the unique features of HDLs for describing target computer instruction sets. The development of a tool is the subject of the ongoing research.

2.3.2. Switch-Level Simulation

COSMOS: A New Switch-Level Simulator

R.E. Bryant

The COSMOS (COmpiled Simulator for MOS) project aims to produce a high quality switch-level simulator with at least an order of magnitude better performance than MOSSIM II. The program also includes additional capabilities such as concurrent fault simulation. Furthermore, it can easily be adapted for execution on any special purpose simulation accelerator that supports Boolean evaluation. Unlike programs that operate directly on the transistor level description during simulation, COSMOS transforms the transistor network into a Boolean description during a preprocessing step. This Boolean description, produced by a symbolic analyzer, captures all aspects of switch-level networks including bidirectional transistors, stored charge, different signal strengths, and indeterminate logic values. Unlike previous symbolic analyzers for MOS circuits, the COSMOS preprocessor produces very concise formulas, generally linear in the circuit size.

Gaussian Elimination of Boolean Equations for Symbolic Simulation of MOS Transistor Networks

T.J. Sheffler, R.E. Bryant

This project is responsible for solving the network equations symbolically to arrive at Boolean equations which represent the behaviour of the network. A method closely related to Gaussian elimination seems promising. Instead of solving the equations in the domain of real numbers, the elimination and backsolving steps will be performed in the domain of Booleans. Much has been written on the relation between Gaussian elimination and solving systems of Boolean equations, however, there has been no clear discussion of this topic with respect to switching circuits. The systems of equations to be solved in this application are sparse in nature, thus sparse matrix techniques will be explored.

Manipulation and Reduction of Boolean Expressions Represented as Directed Acyclic Graphs

K.S. Brace, R.E. Bryant

This project deals with the maintenance and simplification of structures which store representations of Boolean formulas. A formula is represented as a directed acyclic graph (dag). A dag resembles a parse tree except that a subgraph may be shared by more than one branch, yielding a more compact representation. When a new formula is defined simplifications must be made in a standardized way so that equivalent formulas may be recognized as such. The shared subgraphs of the dag structure complicate this. The primary concern of this project deals with the trade-off between the computation involved in simplification and the time and space saved by having an optimally simplified dag.

2.3.3. Timing/Circuit Simulation

SPECS2 : A Timing Simulator

C. Visweswariah, R.A. Rohrer

This project is aimed at the development of a timing simulator called SPECS2. The timing simulator is based on a tree/link analysis of the circuit. Table look up is used for model evaluation. An event-driven approach is employed for simulation. An event is the movement of a device from one region of its characteristics to the next. An event is processed, generating a new event for the time when the device is expected to move out of the present region of its characteristics. This event is scheduled for the future. Time moves ahead to the next scheduled event and the process continues. A new modeling approach based on the conservation of charge and energy is used to build the table models. The simulator does not rely on complex models for good numerical conditioning or to guarantee reliability.

Statistical Timing Analysis

J. Benkoski, A.J. Strojwas

The purpose of this project is to develop a tool that will provide the designer with a fast but accurate statistical estimate of the delays in VLSI circuits. At first the circuit is partitioned into logically meaningful blocks. Each block will then undergo several E-logic (Electrical Logical) simulations in order to fully characterize its delay as a function of the process parameters. The result of this analysis will be the input to output delays for this block and will be decomposed into three sub-delays: the input delay, the intrinsic delay, and the output delay. While the first is a function of the input slopes and the last depends on the loading conditions, the intrinsic delay is independent of the environment in which the block is placed. By using this technique, we can afford to analyze only unique blocks. The last part of our estimation process involves either an event driven simulation of the circuit at the block level or a longest path evaluation.

A Macromodelling Approach for VLSI Simulation

S.R. Nassif, S.W. Director

We have developed a methodology for the simulation of cell-based MOS designs. We attempt to exploit the regularity of such designs by building macromodels of the individual cells which are capable of predicting circuit-level electrical performance. In particular, we derive analytical approximations for waveforms that are generated by typical device-level output stage topologies, and fit these models to waveforms generated by circuit simulation. Macromodels are generated for these cells, such that the output of these macromodels are waveforms, and the inputs are designable parameters such as layout, as well as circuit parameters such as fan-out. An event-driven, waveform-based simulator, called WASIM has been developed which employs these macromodelled cells. The basic events in this simulator are waveform transitions. WASIM is capable of achieving near logic-simulator speeds, while accurately predicting waveforms, delays, and hazards [2].

Efficient Modeling of Small-Geometry MOSFETs

M.J. Saccamango, A.J. Strojwas

This project is concerned with developing more accurate models of small-geometry MOSFET's for circuit simulation purposes. We are currently deriving methods for determining device parameters (threshold voltage, body factor and channel-length modulation parameter) with efficient physically-based models. These methods will be a part of the device simulation portion of the statistical process/device simulator FABRICS II. This phase of the project is focused on the special modeling problems of modern MOSFET devices, i.e. those with small-geometries, nonuniformly-doped channels and/or lightly-doped source/drain regions. The next project phase will involve the use of the physically-based models to extend the FABRICS II device simulation to produce I-V characteristics. From these characteristics we hope to extract device models for circuit simulation which better reflect the bias dependencies of the device parameters. The availability of these I-V curves will also allow the extraction of device parameters to meet the modeling requirements of many circuit simulators presently in use.

Tree/link Based Mixed-mode Circuit Simulator

X. Huang, R.A. Rohrer

This project aims at transcending the borders between switch level simulation and circuit level simulation of VLSI. A mixed mode capability will be accomplished by modeling the circuit devices on variable levels of accuracy. Spatial and temporal latency can be exploited by replacing dormant devices with the simplest models, which very often may be ideal switches. To accommodate these different models, tree/link repartitioning will be employed to avoid ill-conditioning and to effect fast convergence of iterative solution.

Table Look-Up Device Modeling for a Charge and Energy Conserving VLSI Circuit Timing Simulator

C. DellaTorre, R.A. Rohrer

Conventional simulators violate basic laws of physics, such as the conservation of charge and energy. A new method of device modeling has been proposed that is aimed at charge and energy conservation in circuit simulation. This project involves the development of this modeling effort so that it could be incorporated into a simulator, the premise being that this simulator would, therefore, be more reliable and efficient than existing simulators. This modeling effort will incorporate table look-up methods of device modeling consistent with the above constraints. Thus, values entered into these tables will be derived in a manner that ensures that charge and energy are conserved. These tables will be built in the most memory-efficient manner possible.

2.3.4. Yield Prediction and Maximization

Yield Simulation for Integrated Circuits

H. Walker, S.W. Director

We have developed a catastrophic fault yield simulator VLASIC (VLSI LAyout Simulation for Integrated Circuits). VLASIC is a Monte Carlo simulator that uses defect models and statistics to place random catastrophic point defects on a chip layout and determine what circuit faults, if any, have occurred. The defect models are described in tables, and so are readily extended to new processes or defect types. The defect statistical model is based on actual fabrication line data, and has not appeared before in the literature. The output of VLASIC is a population of chip samples with the same distribution of circuit faults as observed in the fabrication line. This circuit fault information can be used to predict yield, optimize design rules, generate test vectors, evaluate redundancy, etc. We have also developed a simple redundancy analysis system as an example application.

A Realistic Yield Simulator for IC Failures

I. Chen, A.J. Strojwas

This research is aimed at developing a CAD tool to realistically estimate the yield losses due to IC structural failures. This tool extends the statistical design rule developer to an accurate and efficient yield simulator. The methodology adopted by the simulator accounts for most of the mechanisms which cause IC yield degradation due to structural failures. For computational efficiency, analytical method rather than Monte Carlo method is used. There are two main parts in this simulator: formulation of yield statistics in hierarchical levels and derivation of the Probability Of Failure (POF) for layout patterns. In the first part, we have successfully derived yield statistics which consider the effects of defect size sensitivity, globally nonuniform distribution (wafer level), and local clustering effects. In the second part, a theoretical method to find the POF for most of the simple patterns has been developed. Thus, given a set of layout design rules, this simulator will be able to predict yield in a hierarchical manner on the device level, chip level, or even wafer level.

Statistical Integrated Circuit Design: Parametric Yield Maximization

K.K. Low, S.W. Director

The goal of this project is to develop an efficient way to optimize the production yield of VLSI circuits using statistical circuit design techniques. Specifically, we will address the parametric yield maximization problem using fabrication process control parameters (such as implantation dose and energy) and device geometries as designable parameters. Our approach differs from most previous work in this area in that we have chosen the space of process inputs instead of device parameters as part of our design space. This distinction is particularly relevant in integrated circuits since the device parameters are correlated. Moreover, previous methods require separate optimizations to be performed at the process and circuit levels which may result in suboptimal solutions. Two major obstacles can be identified in our effort. Firstly, accurate yield estimation is very computationally expensive due to the cost of simulations. Therefore, techniques must be found to reduce the cost without compromising accuracy. Secondly, the dimensionality of the problem must be brought down to a manageable level. This may be achieved by exploiting certain properties of integrated circuit design such as regularity and hierarchy.

3. MANUFACTURING

Minimizing cost-per-chip is the main objective in VLSI design, manufacturing and testing. Our research program in the area of manufacturing has this goal as its principal objective. We have recognized the fact that in VLSI circuit design, statistical characterization of the fabrication process is a necessity in order to describe the random fluctuations in processing conditions, material parameters and point defects that cause drops in production yield. This process level information can be abstracted into the higher levels, i.e. circuit, logic or functional levels, where it can be used to produce realistic IC designs or test programs.

Towards this end the statistical process/device simulator FABRICS II was developed to provide a common denominator for the integrated CAD/CAM [3] system with the capabilities shown in Figure 3. FABRICS II employs efficient (numerical or analytical) models of the fabrication steps and semiconductor devices manufactured in a number of technologies (NMOS, CMOS and bipolar). FABRICS simulation system accepts IC layout and process description, and generates model parameters for the active devices and parasitics. These parameters are compatible with the models implemented in such a popular circuit simulator, as SPICE. The CPU time consumed by FABRICS for the process/device simulation is usually a small fraction of the time consumed in the circuit simulation stage. The accuracy of simulation is accomplished by tuning FABRICS to a particular fabrication process by a statistical optimization system called PROMETHEUS [3]. As a result of tuning, device parameters obtained from FABRICS are in good agreement with the parameters measured in the real fab lines. The current status of software in the CAM system is shown in Figure 4.

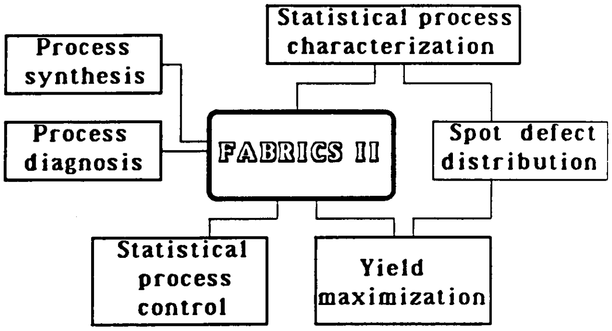

Figure 3. CAD/CAM System Capabilities.

To facilitate synthesis of new fabrication processes, an interactive process interpreter/compiler PI/C [3] has been recently added to the simulation system. It employs a graphical process editor PED [3] and allows the user to specify the process by defining the lithographic masks and process conditions. The user can perform incremental simulations and view the simulation results which are displayed in the form of impurity profiles and device cross-sections. Extensive error checking is performed by the system to help in the synthesis.

FABRICS II combined with a circuit simulator (SPICE or SAMSON) can be employed for a number of tasks ranging from the design verification/optimization to process diagnosis, to statistical process control. The design optimization tasks include:

- Nominal design in terms of process parameters (e.g. minimization of power-delay product of a dynamic RAM in terms of gate oxidation parameters).
- Worst-case design in terms of statistically independent process disturbances.
- Parametric yield maximization in the space of layout and process parameters.

A complete integrated system for process diagnosis PROD [4] has been developed and it uses FABRICS for efficient fault simulation. PROD identifies faults in the process that caused a drop in yield for a particular production run. The approach used in PROD is based on the analysis of distributions of IC performances and employs statistical pattern recognition techniques.

Figure 4. CAD/CAM Software.

To obtain realistic estimates of final production yield, the probability distribution of spot defects (e.g. shorts or breaks due to local lithographic errors) has to be taken into account together with the parametric variations. A yield simulator, called VLASIC, has been developed and can be used for prediction of the decrease in yield due to spot defects. For circuit design purposes, all the random factors affecting IC layout have to be translated into *layout design rules*. A statistical design rule developer STRUDEL [5] has been implemented to derive rules which maximize total yield. Two ongoing projects in this area are described below.

Statistical Quality Control for VLSI Fabrication Processes

P.K. Mozumder, A.J. Strojwas

Random fluctuations, which are inherent in any IC fabrication process, cause the production yield to drop significantly below 100%. The faults which cause the yield drop can be classified as catastrophic and parametric. This project deals with monitoring and controlling the IC fabrication process via statistical quality control. A cost optimization approach to the statistical quality control of IC fabrication processes has been taken. The project aims at creating a system which will, after every step in the fabrication sequence, make decisions as to whether the lot as a whole or in part is to be rejected from further processing. The system, given the constraints, is expected to develop selection criteria for the in-line measurements, which are then used by the system to make quality control decisions. The concept of process observability via in-line measurements, appropriate models necessary for process control, and algorithms for quality control based on yield maximization objectives have been developed.

Adaptive Control of the IC Fabrication Process

C.R. Shyamsundar, A.J. Strojwas

This research deals with adaptive control of VLSI fabrication processes. Based on the in-line measurements that are made during the fabrication of integrated circuits, decisions will be made regarding the values of the future process parameters. Models relating the process parameters to in-lines and circuit performances, will be used for this purpose. These models were built using MULREG (MUlti-Layer REGression program), which has been specially developed for this purpose. An acceptability region in the space of process parameters is also used to arrive at the decisions. The aim will be to maximize the total profit from the fabrication line. With this in mind, a minimum acceptable yield will be determined at each stage. This will not be a constant but will depend on a number of factors including the current stage in the fabrication process. If at a particular stage in the IC fabrication process, the predicted yield is greater than this acceptable yield then the process parameters for the future stages will not be modified, otherwise one or more of these process parameters will be modified so as to meet the yield criterion.

4. TESTING

We have started a research effort to develop a new methodology and associated software tools for the testing of MOS VLSI circuits. Most of the existing fault modeling and test generation techniques are based on the traditional scenario of putting many TTL SSI/MSI packages on a printed circuit board. It is believed that the efficient and effective testing of MOS VLSI circuits requires the development of new approaches and tools. We believe the following three problems associated with traditional testing must be addressed.

1. **Technology independent fault model.** Regardless of the implementation technology, the single line stuck at fault model is the most widely used fault model. We believe that, for VLSI testing, the fault model should be based on the physical defects and should take into account the technology, layout, and process characteristics.
2. **Unranked fault list.** Traditionally, the relative importance of different faults is not considered. We believe that not all faults are equally likely or equally important. It may be more cost effective to rank the fault list and appropriately order the test set so as to detect the most likely to occur faults first.
3. **Single level approach.** Most existing testing methodologies and tools assume the logic gate level model. Although MSI level macros are often used in logic simulators, most systematic test generation algorithms require the gate level representation. We believe, just as in design, a new testing methodology should involve a multiple level or hierarchical approach in order to ease the complexity burden.

As part of our initial step towards the integration of CAD/CAM/CAT, the concept of a manufacturing-based methodology for fabrication testing is being developed. This methodology addresses the above three problems in the following two ways:

- A customized fault list is generated for each circuit being tested. Faults in the list take into account the technology, layout, and fabrication characteristics, and can be grouped into different types depending on the faulty behaviors. Each fault list can be ranked according to relative likelihood of occurrence of the faults.
- Starting with likely defects at the physical level, faults are extracted to the transistor, logic or even functional levels. Test pattern generation is performed separately for different fault types, at possibly different levels. Test pattern composition is then performed to produce the final test set.

The proposed manufacturing-based testing scenario is illustrated in Figure 5. Two ongoing projects in this area are presented below.

Inductive Fault Analysis

F.J. Ferguson, J.P. Shen

Our first project in this area addresses the problem of the inappropriateness of the traditional fault model. Our underlying assumption is that circuit level faults are caused by physical defects which are inherent in the IC fabrication process. A technique called Inductive Fault Analysis (IFA) has been developed which allows the transistor or logic level faulty behaviors of a given MOS integrated circuit to be extracted from the layout level using process level information concerning spot defects [6].

IFA is an example of crossing multiple levels of the design hierarchy and involving elements of CAD, CAM and CAT. It is a systematic fault extraction procedure that spans the process, layout, transistor, and logic levels. A higher level fault model is developed based on conclusions

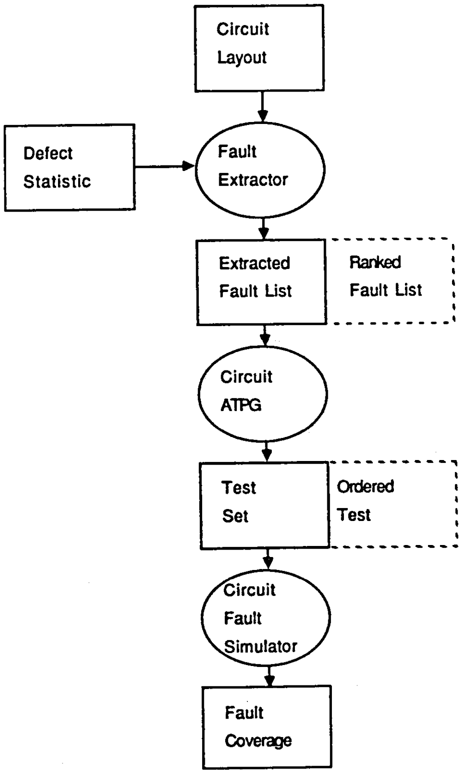

Figure 5. Manufacturing-Based Testing Scenario.

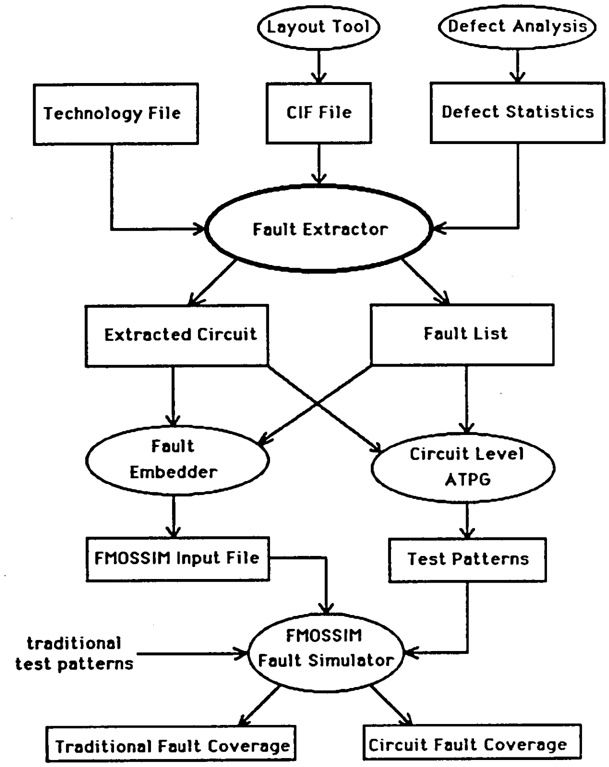

Figure 6. Inductive Fault Analysis Implementation Environment.

drawn from examining particular defects at the lower level, hence the word "inductive".

The four major steps of the IFA procedure are: (1) generation and placement, on the circuit layout, of physical defects using statistical data obtained from the fabrication process; (2) extraction of primitive (geometric) faults caused by these defects; (3) abstraction of these primitive faults to the transistor, logic or even the functional level; and (4) classification of fault types and ranking of faults based on the likelihood of occurrence. Hence, given the layout of an integrated circuit, a customized and very accurate fault model and an associated ranked fault list can be automatically generated which take into account the technology, layout, and process characteristics. A CMOS fault extractor has been implemented. Currently a number of example circuits are being analyzed. The IFA implementation environment is as shown in Figure 6.

Initial application of the IFA procedure to an example circuit led to a number of very interesting observations [6]. Only 64% of the extracted faults can be modeled by the traditional single and multiple line stuck-at fault model. Not all faults are equally likely, and unusual faults, such as the creation of new transistors, are possible. Only 3% of the faults involve transistors stuck at open, whereas 30% of the faults are bridging faults. The IFA procedure can be used to (1) characterize potential faults in a circuit; (2) evaluate the true effectiveness of traditional test sets; (3) provide a basis for more effective test generation; and (4) uncover likely faults that are very difficult to test.

Switch-Level Test Generation

S.H. Robinson, J.P. Shen

This project focuses on automatic generation of test patterns to screen out defective CMOS integrated circuits during fabrication testing. The algorithm developed uses a switch-level model in a search, similar to the D-Algorithm, to find tests for a specified fault list. Backtracking is allowed at each step in the search where multiple alternatives exist, so that if a test exists, it will be found by the algorithm. At the switch-level, transistors are viewed as bilateral switches, and a composite-valued algebra is used to represent the node values within the good and faulty circuits. The switch-level representation of CMOS circuits provides enough detail to model the faults and the bidirectional nature of CMOS circuits while retaining enough abstraction to be computationally efficient [7].

We have implemented this test generation methodology and embedded it within a test generation and test evaluation environment. Using this system, switch-level test generation and fault simulation for several small example circutis has been performed. The fault coverage results are encouraging and suggest that test generation is feasible at the switch level and is a promising area of research.

5. DESIGN ENVIRONMENT

In order to achieve an interactive design automation system that is made up of a set of disparate tools, we must develop a computing environment that has

- the ability to allow various programs that have incompatible input and output languages to communicate with each other;
- the ability to manipulate a variety of hardware description languages and to be able to resolve incompatibilities that may result;
- the ability to organize the flow of information between programs to realize a specified design task;
- the ability to implement automatically a diverse set of design tasks and methodologies;
- the ability to allow the designer to arbitrarily interrupt a design task (such as a specified program execution sequence) and restart or redirect the sequence of operations;
- the ability to explain its sequence of design activities to the designer, and to explain the reasons for particular design decisions;
- the capability of easily introducing new computer aids or tools or substituting newer tools for older ones; and
- the ability to keep track of all design attempts for a particular VLSI chip, and to make some comparison of these attempts, based on quantitative measures.

5.1. EXPERT-SYSTEM BASED ENVIRONMENT

We refer to a computing environment which has the above capabilities as a VLSI design environment. Such an environment, called ULYSSES [8], has been developed and employs AI concepts to achieve the flexibility which the above attributes require.

ULYSSES -- An Expert-System Based VLSI Design Environment

M.L. Bushnell, S.W. Director

The ULYSSES project has created a design environment appropriate for VLSI design. Conceptually, the environment may be viewed as a knowledge-based expert system for choosing which CAD program to execute next. The emphasis here is on controlling existing CAD tools, rather than on writing new ones. Furthermore, the environment is designed so that it will be very easy to substitute new, and hopefully better, CAD tools for existing tools. The environment employs a blackboard architecture originally employed in the Hearsay-II speech understanding system. This architecture is particularly suited for the VLSI problem domain, where many independent CAD tools must be controlled in order to solve various design problems. The *blackboard* is a global data base used for communicating information among various VLSI CAD tools, which are called *knowledge sources.* A language was designed to conveniently describe VLSI design activities, which are called *scripts.* An archival file backup system and a design space are part of ULYSSES. The design space supports comparisons among competing design points, and both the environment and the designer can switch design activities to a different design point when the current one no longer appears viable.

Knowledge-Based Chip Planning

A.M. Dewey, S.W. Director

The objective of this research is to develop computer-aided support for the task of chip planning by utilizing the capabilities of the ULYSSES environment. The chip planning task will assist in the incremental development of more accurate, complete, and consistent chip-level specifications. Chip planning activities can include defining initial functional specifications, studying feasibility issues, and determining realistic performance goals. The purpose of the chip planning activities is to produce a credible chip-level specification that can be used to more efficiently conduct the subsequent detailed IC design and implementation phases. Emphasizing chip planning is in contrast to current design practices where the chip-level specification either simply does not exist or is an informal description which serves only as a guideline for the implementers. Using the chip-level specification as a more formal part of the integrated circuit design process can lead to a more efficient design methodology because major design errors at the specification level are, in general, easier to detect and correct. Thus, chip planning can help to avoid costly redesigns when, halfway into an expensive design cycle, it is discovered that the initial specifications were incorrect, incomplete, or unrealistic.

5.2. USER INTERFACE

With the advent of a design environment such as ULYSSES, we may view the role of the IC designer as that of an intelligent advisor communicating with an "intelligent" design environment. In such a situation, it would become very difficult for the designer to express his intentions in a traditional manner. In order to allow the designer the greatest degree of flexibility in using the design automation system, we feel that a natural language interface is required.

The task of building a natural language interface for CAD is not, unfortunately, simply one of applying an existing AI technology to a new domain. Though the study of previous natural language interfaces is a rich source of ideas, it also underlines the imperfections of these interfaces, and the need for a fresh approach. A key component of a natural language interface is the parser, which analyses a sentence or sentence fragment and produces some kind of structured representation for it. Previous natural language interfaces, in general, have addressed this issue of parsing in rather piecemeal ways. Their coverage of constructions in English (the natural language most interfaces have dealt with) has been motivated and dictated by the domain of application of these interfaces, and not by any systematic study of the structure of English. For the goals of some of these interfaces, these limitations have not been detractions, but they have restricted the utility of the interfaces to other domains. Since most natural language interfaces have been "toy" ones, either restricted to simplified domains, or, by self-admission, never intended for "real" use, their application to substantial problems has always been problematic.

In contrast to the domains for which most natural language interfaces have been intended, the CAD domain is substantial and complex. Hence, we have developed a new approach to natural language understanding. Based on this approach, we have implemented an initial version of a natural language interface called CLEOPATRA [9] that deals with circuit simulation post-processing.

While CLEOPATRA is currently limited to the sub-domain of circuit simulation post-processing, future extensions will gradually address other design tasks. Some of these tasks will not require too much additional programming effort. These include post-processing for functional and behavioral simulators, and data-base query. Our ultimate goal, however, is a natural language interface for our integrated CAD/CAM/CAT environment. A follow-on project to CLEOPATRA is currently being pursued as described below.

An Improved Natural Language Interface for CAD

T.F. Cobourn, S.W. Director

The purpose of this project is to functionally extend CLEOPATRA. Currently, CLEOPATRA is limited to operation in the domain of circuit simulation post-processing. We intend to extend it to handle circuit simulation preprocessing as well. Also, a more user-friendly environment will be developed by integrating the existing system with interactive graphics. The new interface will be tested on designers in industry.

6. CONCLUSION

The SRC-CMU research center for CAD has been in existence for four years under the directorship of S.W. Director, and has a broad-based program aimed at developing an integrated approach to CAD, CAM and CAT of VLSI circuits and systems. Special emphasis has been placed on the investigation of appropriate AI techniques, and the development of manufacturing-based CAD and manufacturing-based CAT. A number of tools have already resulted from these activities; see Table 1. We anticipate the release of a number of additional tools in the near future as well as an environment in which these tools will communicate with each other.

RESEARCH IN RELIABLE VLSI ARCHITECTURES AT THE UNIVERSITY OF ILLINOIS

Jacob A. Abraham

Computer Systems Group
Coordinated Science Laboratory
University of Illinois at Urbana-Champaign
1101 West Springfield Avenue
Urbana, IL 61801

ABSTRACT

A major research program in the design of reliable VLSI architectures is underway at the University of Illinois. The program involves twelve faculty and over thirty graduate students, and addresses issues of testing and diagnosis, concurrent error detection, and fault tolerance. This paper provides an overview of the research directions and describes selected research topics.

INTRODUCTION

Advances in Very Large Scale Integration (VLSI) technology are making possible the manufacture and use of very complex chips and systems. Unfortunately, it is becoming increasingly difficult to ensure that the products are free from manufacturing defects and that they will operate reliably in the field.

The University of Illinois has been active in the field of reliable systems for over 25 years. A major research program is now underway in the design of reliable VLSI architectures with funding from the Semiconductor Research Corporation (SRC) and its member companies. The goal is to find innovative solutions to the problems of quality in integrated circuits. The research program is very broad, addressing areas of testing and diagnosis for both manufacturing defects and field failures, concurrent (on-line) error detection to ensure reliability of computations, and fault tolerance and reconfiguration for bypassing defective or failed modules in a system.

TESTING AND DIAGNOSIS

The complexity of VLSI is making it increasingly difficult to derive high-quality test patterns which will expose defects and failures in chips and systems. Even the problem of grading the fault coverage of test patterns for today's complex chips, such as microprocessors, is beyond the capability of existing tools. The contradictory requirements of addressing realistic failures at the circuit level and, at the same time, the ability to handle chips with hundreds of thousands of transistors, make it seem that it will be almost impossible to solve the testing problem.

Our approach to this problem is two-pronged: the first step is to develop techniques and tools which can derive accurate tests or grade test patterns for realistic failures in relatively small modules and cells. The second step is the development of techniques and tools which exploit the hierarchy present in complex systems to derive tests for them, using the results of the accurate characterization of the modules in the first step. We believe that this will enable us to tackle the testing problems of the next generation of VLSI.

We have developed techniques for generating tests for realistic failures (such as shorts and opens) in MOS circuits [1]. Techniques for reducing the number of faults which need to be considered have also been derived [2]. These techniques produce a set of candidate tests for a module. These tests can be checked for their effectiveness under practical circuit operation (including effects of charge sharing, etc.) using a fault simulator.

We have developed an MOS fault simulator, FAUST, which produces output waveforms for circuits under realistic physical failures [3]. This simulator can thus be used to check whether physical failures are, indeed, detected by tests generated by any of the proposed algorithms and to obtain fault coverage for realistic failures. This tool was used to identify some problems with testing CMOS circuits.

We have determined, using our tool, that tests for shorts or opens in CMOS circuits may be invalid if they were derived using only logic-level considerations [4]. Our approach was to attempt to derive tests using various proposed techniques and to use our fault simulator to determine whether the fault under consideration was, indeed, detected. Some examples of problems with tests are given below:

(1) A logic-level test may not detect a failure because of its electrical behavior.

(2) A fault deemed undetectable because of assumptions regarding resistances may actually be detectable.

(3) A test may be invalidated under variable delays in the circuit.

(4) A test sequence may not detect a failure because of charge sharing in the circuit.

(6) Faults in latch circuits may be detectable only with a long test time.

(7) Faults in sequential circuits may be detectable only by carefully controlling the input timing.

Acknowledgment: The research program in Reliable VLSI Architectures is funded by the Semiconductor Research Corporation (SRC) under contract number 84-06-049 and by grants from SRC member companies.

It was clear from the study that tests for the submodules must be carefully designed. In particular, detailed parameters such as transistor sizes and node capacitances need to be used, since tests for some faults are critically dependent upon them. This was shown to be true even for simple failures such as shorts and opens.

Current fault simulation techniques, such as parallel fault simulation, are not powerful enough for today's very large integrated circuit designs because simulation algorithms show second-order effects. More powerful fault simulation techniques are needed to prevent a crisis in integrated circuit testing. Our research attempts to improve simulator performance through the use of new algorithms and data structures in order to overcome the current limiting factors in fault simulation. We have developed a new fault simulation technique which uses fault lists for primitives; these can be accurately produced by a transistor-level simulator such as FAUST.

Our approach to improving simulator performance has focused on reducing both the space and computation requirements of fault simulation. We substantially reduce the space required by representing the circuit as the combination of a hierarchy and tree, and simulate directly from these structures without flattening the circuit. The hierarchy is used to store invariant information such as module name, number and order of inputs and outputs, and composition in terms of other modules (macromodules). The tree structure is used to store information which is unique to each instance of a module, such as state and undetected faults. As each fault is detected, it can be removed from consideration, which reduces the total number of faults under consideration and speeds up the simulation. While improving performance, this also allows the simulator to report the current fault coverage after every stimulus, if desired. The fault coverage can either be computed for each stimulus or cumulatively for a sequence of stimuli.

These ideas resulted in the development of CHIEFS, a Concurrent, HIerarchical, and Extensible Fault Simulator [5]. A hierarchical partitioning scheme was incorporated to improve the performance; measurements show that it can dramatically speed up fault simulation (6000% on a 24 x 24-bit multiplier). An analytical model which predicts speedup due to concurrent hierarchical fault simulation has been derived; the predictions closely follow experimental results. Figure 1 shows the major components of CHIEFS. The circuit description and fault library are maintained separately. The wrapper can be used to compress a set of interconnected primitives into a single, more complex primitive. This can drastically decrease fault simulation time by reducing the number of primitives. Work is now underway on the test generator which will also exploit the hierarchy in the circuit.

We are also addressing the problem of deriving short but thorough tests for regular structures (useful for VLSI) such as iterative logic arrays and tree structures [6], as well as the design of circuits for easy testability. The problem of hardware support for fault simulation is being researched [7]. Methods for designing circuit structures for higher reliability, for example, to prevent single-event upsets [8], are also being studied.

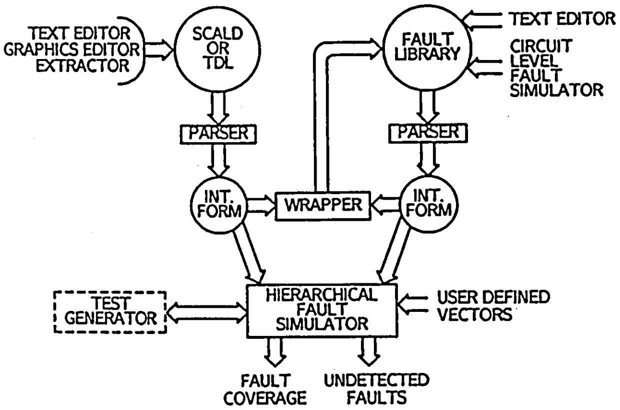

Figure 1. Major components of CHIEFS.

CONCURRENT ERROR DETECTION

Reports from the field and experimental studies indicate that the predominant failure mode in systems is due to transient rather than permanent failures. In these cases, systems should be designed with the capability for detection of errors in the computation concurrently with normal operation, since off-line testing will not necessarily detect transient faults.

A method of Concurrent Error Detection (CED) through exploitation of highly structured VLSI hardware and software module design has been developed [9]. The complexity of current hardware and software systems has encouraged the design of systems that exhibit a high degree of structural regularity. Highly structured design provides an opportunity for comprehensive CED through encoding algorithms that are designed to take into account the structural regularity of the hardware or software module. This method of encoding inputs and outputs of a module such that the module structure is included in the encoding is referred to as *structure encoding*.

Specific forms of highly structured logic arrays have been shown to be strongly fault secure and strongly code disjoint if they were programmed to implement a novel form of input/output encoding developed in this research. This encoding approach allows the use of one checker to detect errors caused by faults on inputs, outputs, or within the array itself. The approach can be modified to reduce the cost of the code-word checker by employing fault-avoidance techniques in the array design. Faults which cause unidirectional errors in the outputs rather than single-bit address or data errors can be avoided by appropriate mask-level layout rules. Such a technique has been employed for PLAs and ROMs in the design of a low-cost approach to CED in these arrays. Figure 2 shows an application of this technique.

Two classes of multistage interconnection networks have also been analyzed. Encoding schemes have been proposed for delta networks and centralized control networks that provide for comprehensive error detection. An example application of the proposed CED techniques to a mask-level design of an nMOS microprogram control unit

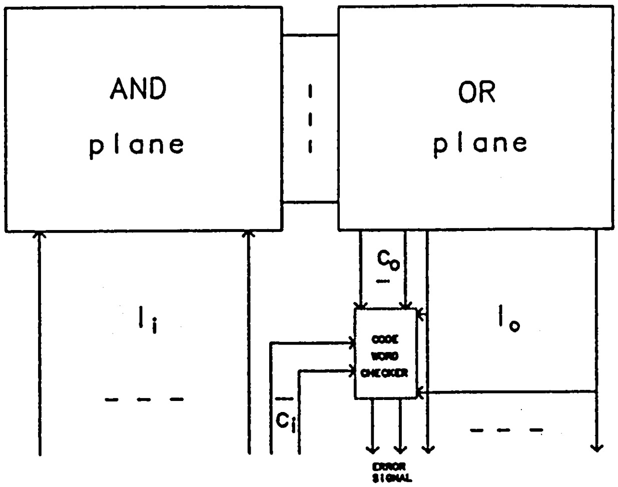

Figure 2. CED Technique for a Programmable Logic Array (PLA)

has been completed and evaluated. Implementations exhibiting a high degree of structural regularity were shown to result in cost-effective CED. These ideas have been extended to the use of structural encoding techniques to detect errors in the structural integrity of linked-data structures. Two techniques of distributed and appended checks, as well as signature access path checking, have been developed for concurrent detection of pointer errors.

We have also developed a novel technique for CED which uses time redundancy, called Recomputing with Shifted Operands (RESO) [10]. Figure 3 shows the application to a general Iterative Logic Array (ILA). The array computes the result twice, once with the normal operands and once with shifted operands. It can be shown that, with the appropriate amount of shifts, any fault in the array will affect different parts of the result in the two tries, causing the error to be detected by the checker.

Ongoing research involves the design of CED capability in complex systems using both space and time redundancy, as appropriate.

FAULT-TOLERANT SYSTEMS

Classical approaches to fault tolerance use large amounts of redundancy to correct or mask errors; an example is triplication with voting. We have developed an exciting new concept which we call *algorithm-based fault tolerance* for obtaining reliable results when computations are performed using multiple computation units (such as array processors). In this scheme, algorithms have their output encoded in a system-level error-detecting or error-correcting code. The algorithms rearrange the computations so that any failure in part of the system will only affect a portion of the result, enabling the correct result to be extracted from the encoding. This technique has been used to design low-cost fault-tolerant systems for matrix operations [11] and signal processing [12].

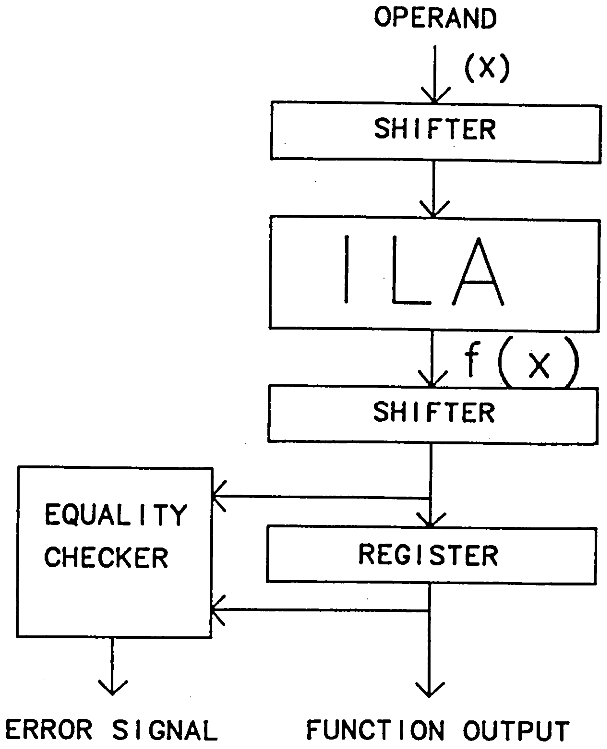

Figure 3. Recomputing with Shifted Operands (RESO).

Figure 4 shows a one-dimensional processor array for matrix-vector multiplication, $AX = B$. $A_{i,j}$ is encoded with a column checksum, where $a_{5j} = \sum_{i=1}^{4} a_{i,j}$. The matrix element $a_{i,j}$ is stored in the local memory of the ith processor at the jth time step, and x_j is broadcast to each processor at the jth time step. Each processor multiplies n pairs of $a_{i,j}$ and x_j and accumulates the products in a register. Each processor thus calculates one element of the result vector and the faulty processor affects only one element. Any error can, therefore, be detected using the fact that there is a checksum on the result. The error can be corrected and the faulty processor identified by appropriately repeating the computation on the set of processors.

Figure 4. Checksum matrix-vector multiplication performed in a linear array.

Figure 5 shows the application of algorithm-based fault tolerance to an FFT processor [13]. The encoding uses the principles of superposition and circular shift, and it can be shown that errors due to any failure of one butterfly module will be detected by the comparator. The error can be corrected by repeating the erroneous computation with a different encoding of the data. This faulty module can also be identified at this time. If spare modules and switches are incorporated in the design, the system can be reconfigured around the faulty module.

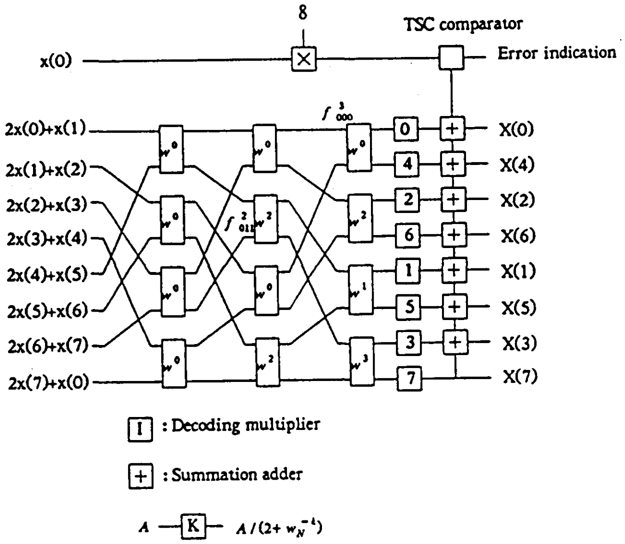

Figure 5. Algorithm-based fault tolerance in an FFT processor.

The hardware and time overheads for algorithm-based fault tolerance are very small compared with conventional techniques. This scheme is being extended to achieve fault tolerance in other signal processing systems, including those for singular value decomposition and calculation of eigenvalues. Attempts are underway to apply these ideas to more general-purpose systems.

Other work in fault tolerance involves the design of reconfigurable systems [14] and techniques for yield enhancement [15]. We feel that this research effort will result in the identification of novel, low-cost fault tolerance techniques for the next generation of VLSI.

ABSTRACT

The broad spectrum of expertise in the Department of EECS at Berkeley provides a stimulating and fertile environment for productive research in all aspects of VLSI. We report on a recent large-scale project that focussed on the development of a suite of synthesis tools in the context of the design of a chip set for a multiprocessor workstation.

INTRODUCTION

For more than two decades the EECS department at U.C. Berkeley has had strong activities in the area of integrated circuits and CAD tools for IC design and more recently also in VLSI architectures. Particularly exciting results are obtained when all of these areas start to interact. In the past, the RISC[1,2] and the SOAR[3] processors developments were strong forcing functions for our CAD environment, leading to such crucial tools as fast circuit extractors, design rule checkers, timing verifiers, PLA optimizers, and interactive layout editors.[4] Often the development of these tools occurred in response to a crucial need of a design job already in progress. This orientation towards getting real problems solved naturally shapes the nature of our tools. On the other hand, the available tools determine the scope of the designs we can hope to complete successfully.

This paper focuses on the most recent and very exciting interaction of the aforementioned VLSI research areas. In recent years the attention given to *synthesis* tools has been growing steadily. During the academic year 1985/86 this activity culminated in a coordinated effort referred to as the 'Synthesis Project'. Organized around a few graduate courses, the "official" goal of the project was to automate the design of digital integrated circuits by enhancing and integrating the various existing synthesis tools into a cohesive framework, and to create first prototypes for the missing links. The final objective is to create tools that perform as well or even better than human designers in each phase of the design process, from behavioral specification, through logic synthesis, to module generation, automated place and route, and final layout generation for a particular fabrication process.

PROJECT ORGANIZATION

In our department there is a tradition of strongly integrating research and instruction at the graduate level. Some part of a long-term research project with a well defined sub goal is made the subject of a special project-oriented graduate course. The structure of formal lecture and meeting times, combined with the hard deadlines for grades at the end of the term, often produce substantial results in a relatively short time. In the past, a lot of exploratory work has been carried out in that manner, and the best approaches were subsequently refined and implemented as MS or PhD work.

The Synthesis Project mentioned above was organized around several courses. It formally involved over forty graduate students, seven industrial visitors, and three regular faculty members. In addition many other students and faculties contributed in a substantial manner as guest lecturers or through technical discussions. The project had two distinct phases.

A preparatory phase from August through December 1985 used a regularly scheduled graduate course (EECS 244) to prepare students for the actual tool development and chip design. All aspects of IC synthesis from floorplanning, placement and routing, to automated logic design, and procedural layout were reviewed. Existing approaches to automating the design process in each area were presented, contrasted with other approaches, and classified. Data management techniques were introduced, and the students had to familiarize themselves with the *OCT* data manager.[5] All students in the course had to develope working tools and interface them to this data management system.

The second phase of the Synthesis Project took place from January through May 1986. Again, the project was

CH2345-7/86/0000/0894$01.00 © 1986 IEEE

embedded in our instructional schedule. Formally, a design-oriented graduate course (CS 292H) and a CAD tool-oriented course (EECS 290H) were used as the organizational framework, and all participants had to enroll in both courses. In the *design class*, each student was a member of one of three chip design teams. In this capacity everybody was responsible for the design of a specific module on one chip and shared responsibility for the overall function of the chip. In the other course, the *CAD class*, each student was a member of one of several CAD tool groups (e.g. logic synthesis, place and route, module generation) and was involved in developing a CAD tool suite that would be usable for all chips. This matrix organization exposed each student to the system aspects of the design process — developing a model and the detailed information flow for a given design style as well as the specific, algorithmic aspects of a particular class of tools. The students uniformly agreed that this organization was very useful in helping them gain an overview of the design process and in clarifying the function each tool must perform.

As in the past, we found it important to tie the development of new tools to a real design project; this helps to formulate realistic and practical specifications for each tool's function, interface, and performance targets. The obvious choice was to select the SPUR project[6] that had been in progress for about a year. This project concerns the development of a multiprocessor workstation for 'Symbolic Processing Using RISCs'. It presented an honest challenge in terms of complexity, as the chip set to be developed consists of three chips with over 150,000 transistors each: the central RISC processor chip (CPU), a cache controller chip (CCU), and an IEEE-standard floating-point chip (FPU). The main goal in teaming up with this project was that we had access to the architects and original implementors for consultation and that we hoped to obtain large parts of chip descriptions in a machine-readable form.

OUR SYNTHESIS SYSTEM

One of the basic requirements of our CAD environment is that it be flexible and extensible. It must be useful for the design of a wide class of circuits, from operational amplifiers to microcomputers, and the system should be able to respond do changing needs as our understanding of the VLSI design process matures. Our general approach is thus a modular set of tools, all interfaced to a common database. In this section we give a brief overview over the database and the various groups of tools addressed in the Synthesis Project.

Our automated synthesis process currently starts at the register-transfer level and converts a behavioral description into state machines, Boolean logic, and registers. The final layout is created by iteration between two groups of tools. Global placement and routing tools are used to outline the floorplan of the chip and produce desirable aspect ratios for the various modules of which the floorplan is composed. A variety of module generation tools then create the individual functional blocks, first at the symbolic level and then as properly spaced dense layouts. These finished macro modules are then reinserted into the floorplan and properly interconnected. Some tools such as a general spacing program may play a role in both phases, first compacting transistors into a dense module, then compacting symbolically routed channels to minimal physical width.

Framework and Infrastructure

To simplify the integration of our tools, we chose to use a single object-oriented data management system, *OCT*, the development of which had started some time ago.[5] OCT has as its basic unit the *cell* which can have many *views* — physical, logical, symbolic, geometrical. A cell is a portion of a chip that a designer wishes to abstract and can vary in size from a simple transistor to the entire floorplan of a CPU. The system is hierarchical, i.e., cells can contain instances of other cells. Moreover, cells can have different abstract representations depending on the intended application, and these are represented in OCT by *facets*, the accessible units that can be edited. OCT provides powerful constructs for complex data structures but manages this complexity unseen by the user.

A graphical CAD shell, *VEM*, was developed that permits the user to inspect and alter the contents of the various cells in the data base in a natural manner. OCT also provides project management support in the form of change-lists, time stamps, and search paths. All evolving synthesis tools were provided with interfaces to the OCT data manager.

Logic Synthesis

The high-level entry point to the design system is a register-transfer-level description of the chip. After evaluating a number of alternatives, we decided to use the ISP-based Behavioral Description Language (BDS) for this purpose. BDS is one of the languages used in the *DECSIM* mixed-level simulation system developed by Digital Equipment Corporation. Digital agreed to provide access to DECSIM during the Synthesis Project which gave us the possibility to use the mixed-level features of the program (behavior, register, logic gate, and switch-level simulation modes) to refine our designs. (During the course we did not get far enough to use all these options.)

In the logic synthesis tool suite,[7] the DEC BDS description is mapped by a language translator into BDSYN, a subset of BDS developed to represent logic partitioned into combinational blocks and latches. From there, another translator maps the BDSYN description into BLIF, the Berkeley Logic Intermediate Format, by expanding high-level constructs into Boolean equations. The BDS to BDSYN translation determines from a BDS description a combinational logic network equivalent to the BDS description.

MIS, a multilevel interactive logic synthesis program, then restructures the equations to minimize area and to attempt to satisfy timing constraints. MIS first implements global optimization steps that involve the factoring of Boolean equations and multiple-level minimization. Local optimization is then performed to transform locally each function into a set of implementable gates. Finally, MIS includes a timing-optimization phase that includes delay approximation based on technology data and critical-path analysis.

Module Generation, Topology Optimization

Once the logic equations have been optimized and the floorplanning tools have provided first targets for optimal aspect ratios and pin positions for the logic modules, the module generators are responsible for optimal packing of the logic into regular or irregular array-based structures.[8] These tools must also consider slack times for critical paths. If any of the objective functions (area, aspect ratio, timing) cannot be met, the floorplanning and/or logic synthesis steps can be repeated.

TOPOGEN generates a standard-cell-like layout at the symbolic level from a description of a Boolean function in the form of nested AND, OR, INVERT expressions.[9] This form is converted in a straight-forward manner into a group of series / parallel blocks of FETs in a complex static CMOS gate. The transistor placement occurs in pairs on two strips of diffusion of N- and P-type, respectively. The sequence of transistor pairs is optimized to minimize the length of the diffusion strips by maximizing the sharing of source / drain areas between adjacent transistors,[10] and to minimize the width of the wiring required between them. The output from TOPOGEN can be inspected and modified with EDISTIX, a graphic editor using a symbolic description on a virtual grid.[9] The symbolic layout can then be sent to one of the compactors mentioned below.

A more sophisticated module generator is the combination of GENIE and MKARRAY.[8] GENIE is a fairly general software package using simulated annealing to optimize the topology of a wide range of array design styles, including PLAs, SLAs, Gate Matrix, and Weinberger arrays. It handles nonuniform transistor dimensions, allows a variety of pin-position constraints, approximates desired aspect ratios by controlling the degree of column folding, and performs delay optimization. Its output is sent to the array composition tool, MKARRAY, which takes specifications of arrays of cells in a topological format. It then places the cells and aligns and interconnects all the terminals.

Layouts of existing cells, or cells where there is a special, optimized implementation that cannot be captured properly at the behavioral level (e.g. multi-ported register cells, barrel shifter), can be introduced into the system either via some adhoc *disassembly* tools, or directly through one of the editors VEM or EDISTIX.

Layout Generation

The modules at the symbolic level have to be spaced or compacted to a dense layout obeying a particular set of design rules.[11] SPARCS is a new constraint-based IC compaction tool that provides an efficient graph-based solution to the spacing problem. It can deal with upper bounds, user constraints, even symmetry requirements. It detects of over-constrained elements, and permits adjustable positioning of noncritical path elements

Another symbolic compactor under development, ZORRO, works in two dimensions and is derived from the concept of *zone refining* used in the purification of crystal ingots. The crystal is slowly fed through a zone of intense heat that locally melts the ingot. Since the generic crystal atoms recrystallize faster than other atoms, most impurities are swept out of the ingot with the molten zone. Similarly ZORRO passes an *open zone* across a precompacted layout. Circuit elements are taken from one side of this zone and are then reassembled at the other side in a denser layout. Early results obtained with ZORRO have shown reduction in layout area of up to 30% after the application of a one-dimensional compactor.[12]

Floorplanning, Place, and Route

These tools are first used to plan the chip layout and to produce optimum size and aspect ratios targets for all the modules. After the physical layouts of all the modules have been generated, the tools are used again to assemble the complete chip. Various tools have been developed to perform module placement, channel definition and ordering, global routing, and finally detailed routing.[13] These tools can handle routing on multiple layers as well as over-the-cell wiring.

TIMBERWOLF-MC [14] performs the placement function using the principle of simulated annealing. This program handles cells of arbitrary rectilinear shape; it accommodates fixed or variable shapes with optional bounds on aspect ratio, and accepts fixed, constrained, or freely variable pin locations.

CHAMELEON[15] is a new multi-level channel router that allows the specification of layer-dependent pitch and wire widths. It has as its primary objective the minimization of channel area and as its secondary objective the minimization of the number of vias and the length of each net. On two-layer problems it performs as well or better than traditional channel routers.

MIGHTY[16] is a 'rip-up and reroute' two-layer detailed switch-box router that can handle any rectagon-shaped routing region with obstructions and pins positioned on the boundary as well as inside the routing region. It outperforms all the known switch-box routers and even performs well as a channel router on problems with a simple rectangular routing region.

Analysis, Verification, and Testing

Throughout the design process, tools for analyzing and verifying performance and function are essential. The Synthesis Project did not make a major push for new tools in this area and used mostly tools that were already available.

With respect to testability we tried at the beginning of the Spring course to establish some clear policies about a design style that would guarantee testable chips.[17] The plan was to follow a scan-in / scan-out strategy.[18] However, some of the predesigned cells from the SPUR group, which we wanted to reuse because of their compactness, did not adhere to this philosophy. Other design teams did not like the extra space taken up by the more complicated scan latches and refused to use them. No consensus was reached on this point during the duration of the course. This is clearly an area that needs more attention, better tools, and much more work.

HARDWARE ENVIRONMENT

When over forty CAD developers and chip designers are working jointly on a major tool and circuit development project, a tightly coupled, highly interactive computing environment is essential. To support this course, we used an extensive collection of ethernet-based workstations and mainframe computers, running both the UNIX (Ultrix) and VMS operating systems. Our backbone machine was a VAX 8650 CPU with approximately 500 Mbytes of disc storage available to the course. This machine was our central design database server, the repository for CAD tools, both new and old, and the main electronic 'meeting place' for the participants in the Synthesis Project. In addition, seven color VAXStationII/GPX workstations and twelve monochrome VAXStationII machines were dedicated to this course. Two of these machines, used as DECSIM servers, ran the micro-VMS operating system and were tied to the other workstations via DECNET. The network capabilities allowed us to run VEM on any particular machine, while the OCT data management software could reside on any machine on the network.

RESULTS

Fifteen weeks is not enough time to build a complete synthesis system (not even at Berkeley). Thus we could not "press the button" on the last day of class and watch the layouts for the three SPUR chips pop out of the computer.

After the fifteen-week course period, all three chip designs had been converted from their original descriptions in 'N.2' or SLANG formats to BDS and inserted into our data management system. In the last weeks of the course, these descriptions were then used to exercise the pipeline of tools that had been created in parallel. Major parts of these designs have run through various tool groups and produced results of widely varying quality. Improvements were quite visible as the tools were debugged and improved.

The major benefit of this course is a very good understanding of the bottlenecks and missing links in our system and concrete plans to overcome these deficiencies. Over all, the Synthesis Project of Spring 1986 must have been a positive experience; the students polled at the end of the term voted strongly in favor of continuing the Synthesis Project in the Fall term.

CONCLUSIONS

The EECS Department in Berkeley offers a very exciting environment for research in VLSI. Circuit wizards, experts on IC processing, CAD tool builders, computer architects, and theoreticians pointing out the fundamental limits, within which the solutions must lie, are all within the same department and are strongly interacting in a cooperative manner. The quality of the chips and tools being constructed at Berkeley would not be as high as it is without this cooperative interdisciplinary interaction.

ACKNOWLEDGEMENTS

We would like to thank our colleagues who helped us, directly or indirectly, to create a powerful CAD environment and thank all the users for their patience with tools that are still far from perfect.

The development of our CAD tools is strongly supported by the Semiconductor Research Corporation, by Digital Equipment Corporation, and by Tektronix.

DEFT - A DESIGN-FOR-TESTABILITY EXPERT SYSTEM

M. Arif Samad J. A. B. Fortes *
School of Electrical Engineering
Purdue University
West Lafayette, IN 47907

ABSTRACT

DEFT is a knowledge-based program which uses Design for Testability (DFT) knowledge to modify circuits into more easily testable circuits. This paper describes the DEFT system and gives an example of its operation. The paper begins with a review of previous research in automated design for testability and then presents an overview of the operation and organization of the DEFT system. This includes a discussion of the Prolog-based knowledge representation scheme used to describe DFT knowledge. The demon mechanism is described which allows DEFT to make use of Lisp functions to handle low-level implementation details. This mechanism allows DEFT to benefit from a high-level representation without sacrificing either efficiency or ease of implementation. An example is presented of an 8 X 8 multiplier to which DEFT adds a scan path. The implementation of the DEFT system is currently in progress. The last section of the paper reviews the status of the implementation effort.

1. INTRODUCTION

DEFT is a knowledge-based design for testability system which accepts as input the description of a circuit that has been designed without any testability features and modifies it into an easily testable circuit. DEFT is designed to work in conjunction with the IBM MVISA Design Automation System recently installed at Purdue University [25]. The MVISA system allows for the design of integrated circuits using standard cells ranging from and/or gates to arithmetic logic units. The transformation of a logical design using these standard cells into a physical design, i.e. a chip layout, is done largely automatically. DEFT takes as input a circuit description created using the MVISA system, adds hardware and makes other modifications to the circuit and then returns a description of the modified circuit to MVISA. In this way, design for testability is incorporated into the design cycle with little effort on the part of the circuit designer. DEFT is able to provide the user with an explanation of its behavior and of related design for testability concepts. The knowledge that enables a program to exhibit expert problem-solving behavior is often not sufficient for the purpose of explanation. Generally, it is necessary to include extra "support" knowledge in the knowledge-base expressly for the purpose of explanation. The DEFT knowledge-base contains a representation of general testability concepts and principles, in addition to specific design for testability schemes. This enables DEFT to provide the user with meaningful explanations of its actions during the course of problem-solving. The DEFT explanation facility is described in greater detail in [27].

This paper begins with a discussion of the motivation for using the knowledge-based systems approach for DEFT. This is followed by a review of previous research in automated design for testability. The architecture of the DEFT system and the knowledge representation scheme used are then examined. An example is then presented of a circuit to which DEFT adds a scan path. The paper concludes with a review of the implementation status of the system.

2. KNOWLEDGE-BASED SYSTEMS IN DESIGN FOR TESTABILITY

2.1. DESIGN FOR TESTABILITY

Design for Testability refers to a collection of techniques that can be used to make integrated circuits easier to test [29,9,4,28]. There are a number of different classes of DFT techniques which focus on different kinds of testability problems, e.g., memory test, PLA test etc. Many DFT techniques are concerned with controlling the memory elements of sequential circuits so that test pattern generation programs for combinational circuits such as those based on the D-Algorithm [26] can be used. Examples of such schemes include LSSD [8], Scan Path [10] and Random Access Scan [2].

There is increasing interest in designing circuits with additional test hardware so that they are able to test themselves. This capability is called Built-In Self-Test (BIST). Many of the ideas developed in connection with the DFT schemes mentioned earlier are relevant to BIST. For example, many BIST schemes make use of the scan path idea [20]. In general, BIST circuitry consists of hardware for test pattern generation and response analysis [23,24]. The most common configurations use linear feedback shift registers to generate test patterns and capture the circuit response, e.g., BILBO [21,22].

2.2. MOTIVATION FOR USING A KNOWLEDGE-BASED SYSTEM

Part of the motivation for designing DEFT as a knowledge-based system, i.e. a system with a distinct knowledge-base constructed using a formal knowledge representation language, came from the nature of design for testability knowledge. The DFT domain is characterized by a large variety of problems, with several possible solutions to each problem. Moreover as technology develops, new testability problems arise. Since testability knowledge is dynamic, it is important that the knowledge

* This work was supported in part by a grant from the AT&T Foundation

CH2345-7/86/0000/0899$01.00 © 1986 IEEE

in an automated DFT system be observable so that the system can be modified easily.

A second motivating factor in using the knowledge-based approach was a desire to incorporate an explanation capability in DEFT. In order for a system to produce meaningful explanations, it must include not just the knowledge used to implement a DFT scheme but also some of the principles and motivations underlying these schemes. Since these motivations are often abstract and complex in nature, it was felt that the flexibility and power of AI-based knowledge representation schemes could be put to good use.

A somewhat philosophical reason for using formal knowledge representation was the desire to codify DFT knowledge in a form that was meaningful to humans but was still rigorous enough for use by a computer system. The advantage of using a relatively high-level language to express knowledge is that the knowledge-base developed can conceivably be used by different programs. For example, the rules used by DEFT describing different DFT schemes could be used by a different program, say a silicon compiler, that needed DFT knowledge.

Recently a number of knowledge-based automated design for testability systems have been presented in the literature. The next section briefly reviews some of this work.

2.3. PREVIOUS RESEARCH IN KNOWLEDGE-BASED DFT

The pioneering effort in the field of knowledge-based DFT systems was the work done by Paul Horstmann as part of his doctoral research at Syracuse University [14,15,16,17,18]. Horstmann used Prolog to implement a system with testability rules that were able to detect and remove violations of the LSSD DFT methodology.

Breuer and Zhu describe the PLA-ESS system that helps choose a DFT methodology for a PLA [5]. The PLA-ESS system uses an evaluation matrix containing the tradeoffs for various DFT schemes for PLA's to choose an appropriate scheme. In case no scheme can be found that satisfies all the criteria specified by the user, the system uses a strategy called Reason Analysis Directed Backtracking to see if some of the criteria specified by the user can be relaxed in order to fit the capabilities of the existing DFT schemes known to the system.

The Testable Design Expert System (TDES) was developed by Abadir and Breuer to work with the Advanced Design Automation System (ADAM) under development at the University of Southern California [1]. The input to TDES consists of a register-transfer-level description of a circuit as well as design goals and constraints. The TDES knowledge-base is organized into Testable Design Methodologies (TDM's) that are implemented as frames.

Fung, Hirschhorn and Kulkarni describe an automatic design for testability (ADFT) system that works in conjunction with the Silc silicon compiler being developed at GTE Laboratories [11,12]. The Silc ADFT system consists of testability rules which are built into Silc's parsing and logic synthesis software, the Testability Evaluator which identifies hard to test parts of the design being synthesized and the Testpert which proposes changes to the design.

As the preceding description shows, significant progress has been made in the area of knowledge-based design for testability. The following section presents the operation and organization of the DEFT system.

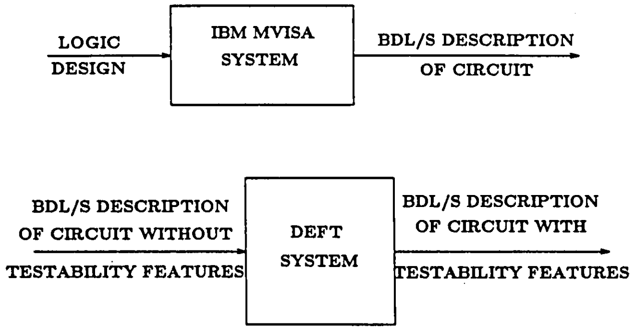

Fig. 1. The IBM MVISA System and DEFT

3. THE DEFT SYSTEM - OPERATION AND ORGANIZATION

3.1. SYSTEM OPERATION

DEFT attempts to incorporate testability considerations into the integrated circuit design cycle without excessively burdening the chip designer. The prototype works in conjunction with the IBM MVISA design automation system recently installed at Purdue (Fig.1). The MVISA system allows the integrated circuit designer to implement his design using standard logic elements such as arithmetic logic units, registers, etc. The designer is responsible mainly for the logical design of the circuit: the mapping of the logical design to a physical design (mask image) is performed with minimal designer intervention. The MVISA system uses IBM's Basic Design Language for Structure (BDL/S) to describe the circuit being designed. The inputs to DEFT consists of a BDL/S description of the circuit which is to be modified to improve testability and a statement of the testability objectives such as fault coverage, hardware overhead, etc. DEFT uses these objectives to choose a DFT scheme and then modifies the circuit to improve testability. These modifications generally consist of the addition of hardware to facilitate test. The added hardware is purely for testability purposes and the circuit function remains unchanged. After DEFT has decided what modifications to the circuit are appropriate, it uses its knowledge of how to implement the chosen DFT scheme to modify the circuit. A new BDL/S description of the circuit is then produced which can be fed back to MVISA. In this way, design for testability is incorporated into the design cycle with minimal intervention from the designer.

After DEFT has finished modifying the circuit, the user can request the system for an explanation of the reasoning steps underlying the suggested changes. DEFT uses a mixture of text and graphics to explain its behavior. The system user can not only query DEFT about the specific case that was being worked upon but also examine general testability information related to the case. The DEFT explanation facility makes use of dialogue and computer graphics to explain various testability concepts. The explanation for a concept generally consists of sequences of images, some animated, that attempt to illustrate the concept. The graphics are presented on an AT&T 5620 bit-mapped display. The DEFT explanation facility is discussed at greater length in [27].

The next section analyzes the characteristics of knowledge in design for testability and other engineering domains. This analysis is used as a foundation for the development of an abstract problem-solving architecture which attempts to provide a framework for the expression of knowledge in DFT.

3.2. THE NATURE OF KNOWLEDGE IN DFT

Most problem-solving systems for DFT (and other engineering domains) have the following kinds of knowledge associated with them:

1. **Heuristic knowledge**
2. **Procedural knowledge (non-heuristic)**
3. **Structural knowledge**

Heuristic knowledge often takes the form of advice on what to do given a particular set of circumstances. Heuristic knowledge can be further categorized into **strategic, meta-level knowledge** (which guides the overall problem-solving process) and **microlevel heuristics** (which are useful in dealing with particular steps during the course of solving a problem). In the DFT domain, the knowledge that is concerned with choosing a testability scheme falls under the category of strategic knowledge. An example of microlevel heuristics would be advice about the order in which hardware modifications should be made to a circuit during the course of implementing a DFT scheme.

The non-heuristic, **procedural knowledge** consists of plans or sequences of actions that must be taken to achieve problem-solving goals. Like the heuristic knowledge described above, the procedural knowledge also appears at different levels of abstraction. A plan can be described at a high-level as a conjunction of abstract goals; each of these goals can then be refined into subgoals at lower levels of abstraction, e.g., a scheme for adding a scan path to a circuit (the goal: make complete scan path) can be described at an abstract level as a conjunction of three goals.

```
make complete scan path :-
   replace all non-scannable memory elements
      by scannable memory elements,
   add hardware for scan path and
      scan clocks i/o,
   connect scannable memory elements to
      form scan path.
```

The third category of knowledge is **structural knowledge** about the domain which could include a **taxonomy** and **causal models** of behavior of objects in the domain. In the design for testability domain, the most important objects are circuit elements. Knowledge about how these circuit elements can be classified and how these classes relate to each other would fall in this category. For example, various latches and flip-flops might be classified under the generic term memory elements. Other structural knowledge might include fault-models and how they relate to each other, and how different DFT objectives are related. Circuit simulators and mathematical models describing the impact of increased hardware overhead on yield would fall under the category of causal models.

While it is possible to categorize domain knowledge in DFT in this way, it is not as simple to describe the interaction of the various kinds of knowledge during problem-solving. An ideal problem-solving architecture must allow for completely flexible invocation of the various categories of knowledge as they are needed. In the next section, an abstract problem-solving architecture is presented which allows the different kinds of knowledge discussed above to be represented and used in problem-solving. The organization of DEFT is patterned after this architecture.

3.3. AN ABSTRACT PROBLEM-SOLVING ARCHITECTURE (Fig.2)

The heuristic knowledge in a knowledge-based system is generally best represented using a rule-based scheme with a **forward-chaining** control scheme. Such an architecture is a good model for the data-directed way in which heuristic knowledge is used during the problem-solving process. For each cycle of the production system's operation, the antecedent of each rule in the system is matched against the global-database to see if the rule is applicable. In this way all the rules that are relevant to the situation at any particular time are applied[13].

In contrast, the non-heuristic, procedural knowledge in the system is most appropriately represented using a rule-based scheme with a **backward-chaining** control scheme. In a backward chaining system, a plan or procedure to solve a problem can be represented using an **AND/OR goal tree** [3] which is traversed by the system from the root, which represents the goal to be solved, downwards towards the leaves, which represent various low-level steps needed to achieve the goal.

The plan to solve the goal at the root of the AND/OR tree is represented in abstract terms on the levels of the tree close to the root and becomes more detailed towards the leaves of the tree. This ability to represent procedural knowledge at different levels of abstraction is one of the advantages of the goal tree representation and has important implications in terms of the efficiency of problem-solving, the quality of explanations produced by a system and the ease with which new knowledge can be added to the system.

The structural knowledge in the problem-solving system can be represented using a **frame-based representation** supporting **inheritance of properties[6]**. A frame network can be used to describe both the relationships between objects in the domain and a causal model for behavior in the domain. Other specialized modeling mechanisms such as circuit simulators, mathematical equations, etc, may also be used where appropriate.

Many existing AI tools support one or the other of the knowledge-representation and inference schemes discussed above. An ideal architecture would consist of an integrated package that allowed for the flexible interaction of the various types of knowledge in the system. This system would have the capability to use specialized representations for domain objects where appropriate. An example of such an architecture is shown in Fig.2.

The system has the following components:

1. A **global data-base** - this data-base contains a description of the current problem.
2. The **domain knowledge-base** - this consists of the heuristic, procedural, and structural knowledge described earlier.
3. The **inference mechanisms** - these use the global data-base and the domain knowledge-base to do the actual problem-solving. The architecture shown here

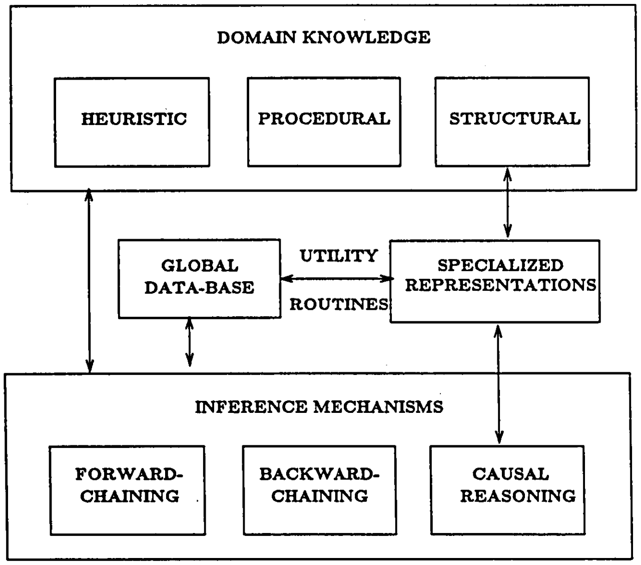

Fig. 2. An Architecture for a Knowledge-Based Problem-Solver

incorporates both forward and backward chaining inference.

4. **Specialized representations** - these consist of efficient representations for domain objects. The term "specialized" is used to distinguish these representations from the knowledge representation scheme being used to represent information in the global data-base. The specialized representations cannot be directly used by the inference mechanisms. For example, DEFT uses a graph to represent the circuit. This graph is represented using a Lisp data-structure rather than Prolog clauses in the global database, allowing for far more efficient operations on the circuit graph.
5. **Utility routines** - these consist of interface routines between the global data-base and the specialized representations. These routines are implemented as demons that watch over the global data-base. When the problem-solving process requires a piece of information that is not present in the global data-base, the appropriate utility routine is triggered and extracts the required information from the specialized representation and then adds it to the knowledge-base. Similarly, the specialized representations are updated by the utility routines to reflect changes in the global data-base. In DEFT, there are a number of demons that use the circuit graph described above to extract any information about the circuit that may be needed during the problem-solving process.

The DEFT system attempts to incorporate many of the ideas presented in the discussion above. The next section presents the DEFT knowledge representation and the demon mechanism.

3.4. DEFT KNOWLEDGE REPRESENTATION AND THE DEMON MECHANISM

DEFT uses a Prolog-based knowledge representation scheme[7]. The DEFT Prolog interpreter is written in Franz Lisp and incorporates a special **demon mechanism** which allows it to interface with Lisp. This makes it possible to use the flexibility of Lisp to enhance program efficiency where necessary. A set of Prolog rules implicitly define an AND/OR graph which is searched in a depth-first manner. DEFT uses Prolog to define AND/OR trees corresponding to different DFT schemes. For example, Fig. 3 shows a set of rules for the DFT modification, **make_complete_scan_path.** These are the rules that are used by DEFT to add a scan path to the 8 X 8 multiplier in the example in section 4. A fragment of the AND/OR tree implicit in these rules is shown in Fig.4.

The rules shown in Fig.3 represent a high-level description of how to make a complete scan path. However, so far we have said nothing about how DEFT actually uses these rules to modify the data-structure representing the circuit under consideration. In the problem-solving model discussed earlier, it was proposed that specialized representations of domain objects be used whenever necessary in order to make an efficient system. In keeping with this philosophy, DEFT represents the circuit under consideration as a graph implemented using a Lisp data-structure. Since DEFT works with actual circuit descriptions from the IBM MVISA system, there is a large amount of information that must be stored and manipulated during the course of implementing a DFT scheme. It is easier and generally more efficient to use specialized data-structures and access routines for this purpose than to represent the entire circuit as clauses in the Prolog database.

Each demon is a Lisp routine that is used by the interpreter as described below. When attempting to solve a goal, the DEFT Prolog interpreter first attempts to use the rules contained in the Prolog database; this is how conventional Prolog operates. However, if the DEFT Prolog interpreter is unable to satisfy a goal using the rules that are contained in the database, it looks instead for a demon corresponding to the goal under consideration. These demons work by adding new clauses to the Prolog database which are then used by the interpreter to satisfy the goal. The demon mechanism can be thought of as a virtual extension to the Prolog database, i.e., demons can be used to access information that is not stored explicitly in rule form in the database whenever it is needed.

The demon mechanism used in DEFT is very similar in intent and implementation to the language FProlog which attempts to combine functional and logic programming [19]. FProlog allows arbitrary Lisp functions to be accessed from Prolog. These functions can return information to the FProlog world by instantiating variables in the FProlog rule for which the function is called. In contrast to this, the DEFT demon mechanism works by adding clauses to the Prolog database as discussed above.

In the rules shown in Fig.3, many of the predicates used in the formulas have demons associated with them, e.g., the predicate "latch" used in the second rule in the set has a demon associated with it (Fig.5). The first time that the predicate "latch" is referenced in a rule the associated demon is triggered. This demon accesses the Lisp data-structure representing the circuit to get a list of latches and then adds a set of facts of the form shown below to the Prolog data-base, one for each latch in the circuit (the names AA100AB and AA100DE are arbitrary).

```
latch(AA100AB).
latch(AA100DE).

       latches)
     (return t)))
```

Fig. 5. A demon for the Prolog clause latch

An interesting and important effect of the demon mechanism is that the it allows the rules used by DEFT to describe DFT schemes to be written in an abstract, technology independent way. For example, the second rule in Fig.3 uses the abstract term "latch". The demon mechanism knows which circuit elements actually used by the IBM MVISA system correspond to the abstract latch. Since the rules themselves make no reference to MVISA circuit elements, they could presumably be used with a different design automation system with the demons appropriately modified.

In addition to endowing the rules with a degree of technology independence, the demon mechanism allows for a description of DFT schemes that is not cluttered by details of how the circuit data-structure is actually manipulated. All that detail is hidden behind the demons. One way of thinking about the demons is that they are equivalent to the routines that would probably make up DEFT had it been developed as a conventional program rather than as a knowledge-based system.

4. AN EXAMPLE - ADDING A SCAN PATH TO AN 8 BY 8 MULTIPLIER

Fig. 6 shows a plot of the chip layout of an 8 X 8 multiplier after it has been modified by DEFT. The modifications to the multiplier include the addition of a receiver for the scan in, a receiver for the A scan clock, a tri-state off chip driver for the scan out, the connection of the A clock to the A clock inputs of the SRL's and the interconnection of the registers to form a scan path. The added hardware is encircled in Fig. 6; the heavy black line represents the scan path wiring. Fig. 7 and 8 show close-ups of the added receivers and off chip driver. Fig. 9 shows a sheet of logic from the MVISA circuit description of the 8 X 8 multiplier before the modification of the circuit by DEFT. Note that the scan in pin and the A clock

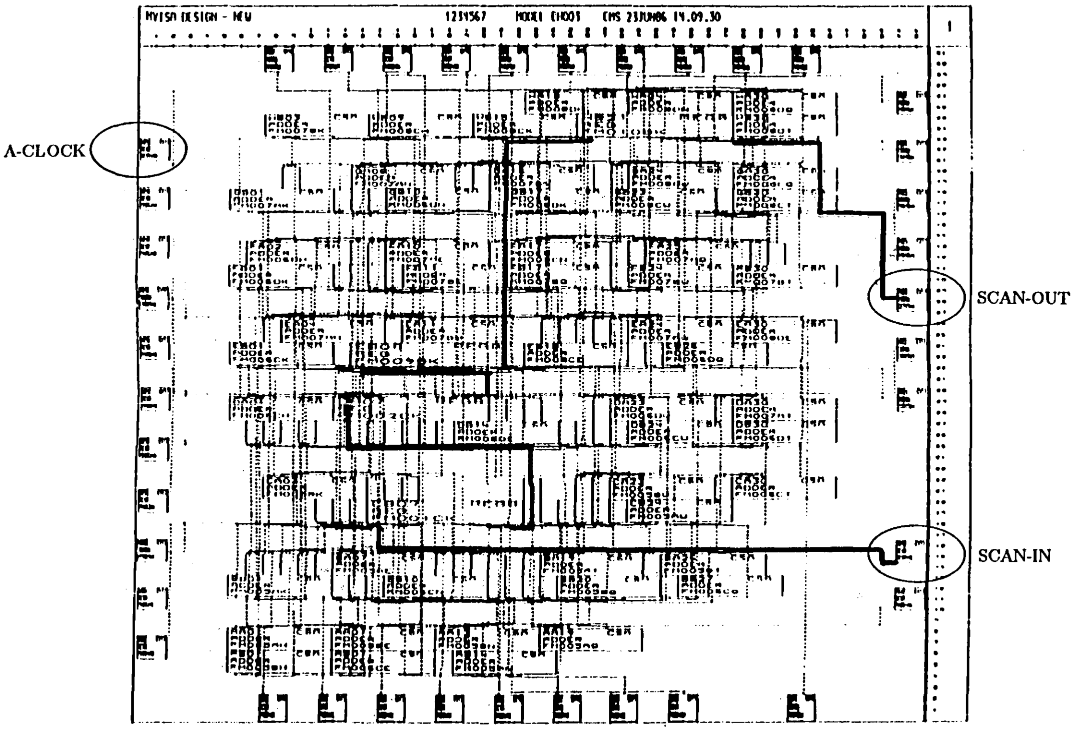

Fig. 6. 8×8 Multiplier with Added Hardware and Wiring

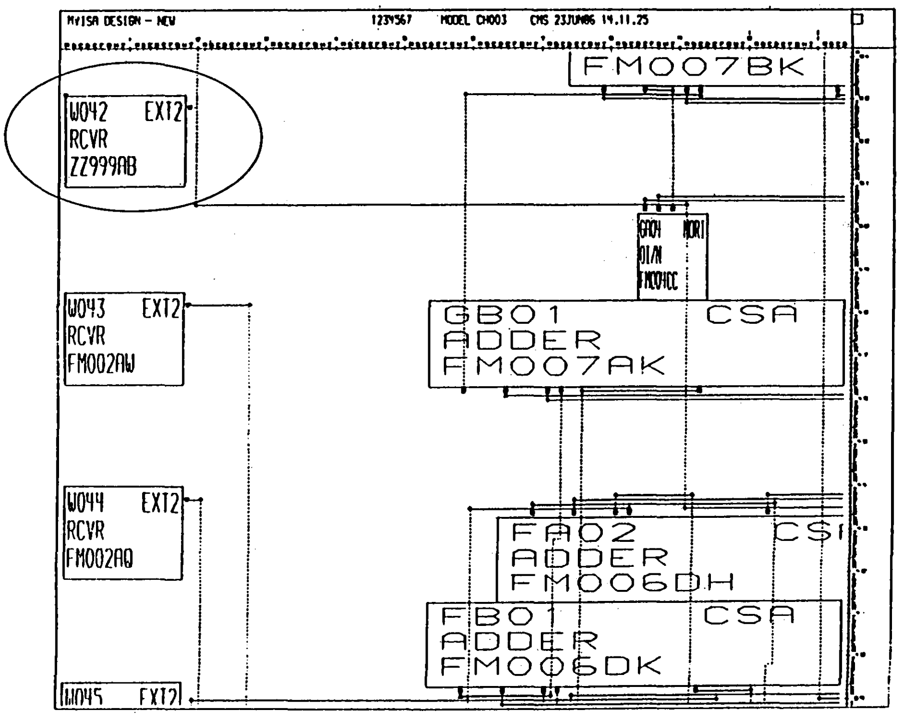

Fig. 7. Receiver Added for A-CLOCK

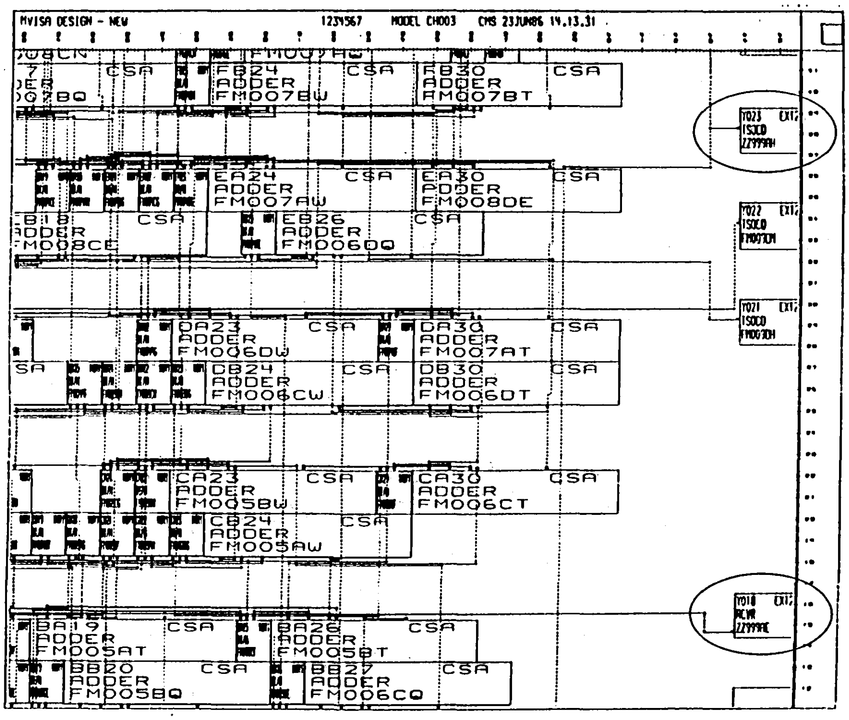

Fig. 8. Receiver Added for Chip SCAN-IN and Off Chip Driver Added for Chip SCAN-OUT

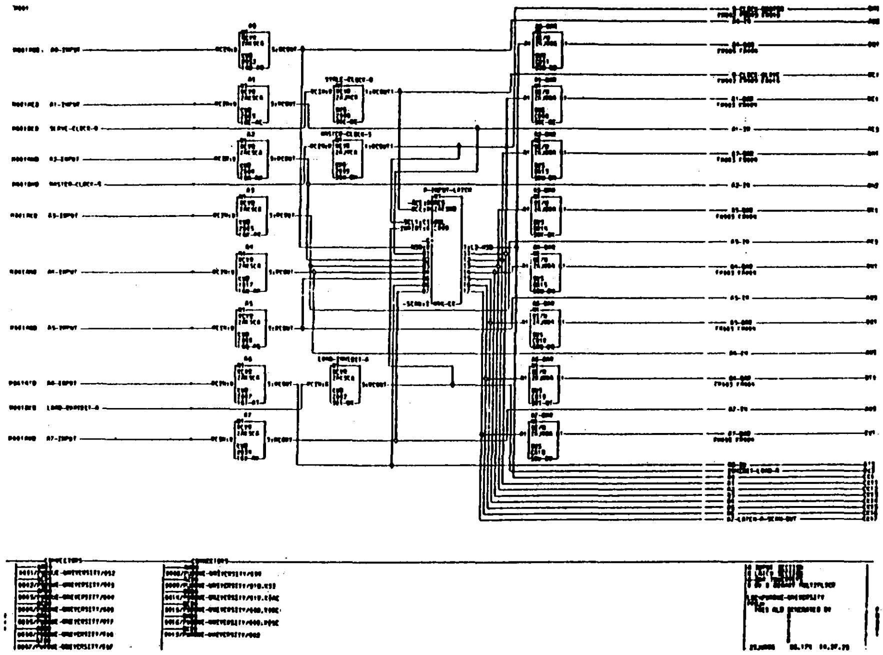

Fig. 9. Sheet of Logic with A-CLOCK and SCAN-IN Not Connected

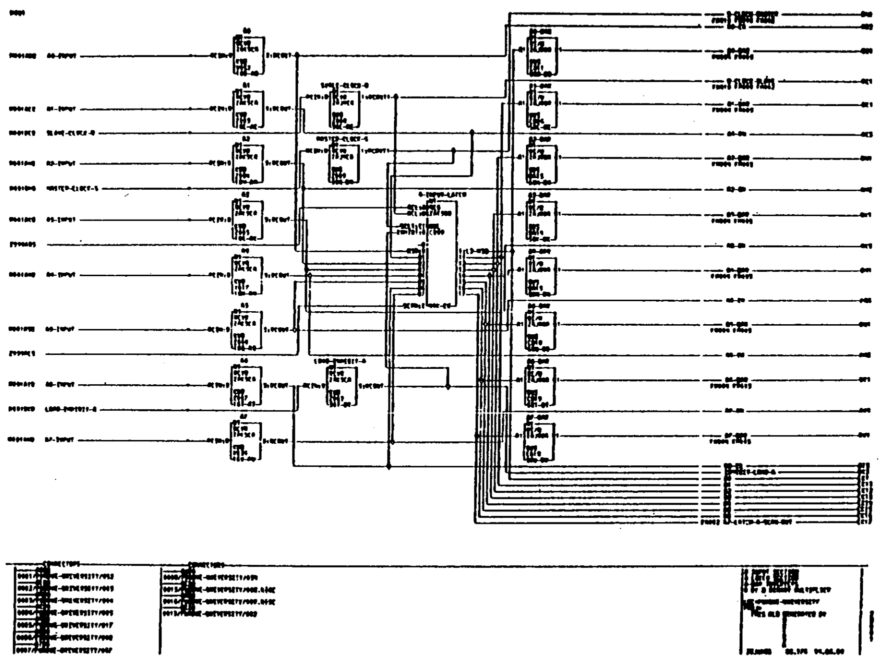

Fig. 10. Sheet of Logic with A-CLOCK and SCAN-IN Connected

pin of the register are not connected yet. Fig. 10 shows the same sheet of logic after the scan path has been wired.

The following steps were taken to produce the circuit modifications shown here:

1. A BDL/S description of the 8 X 8 multiplier without the scan path was produced by the MVISA system. The actual placement of cells making up of the 8 X 8 multiplier on the master image had already been performed by the automatic placement routines on MVISA.
2. The BDLS description of the circuit was used to produce an equivalent Lisp description by the MVISA/DEFT interface routines. These routines also do some additional processing to extract information anticipated to be useful to DEFT.
3. This description was then given to DEFT and the rules shown in Fig. 3 and the associated demons were run to produce a modified circuit.
4. A BDL/S description of the modified circuit was then produced and returned to the MVISA system.
5. The automatic placement and wiring routines were then rerun to produce the final chip layout shown in Fig. 6.

While the example demonstrated here is relatively simple, it serves to demonstrate the feasibility of our approach. Work is currently in progress on the rules and demons necessary to add a BILBO-like built-in self-test scheme to a circuit.

5. IMPLEMENTATION STATUS AND CONCLUSIONS

At the time of this writing the following parts of the DEFT system have been implemented:

1. The interface between DEFT and the MVISA System - MVISA uses IBM's Basic Design Language for Structure (BDL/S) to describe circuits. The DEFT/MVISA interface has two parts. The first part written using C and the Unix compiler writing tools Lex and Yacc, reads in a BDL/S description from MVISA and produces a Lisp description of the circuit. In addition to producing a BDL/S equivalent Lisp description of the circuit, the BDL/S to Lisp interface software also does some processing on the circuit to extract additional information that is anticipated to be useful to DEFT regardless of the circuit under consideration. Examples of such processing include the classification of all circuit elements by type and the generation of a Lisp array representing the layout. The second part of the MVISA/DEFT interface generates a BDL/S description of the circuit from the data-structures used by DEFT. This part of the interface is written in Lisp.
2. The modified Prolog interpreter incorporating the demon mechanism has been implemented using Franz Lisp. A set of Prolog rules and associated demons that implement a scheme to add a scan path to a circuit have been developed.
3. Part of the explanation mechanism has been implemented. Work is currently underway on the graphics routines to be used for this purpose.

The various parts of DEFT described above consist of approximately 2500 lines of C and 3800 lines of Lisp.

DEFT is a knowledge-based system that automatically modifies circuits to make them testable. The use of the knowledge-based approach was motivated by the desire to have a system that was easily modifiable and could provide the user with explanations. DEFT uses a Prolog-based knowledge representation scheme. The DEFT Prolog interpreter is written in Lisp and uses the demon mechanism to interface with Lisp data-structures and functions. The demon mechanism allows DEFT to benefit from a declarative knowledge representation scheme without paying a price in terms of efficiency. Initial experiences with DEFT have shown that this hybrid approach combining rule-based and algorithmic programming has indeed resulted in a modular and easily modifiable system. The Prolog rules describing a DFT scheme are written at a high level and are uncluttered by details regarding how the data-structures representing the circuit are actually manipulated. The high-level representation of DFT knowledge also has benefits related to debugging knowledge during system development: by tracing the rules that are being used to modify a circuit, the behavior of the system can be observed at a level that is meaningful to a person familiar with testability but not necessarily with the details of the data-structures and low level functions needed to implement a working design automation system.

The DEFT prototype described in this paper represents our initial efforts towards the goal of implementing a knowledge-based design for testability system. Work is currently underway to expand the capabilities of the system. Rules are being developed to check for violations of LSSD design rules and to modify circuits to remove these violations. Work is also underway on rules for a built-in self-test scheme based on BILBO. Directions for future research include development of the capability to accept circuit descriptions in VHDL. This will expand the range of circuits that DEFT can handle.

ACKNOWLEDGEMENTS

The authors are indebted to Bill Carlson and Kirk Smith for letting us use and modify their Prolog interpreter.
